The problem of getting the best possible speed regulation from a high pressure turbine or an impulse wheel with needle valve control needs very careful thought if, as is nearly always the case, either of these is located at the end of a long feeder pipe. The great difficulty is that a long column of water possesses so much inertia that its velocity cannot be changed with sufficient rapidity, and moreover the changes in rate of flow which actually occur introduce a element of great danger. Imagine a turbine operating at the end of a feeder pipe 5,000 ft. long. Assume a maximum rate of flow in the pipe of 8 ft. per second, which is frequently exceeded. If the head were 400 ft. and the pipe 5 ft. in diameter this would correspond with an output of 5,600 h.p. In such a case the actual weight of water in the pipe would be slightly over 3,000 tons, which exceeds that of a loaded freight train half a mile long. Now 8 ft. per second is 5½ miles per hour, and it does not require very deep thought to see that it would be a rather difficult operation to start such a train from rest, bringing it to that speed within a second or two; it would not be much easier by the use of the engine alone without brakes to bring such a train back to rest again in the same time interval. Yet this is just what some engineers expect can be done to an equivalent water column. If the water and pipe were absolutely inelastic, it would be easy to calculate the average pressure in pounds per square inch which would be required to stop the moving water within, say, two seconds. This would be equal to about one-eighth of the weight of a column of water of 1 sq. in. section 5,000 ft. long, because 8 ft. acceleration in two seconds is approximately one-eighth as great as the acceleration due to the weight of a substance acting on its own mass. This amounts to 271 lb. per square inch, while the static head is only 171 lb. per square inch. As a matter of fact, the pressure induced in stopping the moving water column by the action of a governor upon the gate of the turbine would greatly exceed this amount, because the retarding action would not be distributed uniformly over the two-second period. An

exact solution of the problem is impossible because of the irregular movement of the turbine gate in combination with the uncertain elasticity of the water and pipe. While it is impossible to determine the actual initial rise of pressure caused by a sudden closing of the turbine gates, the matter is made even more complex by pressure waves, which, originating near the gate, travel back and forth through the water with the velocity of sound, setting the whole mass into vibration like an organ pipe. Because of these waves there are formed nodes and loops of pressure at various points in the length of the pipe, so that it may happen that the stress will be greatest near the middle.

The foregoing argument shows clearly the need of a relief valve wherever a feeder pipe is so long that dangerous pressures will be generated by the necessarily quick action of a governor. However, this solution is not so easy as it seems, on account of the part played by the pressure waves which run back and forth through the elastic water column. Any ordinary valve, such as is used for steam, would open and close so rapidly as to act like a reed upon an organ pipe, and thus maintain and increase the vibration of the mass. In order to be at all effective, a relief valve must be deadbeat; but it must also open quickly. Its time of closing must be long compared with the vibration pitch of the water column. This latter requirement is rather difficult with the exceedingly long pipe lines. which sometimes bring water several miles. Special valves are now built which will open instantly and consume several minutes in closing, the speed of action being, of course, adjustable.

Although it is possible to prevent excessive rise of pressure due to reduction in velocity of long water columns, no means have been devised to produce quick acceleration of the water when, because of a sudden increase in load, the speed of the turbine begins to fall. The governor will open the gates promptly, with the immediate result that the water pressure will drop, and also the already inadequate power of the water-wheel; therefore the speed will fall still farther and the governor continue opening the gates until they are wide open. The reason why the pressure falls when the gates open is simply on account of the inertia of the mass, which cannot keep pace with the demand for water. After a certain time interval, which may be several seconds, the water column will have accelerated sufficiently to supply what is needed by the turbine. By this time, however, the speed may be far below normal. There will be a rapid acceleration of the water-wheel, which will pass normal speed because of the excessive gate opening, and as a result the governor will close the gates quickly, causing the relief valves to operate. If the governor is not made very deadbeat and rather sluggish, this cycle of events will be repeated to the great detriment of the speed regulation. When the governor is made sufficiently deadbeat so as not to encourage pressure oscillation of the water column, it will be found that the speed regulation is poor if the load changes are large and sudden; it is impossible for this to be otherwise, because the water column cannot possibly alter the energy given to the wheel fast enough, whether the gates be in one position or another.

The only complete remedy for the troubles in speed regulation caused by excessive inertia of a water column is some form of by-pass valve directly connected with the water-wheel gates, arranged to open as they close, and thus keep the velocity of the column nearly constant. An arrangement of this kind is substantially equivalent, as regards water efficiency, to an impulse wheel with deflecting nozzle. This involves a frequent waste of water equal to that required for the largest load variations, and cannot well be permitted in many installations. Therefore in such power plants as have been described some compromise is usually reached. Speed regulation is partly sacrificed for the sake of water economy. Frequently such stations are connected electrically with others where the hydraulic conditions are favorable to good speed regulation. This arrangement ensures the even speed of the whole system with good efficiency.

The predetermination of speed regulation obtainable under given conditions is of great importance, and has been left too much to governor manufacturers, in Mr. Warren's opinion. As a result their salesmen have sometimes made guarantees that were impossible of fulfillment without changing the laws of physics. He submits an analysis of the problem which leads to the following equation of the relation between the percentage temporary change in speed, d, the time required for the governor to make a stroke, T, the moment of inertia or flywheel effect of the revolving parts, I, the normal revolutions per minute, S, and the horsepower output from the wheel before and after a change, p and p_1 respectively:

$$d=81{,}000{,}000\ T\ (p-p_1)\div I\ S^2$$

From the form of the equation it is apparent that the percentage speed variation is directly proportional to the slowness of the governor. Under certain conditions the effect of the governor in promptly adjusting the output of the water-wheel after a load change is interfered with by the inertia of the water column in the penstock, and in such cases the predetermination of speed variation is sometimes very difficult. For simple deflecting nozzles with tangential wheels and with most turbine installations the formula is of great service.

Of the quantities in the equation there is one, T, which cannot be exactly determined. Any governor manufacturer will state the time required for a complete stroke of one of his governors, but it should not be assumed that fractions of the stroke will be covered in correspondingly lesser intervals. Experience shows that short governor movements take place at a much slower rate of travel than long ones. It is necessary that this should be so in order to prevent overtravel in adjusting the output of the water-wheel. As a matter of fact, one may assume, without introducing a serious error into the calculations, that the time T required for any governor to alter the power of a water-wheel after a great or small sudden load change will be approximately constant and equal to the time required for a full stroke.

After a power plant is in operation, it is often necessary to determine, among other facts, whether the speed regulation is as good as was guaranteed by the governor manufacturer, or at any rate as good as it should be. A method of obtaining simultaneous measurements of load, voltage, and speed has been devised by Mr. Warren which is free from instrumental defects, and which, while requiring only one or two skilled men for its use, will give results of great value in any power plant where there are two or more independent alternating current units.

It is evident that the number of cycles per second of current generated by any alternator could be used to measure the speed if these cycles could be accurately counted. The oscillograph provides means for doing this in a very interesting way. This instrument is a sensitive reflecting galvanometer, which has such an exceedingly short period of vibration and is so deadbeat in action that the actual current wave, varying, even though it may, as rapidly as several hundred times a second from a positive to a negative value, can be accurately followed and recorded on a sensitive photographic film. If the film could be moved at an absolutely uniform rate, so that the trace of the current value would be drawn as an approximate sine curve, it would be necessary merely to measure the spacing of this curve in order to determine the frequency of the generator and, consequently, its speed. It is not easy, however, to provide absolutely uniform motion for the film, and there are some other difficulties in the way. Since, however, several oscillograph curves may be superimposed on the same film, it is not necessary that the sensitive photographic surface should move at a uniform rate, because one sine curve may be measured in the terms of another sine curve. If one of these is known to pass through a constant number of cycles per second, it may be adopted as the standard unit of time, and its waves, as shown on the film, be used to measure the number of cycles per second of the other curve and, consequently, the speed variations of the machine under test.

The measurement of the comparative frequency of the two curves becomes a very simple matter if they are allowed to overlap on the film, because in such a case interference effects are produced in a very beautiful manner. These interferences are due to the fact that at times the traces of both curves overlap on the film so as to produce a single line; while at other times, one curve having gained part of a cycle over the other, the two lines will be side by side and more or less confused. When the speed of motion of the film is right, the negative shows alternate shaded bands, the distance apart of which, when counted in cycles, is an accurate measure of the relative speeds of two generators being compared. Everything depends upon one generator running at constant speed. In practice it is not difficult to fulfill this condition with ample precision. To do so the generator, which is to serve as a standard measure of time, must be given a perfectly steady load, or, better still, no load at all, excepting the trivial current required by the oscillograph. The gate of the water-wheel which drives it should be disconnected from its governor and fixed in position. The water pressure upon the wheel should be maintained very nearly constant. The generator should be allowed to run fifteen or twenty minutes before measurements are made. Its speed should be observed very carefully by a sensitive recorder of some kind in order to be sure that it is steady. A frequency indicator will answer very well for the purpose, even though its graduations may be far from correct, because it is to be borne in mind that steady speed is the only desideratum. The great inertia of the revolving parts of the water-wheel and generator in the absence of any external load will be found to maintain the speed with remarkable uniformity. There should be no trouble at all in keeping this standard machine steady within 0.1 per cent. without any difficult manipulation of the water-wheel gate. The frequency of this standard machine should be adjusted 5 or 6 per cent. below or above that of the normal frequency of the machine of which the speed is to be measured.

Assuming that the standard generator is running 5 per cent. in speed below the normal frequency of the machine under test, it is clear that the fast machine should gain five cycles over the standard in 100 cycles; or, in other words, the interference points should be twenty cycles apart. If, however, the machine under test should drop in speed 5 per cent., it would then have the same frequency as the standard machine, and the interference points would be an infinite distance apart. If the loaded machine should gain 5 per cent. above its normal speed, it would then be 10 per cent. faster than the standard one, thus gaining ten cycles in each 100, so that the interference bands would be spaced at ten cycle intervals. The extreme precision of the method is shown in the large varia-

tion in the spacing of these interference bands, corresponding to comparatively small variations in relative speed. Another great advantage of the method over any other, however, lies in the fact that not only is the speed of a machine under operating conditions determined with extreme precision, but also that the voltage of such a machine is recorded simultaneously, for the amplitude of the oscillograph curve depends precisely upon the voltage of the machine being tested. By measuring the width of the curve, the voltage value corresponding to each speed value is obtained.

Furthermore it is possible to obtain simultaneous measurements of the current output from the loaded machine, which means practically the variations in load, and this is the most important feature of all. To do this a third oscillograph mirror is impressed into service, being connected with a current transformer in circuit with the generator under test, so that the amplitude of the curve traced by the light reflected from this mirror shall indicate at every point on the sensitive film what the actual output of the generator was, corresponding to the speed and voltage shown by the other two curves. This method makes it possible to conduct a speed test of any alternating current unit, either steam or water driven, under actual load conditions, and is therefore of much greater value than any test, however accurate, under special conditions, which are never exactly the same as when in service.

FORESTRY WORK has been started by the Atchison, Topeka & Santa Fe R. R. in order to provide ties and other timber. It is now planting 700 acres in a ranch of 9,000 acres in Southern California with eucalyptus seedlings, and this planting is to be repeated annually, it is understood. Each tree is expected to yield six ties at the end of 15 years or about 3,300 ties to the acre. These ties will be cut from 700 acres of the orchard annually, after 15 years from the first planting, about 2,250,000 being obtained each year. As the rate of removal will be equal to the rate of planting, the same total acreage will, theoretically at least, maintain the same annual supply of ties. The cost for each cultivated tie is below that of ties of white oak now bought.

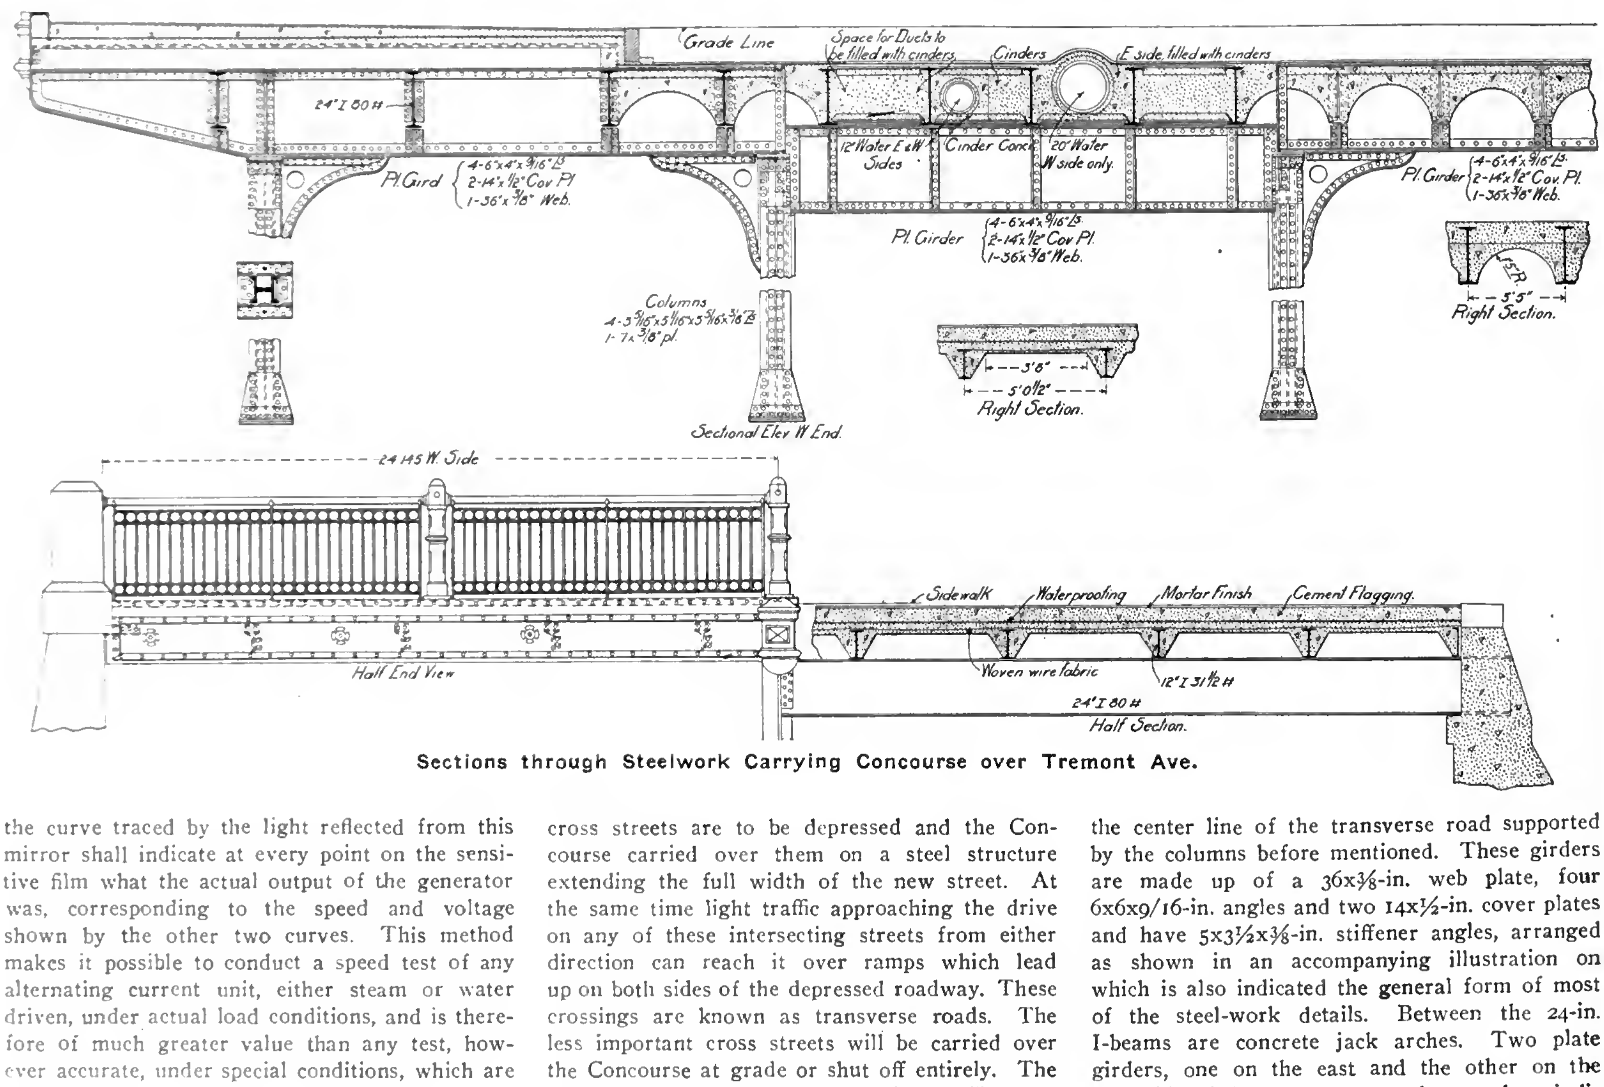
Road Intersections along the Grand Boulevard and Concourse, New York City.

The Grand Boulevard and Concourse in the Borough of the Bronx, New York City, the general features of which were described in The Engineering Record of Aug. 8, 1903, will, when completed, connect Central Park with the parks north of the Harlem River and form an important part of the city's great park system. The concourse is over 4 miles long and has a total width of 182 ft., made up of a 58-ft. central roadway for speeding, two 9-ft. cycle paths with strips of turf along each side, two 24-ft. macadam roadways for pleasure vehicles and two 20-ft. sidewalks, each flagged for a width of 8 ft. in its center, leaving 6-ft. strips of turf along each side. No heavy traffic will be permitted on the boulevard and to provide means for such traffic and for street cars to cross the line of the pleasure drive nine of the principal cross streets are to be depressed and the Concourse carried over them on a steel structure extending the full width of the new street. At the same time light traffic approaching the drive on any of these intersecting streets from either direction can reach it over ramps which lead up on both sides of the depressed roadway. These crossings are known as transverse roads. The less important cross streets will be carried over the Concourse at grade or shut off entirely. The transverse roads under construction at Tremont Ave. and Kingsbridge Road are typical of all that are to be built.

Tremont Ave. crosses the Concourse at an angle of about 70 deg. necessitating a skewed arrangement of the steel structure as shown on an accompanying plan. The depressed central roadway is 45 ft. wide between the faces of the retaining walls. The asphalt block pavement is 36 ft. wide between curbs and has a 4½-ft. cement sidewalk on each side. A line of steel columns, 18.175 ft. on centers, placed on the center line of the roadway, carries part of the weight of the steel work which will be referred to later. The concrete retaining walls in general have the sections shown in the accompanying illustrations, the section in rock where the concrete forms a face wall rather than a support being materially lighter than where the backing is earth or loose fill of any sort. At Tremont Ave. and Kingsbridge Road about 60 per cent. of the cutting was in rock.

Each of the ramps carries an asphalt block roadway 23 ft. wide with a cement sidewalk on the outside. The walk is 10 ft. wide where no outside supporting wall is required an 8 ft. wide where such a wall is necessary. Outside walls are not required at the two crossings mentioned but the maximum section prescribed for such walls, which will be dry rubble, is shown in an illustration. At Tremont Ave. the depressed roadway has a maximum grade of about 3⅓ per cent., 466 ft. long. The west ramps have a length of about 325 ft. in which there is a rise of about 20 ft. The corresponding figures for the east ramps are 466 ft. and 3.4 ft.

The steel work of the overhead crossing consists of 24-in. 80-lb. I-beams parallel to the course of the boulevard, about 3⅔ ft. on centers in general, carried on the ramp walls as abutments and on a single line of plate girders on the center line of the transverse road supported by the columns before mentioned. These girders are made up of a 36x⅜-in. web plate, four 6x6x9/16-in. angles and two 14x½-in. cover plates and have 5x3½x⅜-in. stiffener angles, arranged as shown in an accompanying illustration on which is also indicated the general form of most of the steel-work details. Between the 24-in. I-beams are concrete jack arches. Two plate girders, one on the east and the other on the west side of the concourse are depressed, as indicated in the drawings to afford room for public service pipes between the I-beams, which in these panels rest on top of the girders. In the panels reserved for pipes the jack arches are replaced by 4-in. slabs of concrete between the top flanges of the I-beams and the spaces between the bottom flanges are filled metal plates, and the entire panels filled with cinders. Cinder concrete will be packed around the pipes to hold them in place and prevent freezing. To the surface of the jack arch floor will be applied a waterproofing coat consisting of three layers of roofing felt thoroughly mopped above and below with hot pitch. This waterproofing will be protected by a 1½-in. layer of Portland cement mortar, one part cement and two parts sand. The pavement on these crossings will be macadam to correspond with the Concourse paving. The details of the sidewalks carried by the steel work



Sections through Steelwork Carrying Concourse over Tremont Ave.

are shown in the drawings. The railing has a wrought-iron filling, cast-iron posts, and a 3-in. bronze hand rail.

At each transverse road a complete drainage system will be provided to carry the surface water entering the depressed road and flowing down the ramps from the Concourse into the existing system of sewers. At Tremont Ave. there are three lines of 12-in. drains on concrete cradles with brick manholes at about 100-ft. intervals. The inlets have flat cast-iron gratings. The center drain in the depressed road is for surface water only, but the drains on the ramps are for house drainage as well as surface water.

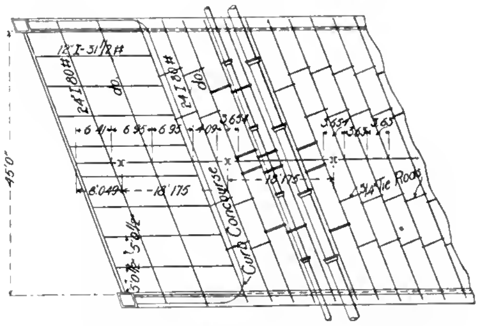
The concrete known as Class A, used in the copings, jack arches and sidewalks, is a 1:2:4 mixture of Lehigh Portland cement, stone screenings and crushed trap rock. The concrete known as Class B, in the column footings, ramp walls and abutments, is a 1:3:6 mixture of the same materials. The broken stone used in Class A concrete passes a 1-in. and is retained on a ¼-in. mesh screen. The limits for Class B concrete stone are 1½ and ¾ in.

At Tremont Ave. most of the concrete was prepared in a Smith mixer, placed near the north edge of the cut about on the center line of the Concourse. The materials for each batch were placed in a 1-yd. bucket and delivered to the mixer by a guyed derrick, with an 80-ft. boom, placed to the eastward of the mixer and operated by a Lidgerwood double-drum hoisting engine supplied with steam by a 60-h.-p. Olney & Warren boiler which also served the steam drills used in the rock cut. The mixer delivered to 3-yd. Koppel cars which were operated by hand on track laid along the outside of both ramp walls, the track for the south wall being carried across the cut on a trestle. In order to bring the cars close to the forms, so that they could be dumped directly into the latter, the track was carried on transverse timbers attached to the form studding at one end and resting on the earth or stone bank at the other. Three cars were used at once, a switch and short stub track being provided to facilitate the passing of empty and loaded cars.

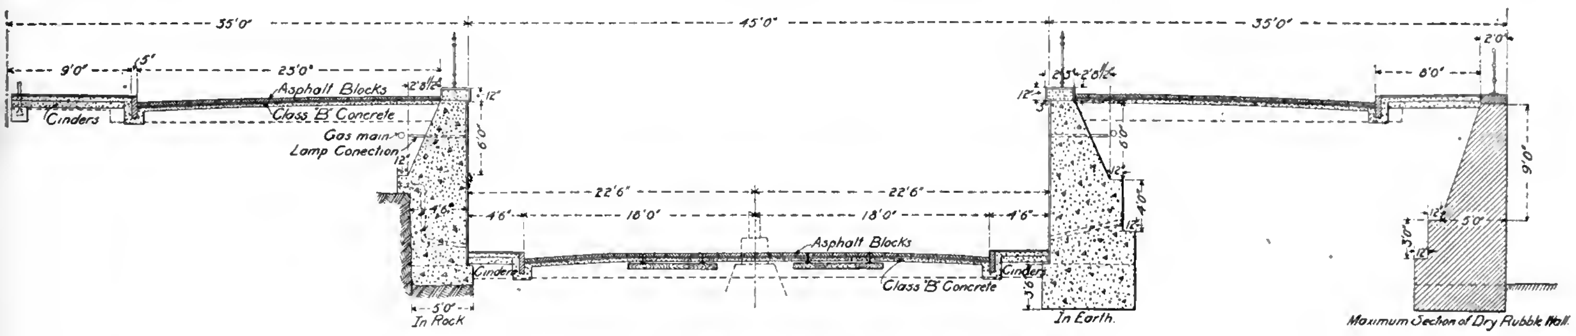
The placing of concrete was begun at the extreme west end of the cut and the two walls were carried forward almost simultaneously. Each wall was built in 50-ft. sections and the concrete in each section was allowed to set before the next one was built, two-ply tar paper being placed in the joint to provide for expansion. A 1-in. cement finish was secured by using ⅛-in. sheet steel face plates, 6 ft. long and about 14 in. wide. The centering for the jack arches between the 24-in. I-beams was supported on cross pieces hung from the lower flanges of the I-beams with L-bolts in the usual manner.

At Kingsbridge Road the stone excavated in the cut is crushed for use in the wall concrete. An oscillating crusher with a capacity of about 60 yd. per day, made by the Farrel Foundry Machine Co., is set up on the north side of Kingsbridge Road, about on the center line of the Concourse. It is operated by a double cylinder vertical Westinghouse Machine Co. engine and produces screenings and ¾-in. to 1½-in. stone. The uncrushed stone is delivered to the platform of the crusher or to storage piles nearby by two guyed derricks on the north side of the cut located near each side of the Concourse. These derricks have 85-ft. masts and 80-ft. booms, and are operated by Lidgerwood double-drum hoists supplied with steam by a central boiler plant composed of an 80-h.-p. Olney & Warren boiler and a 40-h.-p. boiler taken from a New York elevated railway locomotive. These boilers also serve the crusher and mixer engines and the steam drills.

The crusher product is delivered to a bucket elevator which hoists it to the screen over three elevated bins holding about 9 yd. each. These are a few feet east of the crusher. About 20 ft. north of the elevated bins is a guyed derrick, with a 40-ft. boom, handling a 1-yd. bucket. The proper quantities of screenings and larger aggregate are drawn into the bucket from the bins; cement is added from the cement shed just north of the crusher; and the whole is delivered as a batch to the Smith mixer which is on an elevated platform about 30 ft. east of the derrick. The mixer delivers to Koppel cars which are handled on tracks carried just behind the wall forms as at Tremont Ave.



Part Plan of Steelwork, Tremont Ave.



Section of Transverse Road Near Concourse Crossing.

General supervision of all work on the Grand Boulevard and Concourse is exercised by Mr. Josiah A. Briggs, chief engineer of the Borough of the Bronx, New York City. The work is under the immediate supervision of Mr. S. C. Thompson, principal assistant engineer of highways, under whose direction the structures described were designed. The construction work, which is now in charge of Mr. Chas. Gartensteig, assistant engineer, was begun by Mr. R. H. Gillespie, assistant engineer, who resigned last May. Mr. J. C. Rogers, Jr., is the general contractor. The steel work for both Tremont Ave. and Kingsbridge Road was fabricated by the American Bridge Co., and will be erected by the Terry & Tench Co., New York City.

THE WATER encountered at some places during the boring of the Simplon tunnel was remarkable for the entire absence of chlorine from it, in which respect it was new to chemists. Several geologists and analysts have reached the conclusion that the water had never been on the surface of the earth, but no very satisfactory explanation of its presence in the rock at the location of the tunnel has yet been made.

The Choice of a Bituminous Coal.

By R. H. Kuss, Secretary, Committee on Smoke Abatement of the City Club of Chicago.

An ever-recurring problem confronting the operating engineer is that of determining which coal is best suited for his purposes, everything considered, for although he may have reached a satisfactory conclusion at one time, circumstances are bound to arise subsequently which make it desirable to renew the investigation. To the careful buyer, the problem of selecting coal divides itself naturally into a consideration of the following main topics:

1. Availability, contingent upon the location of the mines, labor conditions, transportation, etc.
2. Relative costs of evaporating a certain unit quantity of water or its equivalent.
3. Flexibility and adaptability of the coal within the capabilities of the apparatus in which it is used.
4. Degree of smoke reduction attainable.
5. Quantity and quality of the resulting refuse and ease of its handling or removal.
6. Effect of treatment of the most desirable coal on all of the previous items.

The items enumerated are necessarily interdependent, and, of course, dependent also upon the apparatus in which the coal is used and upon the character of the available labor. The scope of this article will, however, be restricted to the consideration of the six divisions mentioned, with only such incidental references to the apparatus and the method of firing as may be necessary to indicate the leading factors to be treated.

Under the head of availability it is safe to assume that the ordinary plant is destined to lean toward the use of a coal of a character like that which comes from the nearest mines reached by competing coal railways. The force of this influence is particularly noticeable with mechanical stoker installations which may be built particularly for a coal of a special characteristic, such as a coking quality, which eventually gives way to a cheaper coal, however unsuited the latter may be for the apparatus on which it is burned. It is true that in small plants, where there is a likelihood of inadequate equipment and the coal bill forms a small percentage of the total plant operation cost, little attention is sometimes paid to this matter. It is no less true, however, that the good intention of an owner to buy a superior grade of coal in the beginning, so as to reduce smoke emission or the like, is likely to give way to the use of the cheapest available fuel, sometimes even at an increased cost in some other item than the bill because the auxiliary expenses of coal use are not so easily recognizable as the cost of the fuel itself. Most consulting engineers fail to appreciate and to provide for this natural tendency and consequently complain because their specifications as to operation are not fully complied with, when, as a matter of fact, their grievances are not so serious as those of the owner who pays toll every day for the shortcomings of the consulting engineer. Obviously, the conclusion should be that the furnace design should provide the best available means for the

use of the coal nearest at hand, whether that requires an additional initial expenditure or not. Any other course is a makeshift and an example of poor engineering.

The cost of evaporating a unit quantity of water is contingent upon the circumstances of operation, the available equipment and similar factors. By the time the final decision as to the coal to be used is reached the equipment has already been provided and no longer is to be considered a changeable factor. In deciding which is the cheapest fuel to use, it is a mistake to assume that the matter can rest with the relative showings of the particular coals tested, though it would appear at first sight that everything has been taken into account by such a course, the apparatus, as said before, not being considered capable of change to meet the requirements of the different grades. The force of the foregoing statement is apparent from a consideration of the relative costs of handling the refuse, the wear and tear of equipment, the care required for firing to obtain results comparable with those of the tests, and the effect of dust of the fuel on the surrounding firing room and contiguous properties. Of these items the cost of refuse removal overlaps the wear and tear item more or less, depending upon the quality of the refuse, some of which will put an ordinary conveyor system out of commission much sooner than the refuse of other coals or that of the same basic coal treated by washing, sizing or otherwise. Of course, the quantity of refuse to be removed is indicated by the amount found on analysis, though the relative performances of two coals different in uninflammable content do not bear a like relation in actual performance, because one coal may cause a greater percentage of combustible to appear in the refuse than a comparison of the analyses would indicate, even to one who is competent to interpret analyses.

That there are serious disappointments in the use of a certain coal after an apparently fair and careful series of tests is due to the fact that test conditions are not strictly representative of working conditions. The preparation for and performance of all of the tests of a series operates to throw two wholly different coals more nearly on an equality, the coal of the lower grade receiving greater benefit by the same care in firing, whether by hand or by mechanical stoker, than the better grade. To explain by example, a good grade of coal may admit of a range of efficiency of eight per cent. between careful manipulation and ordinary firing, while the poorer grade admits of a range of fifteen per cent. The test series tends to compare only the high performance marks of the several coals while the fuel selected is used according to ordinary treatment.

Another point to be considered is that the test conditions of the apparatus, if brought back for each fuel to equal cleanliness of furnace and heat-absorbing regions at the start of each test run, are in ordinary operation put out of all comparison with the test conditions more quickly with some coals than with others. In spite of the best that can be done, the apparatus as a unit deteriorates rapidly between periods of complete cleanings for some fuels, owing to soot deposits in combustion chambers and tube chambers, while with other coals the trouble is less marked. The test series cannot serve to indicate this difference to the degree desired, although a study of minor happenings in all of the tests is of service to indicate a difference in coal behavior even in this regard. Smoke observations and chamber examinations, the latter both before and after test runs, serve to throw light on this matter. Of course, the degree of ease in removing soot and finely divided refuse from the affected regions is a salient factor in this branch of the subject.

Under the third item, adaptability of coal to the apparatus, there is one of the most difficult features attending the selection of a coal for a particular duty. Here, again, the test series is likely to fail, especially if a whole battery of boilers is available to take care of the variations of duty while the steam delivery from the apparatus employed in the test is maintained without material fluctuations. Nor will a series of tests conducted on the basis of under, even and over-capacity give the information desired. This portion of the subject can be handled to some degree by a study of the quantity and quality of the refuse, and the ease with which it may be removed if the contingency arises. For example, two grades of coal may be compared, the first being one that gives a tenacious, gummy, compact clinker and the other a clinker that is very fragile and easily broken up under the action of an ordinary rocking grate. In the first case we are restricted because the best available means of adjustment, damper regulation, is ineffective, since the resistance of the fuel bed is not capable of easy change, while in the second case we can materially affect the rate of furnace performance. It is not sufficient to dismiss this important subject by declaring that when a fire is in a condition where it refuses to respond to damper regulation it is time to clean, for that would impose the necessity for cleaning very often with some fuels, a service which, in ordinary running operation, is not likely to be performed.

In some localities it is very important to reduce smoke to a degree where it no longer is a menace. In such plants where recourse must be taken to a particular high grade of fuel either because of inadequate furnaces or because of the nature of the service demanded in order to reduce the smoke emission, the situation is indeed unfortunate and the real remedy is a substitution of furnace or method of coal use. An inadequate furnace arrangement imposes, necessarily, an undesirable restriction as to kinds of coal available for use, though it may be said that a bad furnace for one kind of bituminous coal is very likely to be as bad for any other kiud.

In selecting a coal for the primary purpose of avoiding smoke, more progress can sometimes be made by trying the several variations of sizes of a promising coal from one field than by experimenting with a number of coals from as many different fields.

The quantity and quality of the refuse have been previously considered as an important factor under several heads. The quality of the refuse is the more important, since it bears upon the proposition of resistance to air passage to a larger degree than the quantity itself, and besides is the leading factor in determining the ease with which it can be removed. In certain mechanical stokers this matter becomes less important than for hand-firing, though in others it is more important.

The treatment of which a coal is capable presents to the user a field of speculation that seems to offer promising results. First to be thought of in this connection is sizing, the separation of the coal into several groups of which the pieces are of approximately the same weight. The advantage of this treatment is that the percentage of voids in a given thickness of fuel, the pieces being of irregular shape and not fitting into each other, approaches a maximum the more nearly uniform they are in size. Spheres of the same diameter present when piled into heaps a fixed percentage of unfilled space or voids irrespective of what the diameter may be. Now, the same holds true, but to a less extent, with uniformly sized coal. Hence, in the case of a bed of sized coal we may expect to use a thicker layer than with mixed coal. This means that it is possible to have a thicker bed of incandescent fuel on the grate, thereby causing a smaller variation of furnace temperatures to come about when green fuel is fired. Again, it is possible with a thicker fuel layer to have a greater variation in fuel bed thickness with less deleterious results than with a thin layer. It is not difficult to see that the thicker layer can be put on just as evenly as a thin layer, and the same degree of unevenness will not be relatively so important in the case of the thick layer as in the thin fuel bed. Again, the thicker layer of fuel presents an opportunity of taking care of an increase in the demands on the furnace without the same increase of quantity of coal fired that obtains where the fires must be kept thin.

Still another factor must be mentioned before dismissing the subject of sizing, the amount of surface presented to the gases passing through the fuel bed. While the percentage of voids is independent of the sizes themselves, the total surface for a given mass of fuel is a function of the size, becoming rapidly greater as the pieces become smaller. One would naturally expect the greatest surface to be the most effective, which would hold true were it not for the fact that the rate of volatile distillation might become too high for the capacity of the furnace, or if smaller coal did not result in a more compact layer of refuse than larger coal. The tendency surely would be to reduce the size of the coal the better the furnace facilities, other features of the coal being the same, if they can be.

An entirely different aspect of the case comes about in a forced draft installation, for to gain the best results it may not be desirable to impose as little resistance to air passage through the incandescent fuel bed as possible. It is probable that the sizes may well be mixed in such a case, rejecting the smallest as well as the biggest and retaining everything between them.

The use of coal dust under ordinary natural draft conditions is, of course, not a reasonable application of the principle of uniform size selection, since this imposes an abnormally high resistance to air and gas passage. The small interstices demand an exceedingly thin fire to gain the proper combustion rate, a matter nearly impossible in coal of very small size.

The washing of coal is a comparatively recent venture in the Illinois region and unfortunately is not always well done nor effective when every intelligent effort has been expended on the coal. The common impression exists that washing is always beneficial whereas it is sometimes decidedly the reverse. Even in those cases where an apparent gain is made, the good results very often come from the sizing rather than the washing. Comparatively few coals exhibit any noticeable degree of betterment after washing, and in many cases the latter imposes a decidedly unnecessary hardship. A guide to whether a betterment comes about is to compare the analyses of the coal before and after washing. If the ratio of amount of sulphur to the total refuse after washing is greater than before or even equal to it the fuel has not been improved sufficiently to warrant the expense, if a use of the unwashed fuel shows it to be a serious one to handle because of the nature of the clinker. The foregoing test does not follow absolutely, since the washing process may remove the most objectionable sulphur portion allowing the unobjectionable portion to remain. This belief is not commonly entertained, because those who have to do with the use of coal by a study of the analyses are over-impressed with the greater percentage of pure coal remaining after washing. The experiences of the operative are more to the point, however, since he deals with the difficulties of the resulting refuse, not so much because of its quantity but because of its character.

The use of a mixture of small size anthracite and bituminous is one of the best fields of investigation to be considered in this connection. This course is very effective where the

bituminous coal results in a particularly stubborn clinker. The presence of the anthracite refuse in such a case serves to offer innumerable places for clinker fracture when the coals are combined and thereby makes the refuse bed easily tractable. On shaking or rocking grates the advantages of this method are strikingly evident. The combination need not be made with equal parts of the two coals, but different proportions may be tried until a workable combination is arrived at. Necessarily, the effect of combining a high fixed carbon coal with a high volatile one is to create a fuel which is more easily made to conform to an inadequate furnace than a bituminous coal alone.

Ore Handling in the Marquette Iron District.

The mines in the Marquette, Mich., iron-ore district have been worked for over fifty years, but the output from this district has been greatly increased only in the past eight or ten years. The principal mining centers in the district are at Ishpeming and Negaunee, which are about 15 miles from Lake Superior in a direct line, although many other important mines have been developed at various points throughout the district. Two classes of iron-ore are mined in the district, one in the form of very hard rock and the other more like dense clay, or heavy soil. The mines are all worked from shafts, which vary from 100 to 1,000 ft. in depth. The ore is taken out at several levels in each shaft, the spacing of the levels depending largely on the manner in which the ore occurs. Most of the hard-ore mines can be worked without timbering, so the ore is generally removed from the deposits as the headings advance from the shaft. In the soft-ore mines, on the other hand, the general practice is to drive a heading from the shaft to the limits of the deposit to be tapped, and then work back toward the shaft in mining. In this method, only enough timbering is used to hold the roof temporarily, the ground being permitted to cave after mining operations have ceased.

The ore is hoisted from the shafts in the cars in which it is loaded at the working face. When ore is being shipped immediately, it is dumped from the mine cars through a tipple into standard-gauge cars. The remainder of the time it is dumped into stock piles, from which it is loaded into the standard-gauge dump cars by means of steam shovels.

The natural outlet for the district is Lake Superior, which is reached most practically at Marquette, 16 miles from Negaunee, and 19 miles from Ishpeming. A large tonnage of ore, nevertheless, is carried by rail to Escanaba, on the west shore of Lake Michigan, for transportation by water to the steel mills at the lower end of that lake, and also to the lower lake ports. At Marquette the ore is delivered to vessels which carry it to various distributing and industrial ports on the Great Lakes.

The Lake Superior & Ishpeming Ry. was built from Ishpeming to Marquette by the Cleveland-Cliffs Iron Co. and allied interests to handle the output of the mines controlled by that company and those interests. Something less than half of the output of the mines in the neighborhood of Negaunee and Superior is carried by this railroad. The latter is built with 80-lb. rails and has thoroughly modern equipment adapted to the traffic tributary to it. The standard ore cars of the road are of steel and have a capacity of 50,000 lb. They have two four-wheel trucks, and as they are only 24 ft. long, over all, a very concentrated load is brought on the track and structures by them. Ishpeming is 850 ft. above Marquette, so the line is practically down grade all the way, although the maximum gradient is about 1.63 per cent. Consolidation type engines having 22x30-in. cylinders, 80-in. boilers and a combined weight of engine and tender of 173 tons are used in the ore traffic. These engines haul forty-five loaded 50,000-lb. cars to Marquette and return with 45 empties, without a helper at any point, notwithstanding the fact that there is a continuous climb of about nine miles, in which the maximum grade occurs several times. These engines are each equipped with two air pumps for the air-brakes, either pump having sufficient capacity to furnish enough air to operate the brakes of a full train. Since the brakes are applied a considerable portion of the time on the downward trip, the wear on the wheels is heavy, but it has been found that the wear on the tires of the locomotive wheels can be greatly reduced by applying a fine stream of water to them while the brakes are set.

The ore is unloaded from the trains into the vessels through a long, high dock at Marquette. This dock and most of the approach to it are a continuous timber trestle, the dock proper being on piles cut off at the water level. The approach rises on a 2 per cent. grade for about 2,300 ft. The dock is 54 ft. high above the water, 1,200 ft. long and 52 ft. wide. It has two longitudinal rows of ore pockets, one on each side of the center line, and will hold approximately 30,000 tons of ore. Four tracks are extended the length of the dock over the pockets, the latter being spaced so the center dump hopper-bottom cars which are used can be placed one at each pocket. The cars are handled up the approach 15 to 18 at a time by a 130-ton geared Lima locomotive; the switching on the dock is done by an ordinary locomotive.

The ore is fed by gravity from the storage pockets into the holds of the vessels through hinged chutes, which can be raised to permit vessels to pass. In addition to the trainmen and switchmen on the dock, a force of laborers is required to raise and lower the loading chutes and to loosen the ore as it becomes jammed in the pockets. The soft ore, in particular, causes considerable trouble from this source, but the hard ore generally flows readily.

The number of ore trains operated over one of the ore roads each day and the total tonnage for the season of open navigation on the lakes, which averages about seven months, naturally depends chiefly on the output of the mines tributary to it. During the season of 1906 in the neighborhood of 1,800,000 tons of ore were handled through the dock of the Lake Superior & Ishpeming Ry., practically all of which came from mines in the vicinity of Negaunee and Ishpeming.

The Duluth, South Shore & Atlantic Ry., which carries the remainder of the ore traffic passing through Marquette, handled about 1,700,000 tons in 1906 over the three docks which it operates there. Two of these docks are older structures, but the third was completed during 1906, and is now used chiefly for the ore traffic of this road. It is similar in arrangement and construction to the dock of the Lake Superior & Ishpeming Ry., except that the tracks on it are 74 ft. above the water, in order to facilitate the loading of the very large ore-carrying vessels which have been placed in service during the past few years.

The total quantity of iron-ore which passes through Marquette, 3,500,000 tons in 1906, is only a little more than one-tenth of the total tonnage of iron-ore that passed through the locks at Sault Ste. Marie last year. A large percentage of the remainder came from the Mesabe and Vermillion districts, to be northeast of Duluth. The construction, equipment and operation of the roads which deliver ore from those districts to the docks along Lake Superior are much the same, however, as those of the Lake Superior & Ishpeming Ry.

Book Notes.

A little more than a year ago attention was drawn in this journal to the special structural shapes which the Bethlehem Steel Co., South Bethlehem, Pa., will roll on its new universal mills and some of the properties of these shapes fitting them particularly for bridge and building work were pointed out. The company has now issued a handbook prepared by Mr. George H. Blakeley in which complete tables of these properties are given and standard details for connections are illustrated. This pamphlet, entitled "Bethlehem Special Structural Shapes," contains information that every designer of steel work will find it desirable to have at hand, for the company will shortly be ready to begin shipping these shapes.

The Office of Public Roads has recently issued a pamphlet on "Rocks for Road Building," written by Mr. E. C. E. Lord, petrographer of the Office, which describes in some detail with the aid of excellent engravings the most important quantitative methods of rock analysis by means of the microspoe and proposes a classification of material suited for highway construction. Since the establishment of the laboratory of the Office in 1900, over 1,500 samples of rock from nearly every State, as well as Cuba, Porto Rico and Hawaii, have been examined miscrosopically and physically tested. The average mineral composition and physical properties of these samples are given in tabular form, and the various road-making rocks are arranged so far as posible according to their genetic relations, as shown by the tests and examinations. The general conclusions regarding these materials are stated as follows: (1) Igneous and metamorphic rocks, owing to a higher degree of crystallization and a preponderence of silicate minerals, offer a greater resistance to abrasion than nearly all varieties of sedimentary rocks. (2) The coarse-grained intrusive rocks of the igneous class are harder, but break more readily under impact, than the finer-grained volcanic varieties of like mineral composition. (3) The deleterious effect of atmospheric weathering on the wearing qualities of rocks is evident. (4) The cementing value of rocks is, to a certain degree, measured by the abundance of secondary minerals resulting from rock decay. (5) Metamorphic rocks have, as a rule, a low binding power owing to a regeneration of secondary minerals and to the effect of heat and pressure. The foliated types readily part along planes of schistosity and are therefore not well adapted to road construction. (6) The quantitative mineral analysis of rocks serves to a certain extent as a measure of their useful properties for road construction. The pamphlet may be obtained by applying to the Office of Public Roads at Washington.

With the widespread interest in the development of water powers there has arisen a demand for a thorough treatise on turbines, and engineers who are familiar with the German language will doubtless find this need well satisfied by "Die Turbinen fuer Wasserkraft-betrieb," by Prof. A. Pfarr, of the Darmstadt Polytechnic Institute, who was associated for twenty years with Dr. J. M. Voith, the well-known turbine builder, who has done much to raise the standard of such machinery. The book is voluminous and goes into great detail in places, and suffers somewhat from the absence of a good index. On the other hand, it is written from a viewpoint with which The Engineering Record is in complete sympathy and is marked by an absence of obsolete and useless illustrations that is almost as gratifying as the excellent drawings and diagrams that are provided. The author points out that the theory of what water actually does in turbines is based on a great many as-

sumptions, and the best that can be done is to use extreme care in selecting those assumptions which are most likely to be correct, and then to test the theories by careful experiment. The formulas deduced by theory and fitted with working constants derived by experiment have limitations due to both the range of experiment and the liability of error in the assumptions of the theory. Consequently only those who know the steps by which the theory was deduced and the extent and reliability of the experiments are able to use the resulting formulas with the full knowledge an engineer should possess. It is for this reason, also, that the author has not cared to provide a compendium of formulas for "ready reference," but has illustrated his methods by carrying through complete detailed designs with a thoroughness that is likely to be particularly useful to beginners. It is very rare indeed that the complete details of such designing work are given or drawings of actual installations are dimensioned so fully as in this book. The first three chapters discuss the power characteristics of flowing water, the different types of turbines and the work of water within a turbine. Anybody who desires to obtain a good presentation of the theory of turbine action now held among German-speaking engineers will find this portion of the volume clear and comprehensive; in fact, engineers who have already studied the subject somewhat may consider that the author gos into too much detail. Draft tubes and head are taken up in the next two chapters, the former subject being treated with particular fullness. Four chapters follow in which the design of different types of turbines is explained, both analytical and graphical methods being employed. The next section, running through several chapters, is one of the most complete discussions of gates and control that has yet appeared, and is succeeded by one on shafting, bearings, yokes and other parts. The remainder of the book relates to turbines actually built and their installation and governing. The work appears in a text volume of 821 pages of large octavo size and an atlas of 46 admirable plates. (Berlin, Julius Springer, 36 marks.)

Letters to the Editor.

Steel Frame for Concrete Reinforcement.

Sir—I take pleasure in sending you herewith a picture of the reinforcement of the Owl Drug Co.'s building now under construction in Mission street, near Second street, in this city. The method of reinforcement marks an innovation in concrete reinforcement, in that the steelwork forms a complete unit before any concrete is put in place. This unit is so completely formed that it is quite practicable to erect all steelwork before any concrete is poured, as can be seen in the accompanying picture, which shows several stories of free steel.

Among the advantages of this method of construction the following may be mentioned: The steel forms a complete structural unit in itself and does not cause internal stresses in the concrete, allowing the latter to perform the functions for which it was designed. Defects in the steelwork cannot escape notice, and there is little likelihood of derangement of the steel during the pouring of the concrete. The design can be computed readily and permits very quick erection.

Yours respectfully,

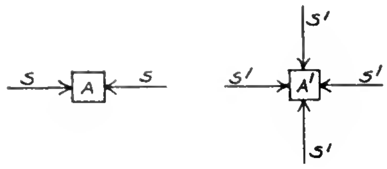
John M. Ettler.

San Francisco, Aug. 15.

Concrete Slab Reinforcement.

Sir—There are two questions I would like to have answered in regard to designing concrete slabs reinforced two ways at right angles.

First, what percentage of the working stress allowed in concrete reinforced in one direction only can you allow as the working stress in each of the two directions when reinforced in two ways? For example, let A be a small portion of a slab reinforced in one direction an A^1 be a small portion of a slab reinforced in two directions at right angles. If a working stress of



S=750 lb. per square inch is allowed on the extreme fiber of A, what should be allowed for the working stress S^1 on the extreme fiber of A^1?

Second, is the steel found by the formula 1/20 $w\ l^2$ the least amount that can be used in each direction of a slab fixed on all four sides, or is there a plate action that will permit using less steel?

Yours truly,

Robert G. Lose.

Wilkinsburg, June 14.

Reinforcement in Owl Building.

[The answers to this inquiry cannot be made very precise, for the theory of flat plates supported on edges is in neither a very simple or satisfactory condition at the present time. It is customary to assume that the plate is supported uniformly on its edges where those edges are simply supported or held rigidly fixed. If the plate is square, it is frequently assumed that the half of the load is carried in each direction and for each direction the plate is assumed to be an ordinary beam. Just what should be taken as the working stress in the concrete for each direction is to some extent a matter of judgment. It will probably be safe to take that working stress at three-quarters of its value in an ordinary reinforced concrete beam. The resultant stress where the bending moment is greatest would then certainly be safe and reasonable. Another method justified by experiment is to take the total load as dead and as uniformly distributed around the edge of the plate and then take moments by the diagonal of the rectangular or square plate, using as the working stress that which would be permissible in an ordinary reinforced concrete beam.]

A Large Moving Operation.

Sir—Much interest has recently been manifested in what is said to be the largest moving job of its kind ever undertaken. The new thoroughfare leading down from the heart of the business district of Brooklyn to the end of the new Manhattan Bridge, now under construction, is an extension of Flatbush avenue. It has been cut through a number of thickly built-up blocks, and one of the most prominent buildings in its path was the old Montauk Theater, later known as the Imperial Theater. This building was considered too valuable to be torn down, and efforts to save it from destruction have resulted in its being moved bodily to a new site a few feet to the eastward of its original position.

The building is of brick, with a steel skeleton, and the weight is said to be about 8,500 tons. The walls are 90 ft. high. The lobby, on Fulton street, has been torn down. The back of the old building was on DeKalb avenue, but in the new position it will be on Hudson avenue, a half block from DeKalb. The moving has consisted of three main movements; a displacement southward towards Fulton street of nearly 40 ft.; a rotation about its own center of mass (clockwise, as view from above) of about 65 deg.; and a further displacement, eastward, of more than 100 ft. to a new brick foundation, which has been already prepared for the building.

In the preparatory work, holes were knocked in the foundations, and I-beams varying from 40 to 60 ft. in length were pushed under. These were built up inside laterally and transversely at intervals of about four feet each way. Altogether, nearly 600 of these beams, representing some 1,500 tons of steel, have been used. Beneath these have been placed railroad rails on wooden ties, but the rails were not spiked down. These rails, which have the standard length of 30 feet, have been placed in groups of four to six. The steel I-beams were braced with stout timbers, and shoes some 24 in. square were built under them along the outer edge of the building, at intervals of 4 ft. Under each of these shoes, and resting upon the groups of rails, were placed in each case about a dozen steel rollers 2 in. in diameter and 24 in. long.

These preparations being made, the building was raised a fraction of an inch by means of several score of jacks, and the weight was transferred from the old foundations to the rollers on the the back of the building, on DeKalb avenue, and rails. A string of heavy timbers was run along anchored securely. Along this string were placed twenty jack screws, well oiled and working in hardwood drums. At a whistle signal, each jack was given one twist, and the building moved just the distance covered by the thread on the screws while making that portion of a revolution. In this manner the building was moved about 12 ft. in four hours.

For the twisting motion, the center of the building was indicated by a red light, and the steel rollers involved in this motion were all placed with their axes and the light in the same plane. The other translatory motion will be but a repetition of the first. The work is being done by Iverson, Gustatson & Co. A new facade facing the new Flatbush avenue will be built and then the theater will be again ready for use.

Yours truly,

Brooklyn. Sidney G. Koon.

Block Signals have been installed on 1,500 additional miles of the lines east of the Pennsylvania R. R. during the past three years, and at present the important mileage of these lines is protected, although about 500 miles of industrial and branch roads have not been equipped. The cost of the additional equipment was $856,520, and it will add $210,816 yearly to operating expenses.

THE ENGINEERING RECORD

Published Weekly by the

McGraw Publishing Company

James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.

MAIN OFFICES:
239 West 39th Street, New York.

BRANCH OFFICES:

Chicago: Old Colony Building.
Philadelphia: Real Estate Trust Building.
Cleveland: Schofield Building.
San Francisco: Atlas Building.

London Office: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico	$3.00 a year
Canada	$4.50 a year
Foreign subscription	$6.00 a year
25 shillings. 25 marks.	31 francs.

Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of The Engineering Record on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

Remittances.—Remittances should be made by check, New York draft, or money order, in favor of The Engineering Record.

Changes of Address.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

Back Copies.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.

Date on Wrapper indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

Club Rate.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD** 16,000 copies are printed. Total circulation for 1907 to date 523,750 copies, an average of 14,549 copies per **week.

TABLE OF LEADING ARTICLES.

Removal Notice.

The offices of The Engineering Record have been removed to the new building of the McGraw Realty Company at 239 West 39th Street, New York. This structure, named the Thirty-ninth Street Building, is but five minutes' walk from the Engineering Societies' Building, and is the most notable example of reinforced concrete construction in the city, as well as the most perfect structure yet erected to answer fully the special and different requirements for office and printing purposes. The Engineering Record will be pleased to see its friends at this new address.

The Utilization of Small Water Powers.

With the growth of electric power transmission has come an awakening to the importance of water privileges and one of the interesting results has been the rediscovery, as it were, of falls half forgotten and entirely passed by. In spite of this a great number of small streams remain undeveloped and offer excellent opportunities, not, to be sure, to the promoter who wishes to float bonds upon them, but to the actual investor and to the manufacturer who wishes power for his own proper uses. The bane of hydroelectric enterprises is "high finance," which saddles upon a proposed plant all the bonds that it can stagger under for years to come. A water power of one or a few hundred horsepower is too small to "finance," yet it often offers a capital chance for the bona-fide investor. Few people, even few engineers, realize fully what can be done with a comparatively small stream when intelligently developed. Other things being equal the smaller the stream for a given power, i. e., the higher the head, the better, since the cost of the hydraulic development is thereby greatly reduced. Also the cost of storage in considerable amount is then brought within reasonable bounds and adequate storage adds enormously to the practical value of the stream, as everybody knows. Few, however, appreciate the full importance of storage as applied to small streams, since on large streams generally developed at low head the practicable amount of storage is limited by the cost of the necessary riparian rights.

The ordinary stream is subject to enormous variations in flow, which cannot adequately be expressed in conventional averages. The spring floods are likely to be from twenty-five to fifty times the real minimum flow, and even more if one compares the maximum flood of a term of years with the minimum of the same period. The value of a stream for power purposes cannot be measured by the average flow since this is determined by unutilizable maxima. In a time of flood the flow is often so great as to cut down the working head, and is always greater than the capacity of any plant that can be profitably installed. Every stream has years of great and small flow scattered apparently by chance. A record of five or six years will catch the ordinary maxima and minima, but at least a quarter of a century is required to stand a reasonable chance of including extreme floods and extraordinary minima. Hence, so far as possible, the water should be stored. It is ordinary custom to store water during the night, thus holding double the normal flow for use during working hours. This is generally easy to accomplish at moderate cost. For instance, at 50 ft. working head a flow of 1,300 cu. ft. per minute will give about 100 h.-p. off the wheel shaft. If the power is used twelve hours per day one can store the other twelve hours' flow in a pond of a little less than 4.5 acres filled 5 ft. deep. This, however, is only the beginning of storage. The next step is so considerable a one that it is seldom undertaken, although it often would be very practicable. The ordinary continuous period of low water, at least in Eastern streams, is seldom more than 30 to 60 days and is preceded and followed by periods of considerably increased flow.

Now if sufficient storage capacity can be secured, say a hundred acres or so, this dry season can be tided over entirely and several times the normal low-water flow used steadily for twelve hours a day. Practically one is then able to use the stream on the basis of a point much nearer the average flow of the year than is possible with merely ordinary night storage, and to sell perhaps two or three times the amount of power that would otherwise be feasible without a stream reserve. One can, of course, go even further and store the entire yearly rainfall in an artificial lake, thus creating a useful water power from a stream entirely too small to consider except for storage. This has been done in a very few instances, and will be done more frequently as time goes on. The main point is that the usual small powers, apparently of little account, can, if the head be reasonably high, be developed by storage into excellent and reliable sources of revenue. The 100 h.-p. assumed at the start can be expanded not only into 200 h.-p. for twelve-hour use, but into 300 or 400 h.-p. and sometimes more. An electrical plant on which the demand for power fluctuates greatly through the day or night has its value determined very largely by the maximum load which it is able to carry over the peak and with good pond capacity this is measured by the capacity of the installation. Ordinarily the peak on a small plant will be three or four times the average daily power, so that if the plant just discussed is properly developed it may be able to carry a peak of 800 to 1,000 h.-p.

Lacking storage the peak must either stop at the normal flow or be eked out by auxiliary steam power. And the point needing emphasis is this, that in many cases, particularly on small streams, extensive storage is far cheaper than auxiliaries. One can hardly hope to install an auxiliary plant for less than $50 to $60 per electrical horsepower delivered, while in the case supposed a hundred acres of storage could generally be obtained, even if farm land had to be bought, for a sum far less than the first cost of the auxiliary it would replace. In these days of high voltage, a few miles of extra distance back in the hills involves no considerable extra cost, so that it would generally pay to develop well upstream where pond space would be available. There are many chances all through the hills of the country for just such small enterprises. In some cases the market will be found in lighting and power in towns a few miles distant, in others a single factory may find it profitable to utilize a stream for its own especial benefit. Many a small industry in which power is relatively a large item can in this way fall into an economy of production that is quite impossible if power has to be purchased or generated at the ordinary city rates. If engineers in drifting about the country on their various works would keep their eyes open for hydro-electric possibilities, they would find a surprising number of capital opportunities. The ordinary state surveys which purport to take account of the hydraulic resources of the country are very imperfect, since they notice only the more obvious falls and the larger streams. It is on the relatively small streams in a broken country that capital chances lie latent until some one with a keen eye brings them to light.

The Operation of Large Turbo-Units.

Few engineers who have not looked into the problem from the practical side realize the broad differences required in operating methods between very large and small or medium capacity power plants. The development of turbo units of 5,000 to 7,500 kw. normal rating demands a high degree of organization in the operating force of the plant which is made up of such large machines and their auxiliaries. In handling generators and turbines or direct-connected engine units of moderate capacity, the amount of money represented by each machine is not large enough, as a rule, to demand the elaborate precautions which one finds in the few great stations thus far built in 5,000-kw. units; and, again, the stoppage of a single machine in a station of a few thousand kilowatts rating does not mean anything like so much as it does in the case of a plant like the Long Island City station of the Pennsylvania or the Port Morris installation of the New York Central. There is no doubt that as the applica-

tions of electric power increase on a commercial scale, the use of very large units will become more common; and it is particularly important for prospective purchasers of such high-powered turbines to realize that the simpler and more easy-going methods of earlier plants must give way to an operating organization demanding real generalship in its handling, if the full reliability, flexibility and economy of the new and costly units are to be enjoyed.

In round numbers, a 5,000-kw. turbo-alternator represents an investment of from $150,000 to $200,000. The penalty of damaging such a machine by crude operating methods is evident on its face. Turbines of this capacity are designed so far as possible to take care of a long list of contingencies as to load and speed, and the governor mechanism may be counted upon to hold the machine within safe limits of turning over through all ordinary exigencies of starting, phasing in or shutting down. At the same time, definite responsibility and order of procedure must be insisted upon both on the switchboard gallery and on the floor of the turbine room itself. One or more sets of signals between the board and the floor are essential, and these must be reliable and simple, without the likelihood of their being confused in times of emergency. Hand signals are doubtless good enough for the working conditions of small plants, but in these very large stations lamp, bell or whistle signals, with supplementary telephone or speaking tube connections between floor and gallery are important features of good operation.

Anticipation of all probable contingencies is the main point at issue in planning for the skilled handling of large units. Under normal conditions the load upon the plant on the first five days of each week tends to follow substantially the same general variations from hour to hour, though the momentary fluctuations show less resemblance from day to day. Hence in routine service experience soon shows the hour each day at which a machine must be ready for service, and the probable duration of its service. Authority to cut in an additional unit may be granted to the floor engineer in charge of a given shift in case it becomes clear that the machines in service are in danger of being too heavily overloaded, but in any case the switchboard operators should be empowered to order in new machines if they are in practice held responsible for the continuity of the station output. The conditions in different plants vary considerably, and the exact measures of responsibility must be assigned with reference to the organization in force, but there should be no chance for things to go wrong because of divided authority. If the entire station is in charge of a single watch engineer, the decision may rest with him when to cut in or out machines, but a suitable organization will provide for fixed limits of continuous overload which shall not be exceeded without a second unit being thrown upon the bus-bars, in case one machine is handling the entire output of the station.

A clear-cut printed list of instructions as to the order of procedure and the signals to be used in bringing a turbine up to speed, synchronizing, cutting it out of service, transferring the load from one machine to another, handling exciters and auxiliaries, starting machines with the utmost possible speed in emergencies, and shutting down with all possible speed, is a valuable aid to operation in plants where such instructions can be properly applied and enforced. It ought to be unmistakable just what machines are designated by a given signal, and in this connection the use of audible signals can be very readily supplemented by lamp indications. Thus, the use of some form of engine telegraph, either with dial or lamp indications referring directly to the printed words "Start," "Stop," "Standby," etc., as in marine service, tends to reduce the chance of mistakes, as does the employment of an electric interlock in connection with the closing of the turbine oil switch which throws the machine upon the operating bus-bars. In some of the later installations it is impossible to complete the oil switch circuit unless the synchronizing plug is in its receptacle, and the circuit breakers cannot be closed unless the voltmeter plugs are in. The use of red and green pilot lamps to indicate the limit of speed conditions on the turbines, of similar lamps to show whether high tension switches are closed or open, with illuminated signs and special calls for emergency conditions, all tend toward reliable service. Foresight applied to minute details is the fundamental need of power plant organization in dealing with units of high capacity.

The Ambrose Channel at the Port of New York.

It is hardly likely that one American in a thousand, even in well-informed circles, appreciates what an important influence on commerce the Ambrose channel at the port of New York is likely to become. A few people have had a very hazy idea that an important channel was being dredged somewhere for some purpose connected with the improvement of the port, and a few engineers and contractors recall the work mainly on account of the troubles of those who originally agreed to carry out the undertaking for a sum about equal to that which an experienced dredging manager estimated as the cost of the necessary equipment to cut the channel in the time stipulated by the original specifications. As a matter of fact, it is the excavation of the Ambrose Channel that has made the "Lusitania" a practicable proposition, and without the work which the Corps of Engineers of the army has been urging forward with all practicable speed that great ship and the still larger vessels that will doubtless be constructed in the future would be hopeless failures. The relation of cause and effect in harbor work has rarely been shown more clearly than in the case of this channel and the famous liner that will shortly thread her way through it on her maiden voyage. The recent passage of the Cunarder "Caronia" through the new channel demonstrated its safety and great advantage over the old course, and showed that commerce will shortly be freed from its chief physical hindrance at the leading American port.

The problem in shipbuilding for the trans-Atlantic trade has been to secure maximum carrying capacity at minimum cost, or to increase the water-line length without an excessive addition to operating expenses. The high speeds attained by some liners cost so much that the vessels are generally understood to be operated at a loss, which is considered justifiable as an advertising proposition and is recouped by the profits of the slower vessels. If it were possible to build longer and deeper vessels, this high speed could be attained without such serious financial sacrifices, but it is manifestly no use to build a ship which cannot get into the harbor which is her destination on this side of the ocean. Up to the present time, therefore, ship-building has been checked, so far as fast liners were concerned, by the winding course and 30-ft. depth of the old Gedney Channel, and it was not until the Washington authorities gave an absolute promise of a better entrance to the harbor that the Cunard Company regarded the project for the "Lusitania" type of ship as practicable. The Ambrose Channel in its present incomplete condition will permit such vessels to come to their docks more easily than smaller liners have formerly made the trip over the old course, while the completed channel will admit vessels of 35-ft. draught at all stages of the tide and of lengths that would be unnavigable in the narrow, twisting Gedney Channel. It will thus be seen that the new channel does away with a physical restriction on the development of an important part of the port's commerce, and opens the way for progress in ship-building, the limits of which nobody can now foresee.

The channel which is making such a marked change in shipping and ship-building is intended to be 2,000 ft. wide and 40 ft. deep at low water eventually, although it will be a good many years before it is completed to these dimensions. At the present time it has a width of about 800 ft. and a minimum depth of 32 or 33 ft. at low water. This depth is not enough to make the channel free for the "Baltic," let alone the "Lusitania," at low tide, if they are fully loaded, but it will permit them to come up at any stage after the voyage over, when their coal supplies have been depleted. The new channel is about seven miles long. It begins about a mile and a quarter southwest of Coney Island, the famous amusement resort of New York, and extends in a generally southeasterly direction to deep water about half a mile north of the Gedney Channel. In the part already completed the channel has a depth of 45 ft. at the ocean entrance and come up for a mile and a half on the southerly side of the proposed 2,000-ft. channel; then crossing over gradually to the northerly side. The trial trip through the channel which was made by the "Caronia" indicates that the time of passage through it from the dock to deep water will be about half that required in going through the old course. The use of the new route for some time will be restricted to vessels of deep draft in order that interference with the work of improvement shall be as little as possible, and it is considered likely that for a time not many of the companies will care to follow the lead of the Cunard people and send their best ships over the new course. Even in its present incomplete state, however, the channel is a most instructive example of the assistance engineering can afford to water-borne commerce.

Riveted Connections in Steel Structural Work.

Notwithstanding the great developments made in steel structural work up to the present time there are a number of important details which cannot yet be satisfactorily designed in consequence of a lack of the requisite experimental data. The eye-bar, which was for many years of a more or less unknown, or at least speculative, character, may fairly be classed among those main details of a steel bridge structure which may be designed rationally and safely, if not with extreme accuracy. There has been accumulated a mass of results of tests of full-size bars of various classes of steel, and with such a variety of proportions as to form a fairly complete empirical basis of design for both large and small members. The design of an eye-bar head of such dimensions as to develop the full capacity of the body of the bar is no longer a matter of material uncertainty; the amount of experimental data now available is ample for its purpose. There are a number of other important structural details about which the same general observation may be made, but there are still others, including both riveted tension and compression connections, whose rational treatment in design is even now impracticable with substantial accuracy in consequence of a lack of sufficient experimental data.

Tests to failure of riveted joints in plates have been made in considerable number, especially for the purpose of determining the ultimate resistances of tension, shearing and bearing in riveted joints, but there have been comparatively few tests of either tensile or compressive connections between angles and plates or of the connections

of angles with each other. There have been postulated certain obvious principles applicable to the design of all classes of riveted joints, such as that requiring the lines of stress in the members joined to pass through the centres of gravity of the groups of rivet holes employed in the connections. It has also been recognized that, in general, the best results in connecting angles to plates will be reached by using angle lugs so as to catch both legs of an angle member with the joint rivets. Furthermore, it has been recognized with equal clearness that the centre lines of stress of all the members meeting at a joint must intersect at one point. In applying these simple principles, however, there is such a paucity of experimental investigations in this class of riveted connections that it is in reality impossible to design such connections with that degree of accuracy which ought to characterize the best class of steel structural work at the present time. Again, the determination of the proper net section where rivet holes in different lines are staggered cannot be made in a rational manner, although an experienced engineer of good judgment may, and does, design his work so as to make this feature of his connections entirely safe. Also, if an angle lug is employed to catch that leg of the steel angle which stands at right angles to the connection plate, the designer is greatly in the dark as to the value of the lug as a detail of the connection. It is even unknown in some cases whether the latter will be improved by the lug or not, but that is practically about all that can be said with any degree of certainty.

Under such circumstances a paper on experimental investigation in this class of riveted details like that on "Tension Tests of Steel Angles, with Various Types of End Connections," read before the American Society for Testing Materials, at its recent convention at Atlantic City, by Prof. F. P. McKibben, cannot fail to be of substantial value. Although the number of tests is not very extended, they were made with full-size angles and there are enough of them to yield significant indications of practical importance.

While the results are not sufficiently extended to be conclusive, it appears that there may be a gain of ten to fifteen per cent. in efficiency by catching both legs of an angle, by the aid of a lug, in a tension connection when the greatest available net section is attained by a suitable staggering of the rivets. This gain appears to increase as the inequality in the lengths of angle legs diminishes. Indeed, that gain may disappear or even become negative, i. e., a loss, if the inequality in length of the angle legs becomes great. At first sight this may seem irrational, but it is what should be expected. When the leg perpendicular to the connecting plate becomes relatively short, as in a 6x4-in. angle, the rivet holes through it, required by the lug, may decrease the net section to such an extent as more than to compensate for the advantage of catching both legs. The tests of connections with that size of angles discloses precisely the results indicated, but with the difference in efficiency so small as to indicate that the 6x4-in. angle lies about at the limit. In other words, it may be advisable to use lugs with a less inequality of lengths of legs, but not when the inequality is more. This is an important practical indication, and its confirmation or modification should be sought by a continuation of tests of this class.

The investigations set forth in this paper also show clearly the importance of a well-considered disposition of the units at the connection. A proper staggering of them, especially with unequal legs, may materially increase the net section and thus enhance the efficiency of the connection. Finally, the results of Prof. McKibben's investigations indicate that it is more advantageous to use equal-legged angles and connecting lugs than those with unequal legs, either with or without lugs, as the efficiencies of the former are sensibly higher than those of the latter.

Few or no compressive tests of this class of connections have been made, in spite of the fact that they are much needed. Compressive connections are simpler in character than those in tension, as the complication of net sections does not exist, but the influence of bending is unknown in amount and can only be determined by actual tests.

Notes and Comments.

THE COLLAPSE OF THE QUEBEC BRIDGE on the afternoon of August 29th was a wholly unexpected occurrence, in spite of reports in the newspapers to a contrary effect. The cause of the collapse of the south anchor and cantilever arms is as much a mystery at this writing as ever, and while several explanations of it have been advanced they rest on such inadequate basis of fact as to be mere speculations which are worse than useless on account of their tendency to warp the judgment. The portion of the bridge that fell had been standing over a year; it had passed through the storms of the winter, and nobody had seen anything about it indicative of any serious condition. It is true that Mr. Theodore Cooper telegraphed on the day of the accident to the builders not to place any more load on the structure until it was looked over, but he authorizes the statement that this telegram meant nothing more than a warning that it was desirable to stop work until the superstructure had been critically examined. Neither he nor his inspector dreamed for a moment that there was any danger of immediate collapse. That the structure fell is, however, one of those grave facts which the engineer must face in all its stern reality. It seems almost hopeless to attempt to seek the cause of the accident in the twisted wreckage or to discover in the statements of those present at the time of the failure any clue to the reason for the catastrophe. Yet until that reason is definitely found engineering will be looked upon by the public with suspicion as daring too much for its resources and as too willing to run risks; the Philadelphia "Ledger" voiced this sentiment as follows: "The world's confidence in the skill and judgment of the engineering profession will be seriously shaken unless it can be shown that the accident was the consequence of unforeseen and unavoidable contingencies." Engineers themselves know full well that probably no structure ever received more careful attention in design, manufacture and erection than the Quebec bridge and they will be unwilling to attribute its collapse to defective proportions, inferior materials or faulty erection until definite proof is established to the contrary. Full details of the design and the method of erection have been published in a long series of articles in this journal, and elsewhere in this issue is a statement of all the facts that have been brought to light concerning the accident and the local conditions at the time it occurred. An examination into the accident is now being made by the Canadian authorities and it is to be hoped that this will be so thorough and complete that the cause of the collapse will be definitely revealed. Until it is known, the hazard of bridge-building on such a great scale will be something to consider with apprehension.

THE ELECTRIFICATION of the Sacramento division of the Southern Pacific Ry. will be studied by Messrs. Frank J. Sprague, the eminent electrical engineer, and Mr. Allen H. Babcock, the company's electrical specialist. The latter has been investigating the electrification of the road from Rockline to Sparks for three years and the engineers of the large electrical manufacturing companies have made a special study of the subject. In many respects the problem of increasing the capacity of the division in question is one of the most important in the railroad world. It is over this division that the entire freight and passenger traffic of the transcontinental Union Pacific system, for Central California, is carried, and likewise the eastbound traffic. Some idea of the difficulties may be judged from the fact that in a distance of 83 miles there is a rise of nearly 7,000 ft., this section forming a part of the division on the west and east slopes respectively.

A BLOW-OFF TANK EXPLOSION in a St. Louis store resulted in the death of a power-plant operator, whose widow brought suit against the owners of the building for the death of her husband. The case has recently been decided, 103 S. W. Rep. 588, by St. Louis Court of Appeals in a decision of importance to consulting engineers. There were two blow-off tanks, sunk flush with the floor and separately connected with the boilers and the sewer. A 3-in. vapor pipe was provided for each tank, running up a few feet, then horizontally 12 ft., making three 45-deg. turns before rising to the roof. There was an upper and a lower valve in the pipe connecting the boilers and each tank, the lower valve being opened first and then the upper valve opened very slowly. The tank that exploded was within 18 in. of a boiler, so that to blow off the latter it was necessary for the operator to stand on the top of the tank, which was made of cast iron. While the operator was blowing off the boiler in the usual way this cast-iron top blew off and he was killed. The top was broken into pieces which were found to be honeycombed with holes. The owners of the building claimed that they were not liable for the results of the explosion, because they contracted with experienced and reputable people to furnish and install the machinery under the supervision of competent mechanical engineers also employed by them. They showed by witnesses that the blow-off tanks were of the standard type employed in the city and installed in the customary way, and consequently they claimed freedom from responsibility. The court has refused to uphold this contention and damages have been awarded against the owners of the building. It is laid down as good law as well as simple justice that the owners could not shift to the shoulders of another the responsibility for insuring the safety of the working place for their employees. The evidence showed conclusively that the lid was not subjected to any kind of test, and the court held that any ordinarily prudent person would have tested its soundness before putting it into use. This was the duty of the mechanical engineers engaged for the purpose of insuring the installation of a good plant, and these engineers were the owners' agents in the matter, so that their negligence was legally the negligence of the owners, for which the latter were liable in damages. This brings up a proposition which those who are struggling with proposed professional codes will do well to consider. According to the court's decision, "that the engineers were negligent in failing to test the head of the blow-off tank which blew up, does not admit of doubt." This being the case, should the engineers be considered responsible to the owners for the results of such negligence? According to the court's decision the accident was not due to an error in judgment, for which no professional man is properly held responsible in this way, but was caused by pure negligence, which is a very different matter. The question whether a professional man is liable to his client for damages in such a case is manifestly one that is open to considerable debate.

THE HYDRO-ELECTRIC DEVELOPMENT OF THE GREAT NORTHERN POWER CO.—PART I.

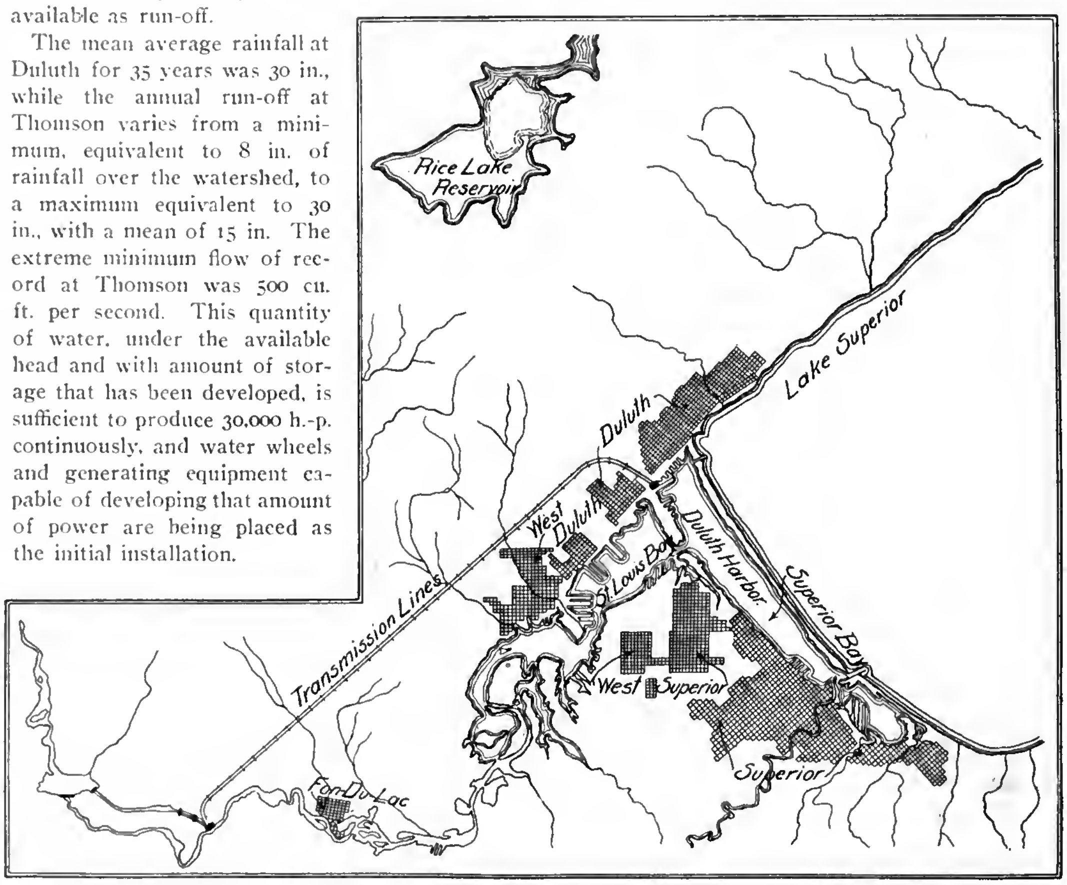
The hydro-electric development of the Great Northern Power Co. on the St. Louis River, near Duluth, Minn., is one of the most comprehensive hydraulic power projects that has been undertaken in this country. The important part of the hydraulic features of this development are practically completed, and that portion of the electrical generating equipment to be installed at first will soon be ready to operate. A service reservoir, with a capacity of 130,000,000 cu. ft., has been developed on the river at Thomson, 17 miles from Duluth. The river is by-passed from this reservoir to the power station, which is 2.8 miles down stream in a direct line. This by-pass consists of an open canal, 1⅔ miles long, that leads across a level plateau above the steep river valley, and of pipe lines extending from a forebay 3,500 ft. long, at the end of this canal, down the side of the river valley to the power station, which is at the edge of the river. The market for power generated in the station includes within easy transmission distances the cities of Duluth and Superior, the Mesaba, Vermillion and Gogebic Iron Ranges and other power consuming centers.

Water Power Available. The St. Louis River offers the only opportunity for any large, or important water-power developments within more than 100 miles of Duluth. The course of the stream is approximately a semi-circle, 150 miles in length, the headwaters of the main river being about 60 miles northeast of Duluth. The river flows west from its source, gradually changing in direction to south and finally to southeast near its mouth, which is 10 miles southwest of Duluth, in St. Louis Bay, an arm of Lake Superior. The Cloquet and the White Face Rivers are the principal tributaries of the St. Louis River. The headwaters of the former are about 15 miles southeast of the headwaters of the main river, the general course of the stream being toward the southwest for its entire length of approximately 75 miles. The Cloquet River passes to the north of Duluth, 15 miles from the city and joins the main river 30 miles from the mouth of the latter. The source of the White Face River is between the headwaters of the Cloquet and the St. Louis Rivers, the course of this stream, which is approximately 55 miles in length, being generally parallel to, and 15 miles north of the Cloquet River.

The sources of the three rivers are in the neighborhood of 1,150 ft. above Lake Superior, but only 585 ft. of this total fall of the main river occurs between the headwaters of the latter and a point 15 miles from its mouth. At this point there is a fall of about 45 ft., and in the next 4 miles a series of light rapids introduce a gradual fall. In the remaining 10 miles, from the upstream end of the service reservoir to the mouth of the river in St. Louis Bay, the total fall over a series of rapids is 465 ft., all of which will be utilized eventually by the Great Northern Power Co. Of this total fall, 378 ft. has been developed for the present hydro-electric station, and the remainder of the fall, which occurs below that station, will be utilized in a hydraulic development near the mouth of the river.

The total drainage area of the St. Louis River and its tributaries is about 3,700 square miles, consisting largely of connecting swamps, with alternate ridges covered with timber, dense undergrowth and small lakes. Although this territory has been made accessible recently by railroads from Duluth to the Mesaba Iron Range, which range is along the northern edge of the drainage area and about 60 miles from the city, it contains only a few settlers' clearings, county highways and logging railroads. Practically all of the pine that once covered the catchment area has been removed, but a dense forest of balsam, tamarack and hardwoods of various kinds still exists over most of the area. The surface of the latter consists of heavy glacial deposits of mixed gravel, sand and clay; these glacial deposits are underlaid on the headwaters of the river with hardpan, then for a width of 10 miles just above the present development, with slate, and from the end of this underlying slate to the mouth of the river, with brown sandstone. The catchment area is thus an excellent gathering ground for water, which is so gradually delivered into the streams that a relatively large percentage of the rainfall is available as run-off.

The mean average rainfall at Duluth for 35 years was 30 in., while the annual run-off at Thomson varies from a minimum, equivalent to 8 in. of rainfall over the watershed, to a maximum equivalent to 30 in., with a mean of 15 in. The extreme minimum flow of record at Thomson was 500 cu. ft. per second. This quantity of water, under the available head and with amount of storage that has been developed, is sufficient to produce 30,000 h.-p. continuously, and water wheels and generating equipment capable of developing that amount of power are being placed as the initial installation.



Map Showing Power Development, Duluth and Superior.

In order to provide for additional power installations, other storage reservoirs will be developed on the watershed. This reservoir development can be carried out very economically, as the swamps which make up a large proportion of the country at the headwaters of the three rivers offer unusually favorable opportunities to create immense storage reservoirs. The latter can be developed by simply placing dams across the small streams where these streams have broken through the glacial ridges. These dams for the most part need be only small structures, and it is estimated that the average cost of storage which will make 30 per cent. of the mean annual rainfall continuously availabe for power is approximately $1,500 per square-mile-foot.

Based on the development of storage areas which will render continuously availabe this 30 per cent. of the mean annual rainfall, another project, known as the Duluth Heights System, which is entirely distinct from the development at Thomson, is under consideration. This project contemplates the diversion of the headwaters of the St. Louis River and its tributaries through a series of canals and storage reservoirs to the crest of the steep hillside on which Duluth is built. This hillside reaches an elevation of over 800 ft. within a short distance from the water front of the city, and farther back forms the divide between the St. Louis River and the small streams flowing through the city into Lake Superior. A depression occurs in this divide through which the headwaters of the three rivers can be delivered into the central part of Duluth with a fall of 740 ft., or nearly twice as great as that available at the station on the St. Louis River. A reservoir which contains 17 square-mile-feet of storage has already been developed at Rice Lake in this depression, and for the time being will deliver water to the station at Thomson, but it is the controlling feature of the diverting scheme.

In case this scheme is carried out, 2,375 square miles of catchment area will still be tributary to the present station. If sufficient storage capacity is provided to render available 30 per cent. of the rainfall on this area, or one-half the total run-off, 80,000 electrical horse power can be developed in this station, based on a 42 per cent. load factor. At the same time 10,000 electrical horsepower can be developed in a station in Duluth operating on the water diverted from the three rivers under the available head of 740 ft. made possible by this diversion, and based on the same amount of storage and the same load factor as is contemplated for the station at Thomson. In addition to these two developments, 15,000 h. p. can be rendered available by the construction of a dam and power station to utilize the 70 ft. of fall in the river below the existing station.

Service Reservoir. The principal function of the service reservoir at Thomson is to conserve and regulate the flow equalized by the storage reservoirs so the variable demands for power each day may be met without loss of water. The capacity of this reservoir between the crest of an overflow spillway and the lowest depth to which water may be drawn into the canal leading from it to the power station, in a total draft of 12 ft., is 130,000,000 cu. ft., which is sufficient to accomplish this purpose of conservation and regulation. This reservoir is also capable of furnishing water to operate the ultimate installation of 80,000 electrical horse-power at 50 per cent. load factor for 23 hr. without supply from the river. Furthermore, it will permit sufficient time to obtain a supply from the storage reservoirs in case of an emergency, without interruption to the service.

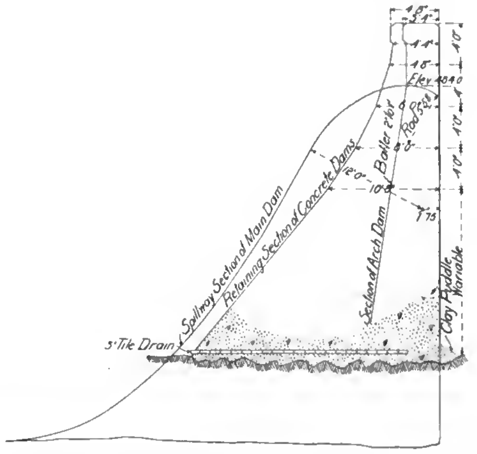
The service reservoir is about 1½ miles long and ½ mile wide, its long axis being nearly at right angles to the channel of the river. The latter in this vicinity cuts across a series of ridges of dense slate rock, which rise 10 to 60 ft. above the general level of the country, one of these ridges forming the downstream side of the reservoir. A main dam was built across the channel which the river had cut through this rock ridge and a series of low dams were erected to close the breaks in the latter.

The main dam has a total length of 1,120 ft., and is a gravity-section concrete structure. The spillway section of the dam is 40 ft. high from the bottom of the foundations to the crest, 42 ft. wide at the base and 365 ft. long. At one end of this section three sluice-ways are extended through the dam near the bottom so the reservoir may be drawn down through them. Each of these openings is controlled by a 7x9-ft. sluice gate. These gates have non-rising stems which pass through operating stands in a concrete gate house built on top of the dam. The stands are geared so they may be operated by hand.

A retaining section of the dam, 609 ft. long, extends from the gate house to a high point on the rock ridge, and a second retaining section, 146 ft. long, extends from the opposite end of the spillway of the dam to a spillway that has been formed by cutting down the rock ridge. The crest of the spillway of the dam is at Elevation 484, as referred to the level of Lake Superior; the top of the remainder of this dam and of the smaller dams around the reservoir are at Elevation 490, except two earth dams, the crests of which are at Elevation 492. The spillway formed on the rock ridge has a length of 1,000 ft., and is 18 in. higher than the crest of the main dam, that is, at Elevation 485.5. An extreme flood of 60,000 cu. ft. per second can be passed over the spillway of the main dam and this rock spillway without overtopping any of the retaining dams. This is in excess of any floods that may reasonably be anticipated, however, as the maximum flood of record is 52,000 cu. ft. per second.

Seven of the smaller dams, of which eleven were built, are gravity-section concrete structures. Two low earth dams, with paved slopes on the water side, one rock-fill dam having a concrete core wall, and one arch concrete dam make up the remainder. The rock-fill dam was built with the material removed to construct the spillway over the rock ledge. The core wall of this dam rises to the same height as the retaining dams. The arch concrete dam was built across a deep, narrow opening in the rock ridge in order to save concrete as compared with a gravity-section dam. It has a clear span of 60 ft. at the crest, is 60 ft high at the middle, and is built as an arc of a circle with a 100-ft. radius.

Upper Head Gates on Canal. The outlet from the service reservoirs into the canal connecting the latter and the pipe lines leading to the power station, is through submerged openings in a concrete retaining dam at the end of the reservoir closest to the station. The design of the outlet is such that the water will be drawn from the bottom of the reservoir in a manner that will keep the velocity of approach low, so that very little ice or floating matter is expected to pass through the submerged openings and enter the canal. The substructure for a gate house, 35x83 ft. in plan, is built into the dam and contains the outlet openings, of which there are eight, each controlled by a 6x9-ft. sluice gate. These gates are each in a well on the reservoir side of the substructure, the water entering these wells through a heavy timber rack. This rack, which is expected to intercept floating debris and ice, consists of 3-in. planks, set on edge and spaced 10 in. apart on centers. These planks are supported by steel frames arranged so sectional iron grate bars of any spacing that may be found desirable may be installed later in place of them. The rack is outside of the gate house superstructure, a platform walk being provided along the top of it to facilitate the removal of debris intercepted by it. Three of the eight sluice gates are now installed, and the remaining five openings are closed with stop logs placed in the channels provided in the concrete on both sides of the gates until such time as more gates are required. These gates have rising stems, each of which passes through a ball-bearing operating stand in the gate house. These stands are arranged so the gates may be operated by induction motors, which will be started and stopped automatically by a float in the well connected with the canal; the motors may also be operated by switches in the gate house; or the gates may be opened and closed by hand.



Sections of Concrete Dams.

Main Dam and Spillway over Rock Ledge at Service Reservoir.

Canal. The canal has a total length of 1¾ miles between these headgates and the forebay and is entirely in excavation. It has been built to supply water to operate the ultimate installation of 80,000 h.p. The first mile of it from the service reservoir is through an earth cut, which crosses occasional rock ridges. This length of the canal was designed to be 36 ft. wide on the bottom, 15 ft. deep and to have side slopes 2 on 1. The grade of the bottom is 0.00015 and the coefficient of roughness of the wetted perimeter is assumed to be 0.03. The maximum velocity of flow through the earth section when the canal is running to its full capacity will be about 2.8 ft. per second and the discharge 2,900 cu. ft. a second. The excavation was largely made with a steam shovel, and in order to reduce the cost of this work, the cut was made 66 ft. wide in the bottom and has steeper side slopes than specified by the design. It is expected these slopes will flatten out later, probably to an excess of 2 to 1. The remainder of the canal, a length of about 3,500 ft., has been excavated through slate rock with occasional short sections of earth reaching nearly to the bottom in some cases. The cut through the rock was designed to have as a minimum cross-section a rectangle 36 ft. wide and 15 ft. deep. As actually constructed the section is somewhat irregular, but in no place is the cross sectional area less than 450 sq. ft. The grade of the canal in this rock section is 0.0015, and the coefficient of roughness 0.033. The maximum velocity through this section will be about 7.5 ft. per second, with a discharge of 2,900 cu. ft. per second, the same as for the earth section.

The canal crosses one of the tracks of the Northern Pacific Ry. about ½ mile from the upper head gates. According to the original location the canal and the railroad formed an acute angle at this crossing, but it became necessary to introduce a reverse curve in the canal in order that the railroad might be crosssd more nearly at right angles. The railroad crosses the canal on a 70-ft. span deck plate-girder bridge carried by concrete abutments, which are built for a double-track bridge. The sides of the canal are lined with concrete in the form of warped surfaces in both directions from the abutments in order to bring the side slopes of 2 to 1 in the earth section to the vertical at the abutments, and to prevent wash at the sharp turns.

A concrete wasteway, 200 ft. long, is built in the right-hand side of the canal just below the railroad crossing, where water can be discharged over it into a ravine. This wasteway has a concrete lining, 18 in. thick, and is sloped 2 to 1 on the canal side, a discharge apron of paving stones set in cement mortar being placed on the hillside below it. The crest of the wasteway is at an elevation which will prevent the overtopping of the embankment that forms one side of the forebay at the lower end of the canal. The latter being all in cut is protected against such difficulty, as well as against breaks.

Forebay. The 40-acre forebay at the lower end of the canal is included to provide for sudden fluctuation of station load without necessitating continual changing of the upper head gates on the canal. The forebay also acts as a settling reservoir which prevents grit being carried to the water wheels. It has an average depth varying from 25 to 30 ft., and an available capacity of approximately 15,000,000 cu. ft.

The forebay is formed on the side of the hill by an embankment 3,500 ft. long and with an average height of 30 ft. This embankment was designed for a top width of 20 ft., with a slope of 2½ to 1 on the water side, paved to a depth of 3 ft. with rock from the canal excavation, and a slope of 1½ to 1 on the outer side. As built

the embankment has greater dimensions and contains more material than called for in the design, spoil from the canal excavation which was unsuited for the embankment proper having been wasted on its outer slope. The inner slope is also somewhat steeper than specified and is covered with rock from the canal excavation which was thrown on it roughly. About 85,000 cu. yd. of treacherous material was removed from the site of the embankment in order to reach a hardpan foundation. A timber core wall, consisting of a double-lap row of 2-in. planks, was built up on the center line of the embankment, extending from the hardpan nearly to the top of the latter. Material was dumped into the embankment from cars on a trestle, and was sprinkled as it was placed. The bottom of the forebay consists of a 3 to 10-ft. layer of good clay which forms a water seal with the core of the embankment. The latter has been finished nearly two years, during which time it has consolidated and retains the water in the forebay without any leakage.

Ice Conditions. Ice conditions on the river have been carefully observed and provisions have been made in all open water-ways to prevent interruption to the operation of the power station by ice in any form. It is believed that surface and needle ice will neither one be specially troublesome. A water-power development at the 45-ft. fall which is 5 miles upstream from the service reservoir has operated for 7 years without interruption by ice, although no provision to avoid difficulty from this source has been made and the natural conditions are much less favorable than at Thomson. Very little needle ice has been observed in the river at the site of the service reservoir, because the stream above this point freezes over in November, the ice remaining intact and covered with snow during the entire winter. The water is thus protected from direct contact with the cold air and the formation of needle ice is reduced to a minimum. Furthermore, the river enters the reservoir something over a mile from the upper head gates on the canal, so any needle ice that may reach the reservoir will probably be dissipated in passing this distance. The ice sheet formed in the river has thus far melted in place in the spring, so very little floating ice has been observed in the reservoir.

The expectation is that ice will form over the water in the earth section of the canal, in which the velocities are low, during such time as only enough water is supplied to operate 30,000 h. p. and probably until nearly the ultimate of 80,000 h. p. has been installed. It may also form over the water in the rock section of the canal at the start, but the water in this section is nearly certain to be more or less open when the full installation is in service. The period of time that the water will be exposed in the open sections of the canal will be so short, and the depth and volume of water in these sections so great that little, or no needle ice should be formed while the water is passing these sections. The water in the forebay will be frozen over and will afford the same protection against needle ice entering the pipe lines that is afforded to the canal by the service reservoir.

Lower Headgates. The outlet from the forebay into the pipe lines is through headgates at the downstream end of the forebay. A heavily reinforced concrete substructure for a gate house, 40x145 ft. in plan, is built across the end of the forebay, the reinforced-concrete bottom of this structure being on hardpan at the same elevation as the bottom of the forebay at the approach to it. A concrete cut-off wall extends 10 ft. into the hardpan on which the bottom of the structure rests, and the full length of the latter. The bottom also extends into clay puddle at the front of the structure, the junction being protected by rock paving. Concrete wing walls are built from each end of the gate house into the adjoining banks in such manner as to form a perfectly safe seal that prevents water from escaping around the ends of the structure.

The upstream side of the gate house substructure is a heavy curtain wall containing eight submerged arch openings through which the water passes to enter a rectangular chamber for racks that intercept any floating debris that may reach this chamber. These racks consist of steel bars spaced close together and assembled in removable sections. In the rear of the rack chamber, which is within the lines of the gate house that is to be erected on this substructure, are eight wells, each 15x20 ft. in plan. The openings leading to the pipe lines are each controlled by a 6x9-ft. sluice gate, one of which is to be placed in each gate well. These gates have non-rising stems which pass through ball-bearing operating stands on the floor of the gate house. The pitch of the screws on these stems was made high so the gates can be closed very rapidly by hand. Provision has also been made so the gates may be operated by motors, and as it will require considerable time to open the latter by hand, the motors will probably be installed and will be arranged so they may be controlled directly from the switchboard in the power station in case of an emergency.

Head Gates at Lower End of Forebay during Construction.

Spillway of Main Dam Prior to Erection of Gate House.

Thus far only three of the eight wells are provided with gates, the others being closed with stop logs until such time as they are needed. Grooves are built into the forward end of each well so stop logs may be inserted on that side of each gate to facilitate repairs to the latter.

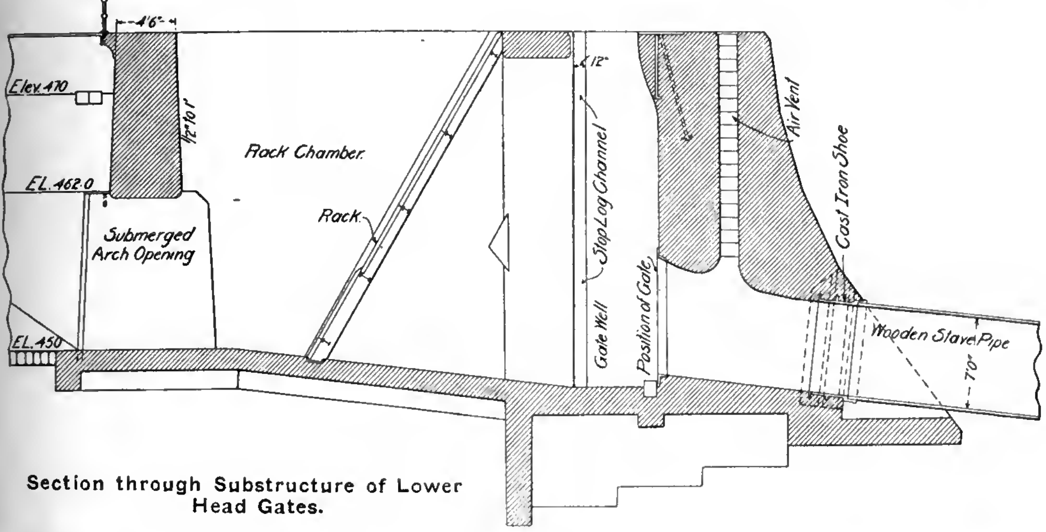
The ice and debris which collect in front of the curtain wall can be flushed out of the forebay through a rectangular sluice way opening in the wall at one end of the gate house substructure. The bottom of the sluiceway is well below the quiescent water level in the forebay, and a rising gate is provided in the sluiceway so ice and other debris may be flushed over this gate at different stages of water. A wooden sluice box on a trestle extends out on the hill side for a short distance to a point where a drop of about 20 ft. is secured. The flow from the sluice drops on a wooden apron and is carried away from the works at the end of the forebay.

Construction View of the Wasteway on the Canal.

Pipe Lines. Three 7-ft pipe lines have been laid in a trench from the lower head gates to the power station, a distance of 5,000 ft., and will be covered with 2 ft. of earth. Wooden-stave pipe was used for the first 4,000 ft. of these lines from the head gates, in which distance the fall is 150 ft., and riveted-steel pipe in the remaining 1,000 ft., in which the total fall is 228 ft. The grade on which the wooden pipe is laid is continually descending and at the flattest point is

sufficient to maintain velocities that will prevent any tendency toward a collection of air in the pipes. It was determined that the economical point to end the stave pipe and begin the steel pipe was where the pressure was equivalent to 150 ft. of head. The cost of wooden-stave pipe up to this head was estimated to be less than that of steel pipe, owing to the fact that the bands which take the strain can be placed in such manner as to obtain the most efficient distribution of metal, which variations would not be practicable with steel pipe. It is expected that the steel bands may rust out in 20 to 30 years, but in such event, they can be replaced one at a time in a manner that will avoid interference with the operation of the pipe lines. It is believed that the staves will last indefinitely, as they will be kept saturated by water under pressure.

The staves are of California redwood, which was almost perfect lumber, without knots or flaws. They are each 3½ in. thick and were cut



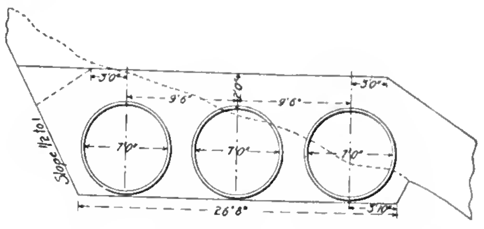
Section through Substructure of Lower Head Gates.

accurately to a template with arcs and radial sides of a 7-ft. circle. The bands are made of round ¾-in. steel, the shoes and turnbuckles used to join them being malleable cast-iron. The bands and shoes were dipped in hot asphalt before being placed and were spaced according to the pressure in the line. Leakage between the butt ends of the staves is prevented by inserting plates of metal, which were placed in saw cuts and then driven to a tight fit. The wooden stave pipes, which were built by the Excelsior Wooden Stave Pipe Co., of Lynchburg, Va., proved perfectly satisfactory when tested.

The joint between the stave and the steel sections of each pipe line was made by inserting the stave pipe into a cast-steel bell on the steel pipe and calking the joint with oakum and lead. A similar joint was also made at the end of each wooden-stave pipe at the gate house, where a cast-iron bell flange for each pipe was set in the concrete.

The 1,000 ft. of steel pipe at the lower end of each 7-ft. pipe line is built up of steel plates. The longitudinal seams are triple-riveted, with double-butt straps and the circular seams are double-riveted, with double-butt straps. The pipe was designed with a factor of safety in excess of three, an additional 1-16 in. of metal being added for rust. The pipe was dipped in hot asphalt and is laid in a trench and backfilled the same as the stave pipe. The grade at which the steel pipes are laid is all in the direction of the power house, the fall being about 228 ft. in the 1,000 ft. of pipe. The lower ends of the pipes are anchored securely in concrete and are tied into the brown sandstone ledge under the foundations of the power station with railroad rails. No expansion joints were placed in the steel pipe, as it is assumed the expansion caused by the variation between the limits of temperature during operation would be taken up by the elasticity of the metal. Reaction to insure this occurrence is obtained by angles which are riveted to the pipe at short intervals and flare out into the backfilling. Care was also taken to make the last joint in the steel pipe when the temperature was about the same as the average temperature of the water. The pipe was built and placed by the Riter-Conley Mfg. Co., of Pittsburg.

Manholes are provided at suitable intervals



Trench for Three 7-Foot Pipe Lines.

along each pipe line and two automatic air valves are placed in each pipe to prevent any tendency toward the formation of a vacuum due to a very sudden acceleration in the flow of water. These air vents are at changes in the grade of the pipe lines, and an open vent is placed on each pipe inside the gate house at the upper end of the pipe lines. The outside vents are protected from freezing to insure their action in cold weather.

The velocity of flow in each of the 7-ft. pipe lines when delivered 335 cu. ft. of water per second, which is equivalent to 10,000 electrical horse power at the generator, will be 9 ft. per second, and the maximum velocity will be about 11 ft. per second. The average velocity, due to a 50 per cent. load factor, will be about 5 ft. per second. The average friction loss in the entire 5,000 ft. of stave and steel pipe lines will be approximately equivalent to 10 ft. of head.

Stand Pipe on Pipe Lines.—Each of the three 7-ft. steel pipe lines from the forebay to the power station is connected to a large steel standpipe erected on a tower which spans them at a point about 500 ft. back of the station and 155 ft. above the water level in the river. A cross receiver, 8 ft. in diameter and 36 ft. long, is placed horizontally over the pipes and between the legs of the standpipe tower. Each pipe has a short 60-in. riser connecting it with this receiver through a 60-in. valve. A 6-ft. riser extends from this receiver to the standpipe tank, which is 30 ft. in diameter and 69 ft. high. The top of this tank is 235 ft. above the footings for the standpipe tower and 495 ft. above the level of Lake Superior, while the water surface in the forebay will be 472 ft. above that level. This standpipe was built and erected by the Chicago Bridge & Iron Works.

The standpipe has several important functions in connection with the operation of the water wheels in the station. First, it will relieve the pipe lines of excessive pressures due to a sudden closing of the gates in the water wheels following a quick drop in the demand for power. Second, it will also maintain pressures and speed regulation in the station when sudden demands are made for water; the 30-ft. standpipe has sufficient capacity between Elevations 426 and 472 to supply enough water to the wheels to meet a sudden demand for power up to 15,000 h.-p. and to maintain the head required for good regulation by governors on the water wheels until the water in the pipe lines back to the forebay is given an opportunity to accelerate sufficiently to meet the added demand for power. Third, the top of the standpipe being well above the water level in the forebay, enough back pressure will be exerted on the pipe lines to prevent any tendency toward the formation of vacuum at the changes of grade where the air valves are placed. Fourth, the cross receiver and standpipe will permit a flow to be maintained continuously in all the pipe lines during freezing weather, even though all of the water wheels in the power station are not in service; the friction losses in the pipe lines can also be reduced when the station is running at part load by continuing all the pipes in operation through the cross receiver. And, lastly, the standpipe provides a vent for the escape of any air bubbles or entrained air that might otherwise tend to produce water hammer in the casing of the water wheels. The principal value of the standpipe, however, is the saving it will effect in the water that

Three 7-Ft. Wood Stave Pipe Lines Looking toward Lower Head Gates.

would otherwise be wasted through relief valves which are provided at the water wheels in order to secure proper speed regulation and to avoid dangerous excess pressures in the water system.

The cross receiver and the base of the four legs of the standpipe tower are on heavy concrete footings. The 60-in. connections for four pipe lines are imbedded in the concrete under the receiver, so the fourth pipe line can be attached when it is laid. The four additional pipes, which are contemplated when the ultimate installation is completed, will be connected with an extension of the cross receiver.

The standpipe tank is of standard design with a hemispherical bottom. The 6-ft. riser has a slip expansion joint at the bottom of the tank, but it is to be so protected as to prevent the water from freezing. A frost box, 9.5 ft. in diameter, will be built around the riser, and the tank will also be lagged, so during excessively low temperatures warm air may be passed through the space enclosed by the frost box and lagging.

(To be continued.)

Glass Blocks for Tunnel Lining.

The Pennsylvania R. R. has for some time been seeking a thoroughly satisfactory lining for the passenger tunnels leading under the tracks from the stations to the platforms on the opposite side, and though repressed and waterproof brisk, glazed and glass tile, and enamel brick have been used, none of them have been free from objections. On the other hand, some of them possess quite marked merits as a material for a finished lining for tunnel work. Some of the materials mentioned are subject to cracking on account of changes of temperature, others chip and spall off under the action of frost, and a number of them being non-porous allow the moisture which accumulates on their surface to drip down upon passengers going through the tunnels. The main trouble occurs in the winter when the temperature rises above the freezing point after several days or weeks of severe freezing weather. The bench walls become chilled and remain so for about 24 hr. after a change to warmer weather. At such times the condensation upon the surface is heaviest and the spalling off and crazing is most severe.

After a consideration of the materials mentioned it was decided to try something new, and accordingly specially designed glass block will be used in the passenger tunnel now building at Edgewood, a suburb of Pittsburg. Certain features have been embodied in the design of the new material, which it is hoped, will result in doing away with the objections found in the other linings.

The defects of all of the materials thus far experimented with can easily be seen by anyone making a casual inspection. Repressed brick, which is usually of a porous nature, absorbs moisture condensed on its face, and owing to its damp condition becomes a lodging place for dirt and grime and in a short time presents a very unsightly apeparance. Waterproof brick, on the contrary, does not have the most objectionable feature of porous repressed brick but does condense the moisture permitting it to run down the face of the lining to the floor. The experience with enamelled brick has been very extensive, almost every make and size having been used. Some of these have been found to craze and spall off under the action of frost, while those not affected in this manner nevertheless condense the moisture, the same objection mentioned in connection with waterproof brick.

Glazed tile will absorb moisture, and in zero weather this moisture freezes and spalls off the glazed face together a portion of the tile itself. These unglazed portions soon become black and the whole lining assumes an unsightly appearance. Glass tile has been found to be nearly impossible to bond to the plaster lining necessary in tunnel construction, and the moisture eventually gets in between the tile and the plaster and in freezing weather forces off the entire tile face.

It is recognized that a lining for this purpose must meet rather severe conditions owing to its exposure to large temperature variations, and the fact that the temperature of the lining will not change concurrently with changes in the atmosphere, due to the tunnel being surrounded by the earth embankment of the railroad. In designing the new blocks, therefore, these severe conditions have been held continually in mind, and the elaborations of the constructions is justified by the difficulties which it is expected to overcome. The glass brick which will be put in at Edgewood measure 2 x 4 x 8 in., and have a hollow center, the wall forming the face being 5/8 in. thick. The brick is to be laid on a specially prepared concrete foundation offsett, having a 2-in. invert to receive any condensation from the interior of the brick and conduct same to the sewer. In addition to this precaution the hollow interior allows the brick to be well ventilated and the passage of air through it will insure almost as rapid a change of the temperature of the lining as of the atmosphere itself. The ventilation is provided for by placing brass grills the same size of the brick, every tenth brick in courses next to the floor and the ceiling.

It is not expected that condensation will be entirely overcome, but as glass rapidly assumes the temperature of the air it comes in contact with, and as precautions have been taken to insure good ventilation, it is hoped that the condensation will be brief and practically unnoticed. As glass is non-porous there will be no trouble with the face of the work spalling off, due to frost, and no trouble is apprehended from crazing, as experience has shown that this does not occur where glass is used alone. The glass naturally has the same advantages as enamelled brick and glazed tile in giving a smooth, pleasing finish and a surface that does not afford lodgment for dirt.

Mr. W. C. Richey, master carpenter, Pittsburg, has charge of the work.

Oiling Roads as a method of laying dust has aroused considerable criticism in some quarters, and for this reason some statements concerning a piece of work of this sort in Morristown, N. J., recently made by Mr. Wm. S. Bacot, one of the leading road engineers of this country, deserves considerable attention. Mr. Bacot states that a stretch of about 2 miles in Morristown has been oiled with an odorless compound unknown to him, but the results are so satisfactory in laying dust that he considers the experiment an important one. Prior to the oiling of the road, the large number of automobiles using it made the dust in the vicinity of the road so heavy that, in his opinion, the oil treatemnt would be advisable even if the roads wore out faster on account of its use. Fortunately the wear on the road does not seem to be at all comparable in amount with that on other roads in the vicinity, supporting an equal travel, but sprinkled with water regularly. Mr. Bacot states that he has observed the effect of oiling a hard road free from dust to be more lasting than is the case with roads having a surface of considerable loose material, which required frequent applications of the oil to produce the same results. In this connection reference may be made to the report of a commission appointed by the Minister of Public Works of France, noticed in this journal four weeks ago, expressing the same opinion.

A Combined Underpinning and Sheeting Job.

A new six-story steel cage bank building on the southwest corner of Murray St. and Broadway, New York, is enclosed on two sides by an L-shaped seven-story and basement office building, with the floor beams supported without columns in the thick brick wall, having their foundations seated about 12 ft. below the curb on coarse sharp sand. The adjacent walls of both buildings are throughout their entire length in contact upon the party lines and recesses had to be cut in the face of the long wall of the old building to clear the steel columns of the new building. The vaults for the new building extend about 15 ft. under the sidewalk in both streets and are enclosed on the outer sides by heavy brick retaining walls about 24 ft. high with their foundations at the same level as those of the other footings, above water level on the dense sand about 24 ft. below the curb. After the demolition of the old building the first work was the underpinning of the adjacent building and the sheeting and bracing of the outer side of the excavation to retain the earth under the roadway. The contract for both sheeting and underpinning and for the construction of a sidewalk bridge and overhead platform on two faces of the lot was awarded to Miller, Daybill & Co., Brooklyn, and is now nearing successful completion.

Six equidistant pits about 6 ft. square in a line parallel to the long wall of the adjacent building and about 10 ft. distant from it were sheeted down to a depth of 24½ ft., about 6 in. below sub-grade of the new cellar, and in each of them there was built a timber crib 5 ft. square and about 15 ft. high. Four lines of 12x12-in. timber breaking joints, were supported on the tops of the cribs forming a continuous 48x48-in. longitudinal girder about 125 ft. long parallel with Murray St. At the end farthest from Broadway this girder supported one end of a similar 48x48-in. transverse girder, about 25 ft. long with the opposite end carried on a similar crib pier. The two girders thus formed a continuous L-shaped footing extending around two sides of the lot to receive the ends of the needle beams used for supporting the walls of the adjacent building while they were underpinned.

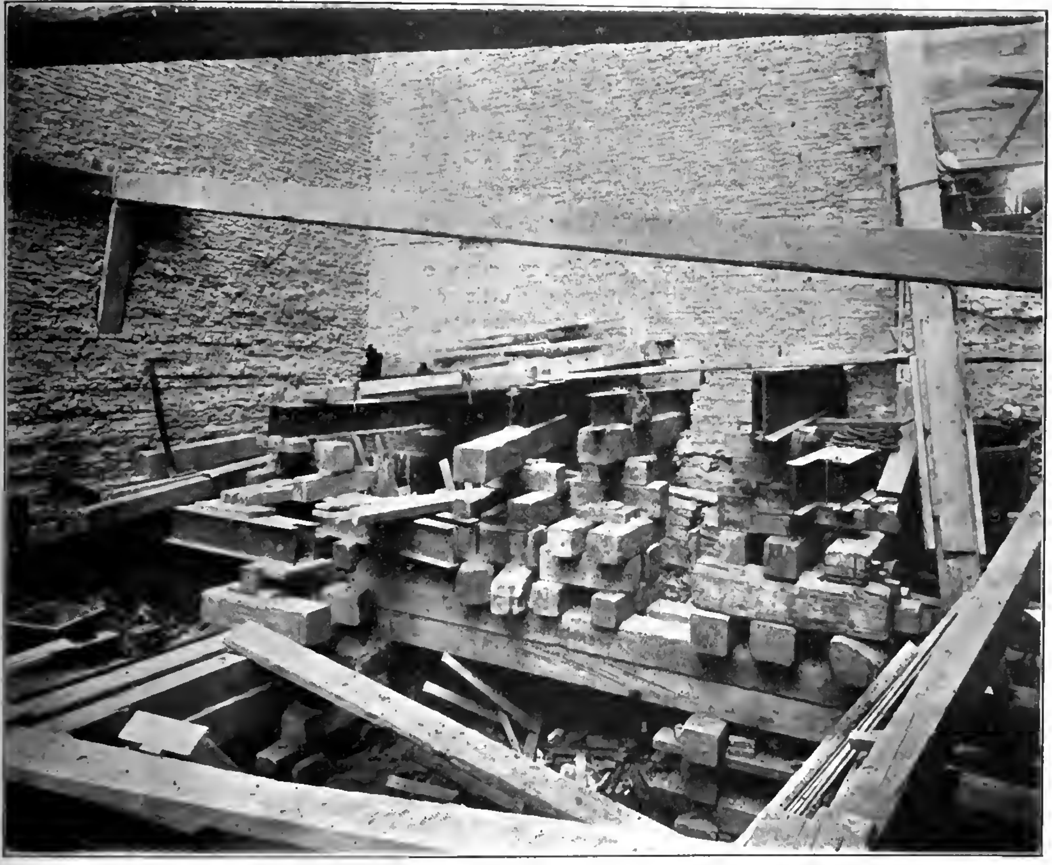
The basement of that part of the adjacent building which fronted on Broadway was occupied and therefore inaccessible to the contractor who was obliged to do his work without interfering with it. He therefore cut holes about 6 ft. apart on centers through the footing of the wall below the level of the basement floor for the needle beams and from these holes excavated short horizontal transverse drifts about 15 ft. long under the basement floor. From the extremities of these drifts a tunnel about 5 ft. deep and 4 ft. wide was driven the full length of the wall, 135 ft., and on the bottom of it were laid four tiers of 12x12-in. timbers, breaking joints and making a 48x48-in. continuous sill comparable with the girder on the opposite side of the wall and intended to receive the inner ends of the needle beams. A set of three 15-in. I-beams about 25 ft. long was inserted in each of the holes with the ends resting on the 48x48-in. girders and sills in the old building and on short cribbing piers on top of the 48x48-in. girder in the lot. A 15x¾x20-in. horizontal bearing plate was laid on the top flanges of the group of girders in the plane of the wall and a corresponding piece of plank 3 in. thick long leaf yellow pine covered with cement mortar was set on top of it filling the space between the top of the beam and the upper part of the hole in the brick work. As soon as the cement commenced to set wedges were driven between the steel plate and wooden plank and forced the latter up to make solid

bearing against the old brick work when the remaining cavities between the wedges were filled with grout and the whole allowed to set and form tight packing between the needle girder and the wall. A thick horizontal cast-steel plate engaging a special 4-in. 24-ton jack screw with bevelled threads was set on a pair of beams built into the crib-work under the outer end of the needle beam with the upper end of the jack-screw bearing against a cap plate engaging the lower flanges of the I-beam. The jack screws under the needle beams were simultaneously operated until their supports were thoroughly compressed and settled and the full weight of the wall was taken by the needle beams giving them a deflection of about ¼ in. at the center point.

Similar needle beams under the 40-ft. long wall parallel to Broadway were allowed to penetrate the unoccupied basement in that wing of the old building and were therefore supported at their outer ends on higher timber cribs built up from the top of the 48x48-in. transverse girder. As the width of this wing of the building is only 15 ft. from out to out, the needle beams were carried entirely across it and their inner ends projected through holes cut for that purpose in the opposite wall and were seated on the brick work there thus making the wall and its footings serve as a sill distributing the load from the needle beams, instead of preparing a special sill as in the other wing of the building.

At an angle formed by the intersection of the walls of the old building the corner pier of the brick work was carried by a needle beam making an angle of 45 deg. with each wall and intersecting both just beyond their point of intersection so as to secure full bearings on both. This needle beam consisted of two 15-in. I-beams 20 ft. long seated on one 12x12-in. timber 25 ft. long that was supported at both ends on the adjacent needle beams carrying the intermediate portions of the wall as already described.

The wall parallel with Broadway terminates at Murray St. with a 3x4-ft. brick pier having an estimated load of 100 tons. On account of the small area of the pier it was underpinned in sections and care was taken to cut away only a small portion of the brick work and immediately support it on a part of the sectional underpinning before reducing the area of the pier to any great degree. A recess 6 in. deep and 24 in. high was first cut on the outer face of the pier and in it was placed 2 20-in. I-beams supported at the extremities like the other needles and wedged and cemented to solid bearing against the brick work. A similar recess was then cut across the opposite face at a little lower level and a pair of I-beams inserted in it and in a hole cut through the face of the adjacent wall so that the pier was carried by needle beams engaging shoulders on each side. To give it still further security a recess, at right angles to the first two was cut across the inner face of the pier and a short horizontal I-beam was seated in it and supported at both ends on the two needle beams already mentioned. The pier at the termination of the outer wall at the Broadway front had also a load of about 100 tons and was underpinned in the same manner. The Murray St. pier was braced by two 12x12-in. spur shores about 40 ft. long at right angles to each other, one of them reaching across the sidewalk and at a clear height sufficient to prevent obstructing it and the other at a somewhat smaller angle with the vertical being carried down to a footing in the bottom of the excavation. Both of these spurs had their square upper ends set in recesses cut in the brick walls and their lower ends adjusted by pairs of wedges on transverse horizontal sill pieces. An additional brace was provided by a 12x12-in. horizontal timber about 20 ft. long which was placed at an angle of 45 deg., with both of the underpinned walls which had recesses cut in them at the second floor level to receive the ends of the beam which were brought to bearings by pairs of wooden wedges driven by a man suspended in a boatswain's chair suspended from the roof at a height of about 40 ft. above the bottom of the excavation.



Needlebeams under Murray Street Building.

After the weight of the building was transferred to the 48x48-in. girders, six 12x12-in. inclined horizontal transverse braces were set with their lower ends engaging the long 48x48-in. girder and their upper ends engaging the lower horizontal ranger piece for the sheeting which retained the side of the excavation for the Murray St. vault. These braces were continued from the opposite side of the girder to footings of the old building thus providing balanced reaction and utilizing both the inertia and weight of the old building to resist the lateral thrust of the earth in the street. The upper rangers for the same sheeting were braced by transverse 12x12-in. struts inclined upwards in the same vertical planes as the lower struts. The opposite ends of these struts took bearing on 12-in. horizontal pieces about 6 ft. long laid against the face of the wall of the old building and distributing the pressure on it, thus acting both as for shores for the wall and as cross bracing for the retaining wall. The upper ends of these braces are supported by struts about 6 ft. long slightly inclined from the vertical with their lower ends seated in recesses cut in the face of the brick wall, their upper ends being stabbed to the lower surface of the 12x12-in. struts.

The sheeting around the sidewalk vault is made with 3x10-in. square edge planks about 24 ft. long driven as the excavation progressed, but having their lower ends always kept 3 or 4 ft. below the bottom of the pit. They were rapidly and economically driven by a No. 4 Ingersoll-Sargent steam drill having the rotating device removed and the drill bit replaced by a square ended bar striking on a heavy removable steel cap which enclosed the top of the pile. The sheeting is allowed to remain permanently in the ground, and is faced up on the inside with a 4-in. brick wall to which the water proofing is applied and after which the heavy foundation wall is built up against it. At the Murray St. pier the cross wall at the end of the vault was carried on vertical shores reaching to the foot of the excavation and located so that it was very difficult to remove them and they were permanently built in and enclosed by the outer brick work for the water proofing. At this point the excavation was very difficult and it was necessary to put the sheeting in with short vertical boards set and braced as fast as the pit was carried down.

The work was executed without difficulty from water and although very heavy and somewhat complicated has been done rapidly and successfully. The principal difficulty was to arrange the girders, piers and both systems of struts so as to clear the permanent structural work in the building and this has been done so successfully that it was only necessary to move one of the struts to permit the building of the brick work and the erection of the steel frame work.

As the excavation was carried down to sub grade the footings under the adjacent walls of the old building were removed and the basement floor was shored up when necessary. A new concrete footing and brick foundation wall was built in the bottom of the excavation up a height just clearing the lower flanges of the needle beams. Between the groups of needle beams brick piers were built a little higher and capped with pairs of cut stone. The upper stone was well covered with cement mortar and double steel wedges being driven between the stones, the mortar was forced up against the lower side of the old brick work, making a solid bed for the latter. The pairs of wedges were gradually driven until the weight of the wall was transferred from the needle beams to the piers between them and the needle beams were released, a condition which was indicated by the disappearance of their flexure as they sprung back to a horizontal position.

Marc Eidlitz & Son are the general contractors for the building and the underpinning and sheeting have been done by Miller, Daybill & Co., under the personal direction of Mr. Alfred Daybill.

A 7-Ft. Steel Pipe Line at St. Louis.

Among the improvements to the water supply system of St. Louis, Mo., that are under construction is a 7-ft. steel pipe flow line, 19,634 ft. in length. This flow line extends from a series of settling basins near a low service pumping station, at the Chain of Rocks, 10 miles above the central portion of the city, to a high-service pumping station in the northern end of the latter. Water is drawn from the Mississippi River by pumps in the low service station, from which it passes through the settling basins before being delivered to either of two high-service pumping stations that supply the distribution mains directly. A general description of the settling basins, including the design and construction of two large reinforced concrete basins was printed in The Engineering Record for July 6, 1907.

A horseshoe-shaped brick and masonry conduit, 11 ft. wide at the springing line of the arch and 9 ft. high, extends from these basins to the two high-service pumping stations at Baden and at Bissell's Point, the former being about 4 miles and the latter 7 miles down the river from the basins. Although this conduit has a sufficient carrying capacity to supply the two high-service stations, even during periods of maximum demand for water, it is at present the only means of conveying water to those stations, so the 7-ft. steel pipe line is being laid to the first high-service station to insure a supply at all times.

The new flow line starts at an outlet gate chamber near the down-stream end of the basins at the Chain of Rocks and parallels the brick and masonry conduit at varying distances to a 25,000,000-gal. storage reservoir at the Baden high-service station. The gate chamber from which the flow line starts has conduits connecting it with all of the settling basins, so water may be drawn into it from any of the latter. The pipe line is laid on a grade of about 6 in. to the mile from this chamber, which gives it an estimated carrying capacity of 35,000,000 gal. per 24 hours without head; it can, however, be operated under a 15-ft. head and will then deliver 10,000,000 gal. per 24 hours. It is nearly all in cut, only a few crossings of waterways being required. At most of these crossings the pipe line is close enough to the brick and masonry conduit so the crossings which were constructed when the latter was built are being extended to serve the pipe line.

A creek crossing about midway on the line requires the only bridge structure of any size. This bridge is a 137.5-ft. span having two Warren trusses with riveted connections, which are 14 ft. apart on centers, the height of the truss from center to center of chords being 11 ft. The bridge has a tight concrete roof and floor, both carried by transverse steel beams between the trusses. The floor system is designed to carry a live load of 50 lb. per square foot, in addition to its own weight, the weight of the 7-ft. flow line filled with water and the concrete supports of the flow line. The roof is proportioned to carry a uniform live load of 100 lb. per square foot in addition to its own weight. The wind pressure for which provision is made in the design is assumed to be acting horizontally in either direction at 30 lb. per square foot of a surface bounded by the extreme dimensions of the bridge. The allowable stresses of the steel and the methods of testing the latter are generally the same as those usually employed in railroad bridge design.

The pipe line is made of soft open-hearth steel plates ½ in. thick, and 84 in. wide, only one longitudinal joint being allowed to each plate. The steel is required to contain not more than 0.05 per cent. phosphorus, 0.05 per cent. sulphur, 0.05 per cent. silica and 0.5 per cent. manganese. The tensile strength specified is between 52,000 and 60,000 lb. per square inch, the elastic limit being required to reach at least 30,000 lb. per square inch. The pipe is assembled with taper rings in 28-ft. lengths, each made up of four rings. The small end of each ring at the transverse joint is inserted within the end of the next adjacent ring, the inside diameter of the small end of each ring being 84 in., and the inside diameter of its large end great enough so that the end will fit over the small end of the adjacent ring.

The lengths of pipe are tested at the mill under a hydraulic pressure of 30 lb. per square inch before being coated. After passing the test the lengths of pipe are cleaned and heated and are then dipped in a bath of mineral rubber asphalt coating. Suitable care is taken to protect this coating from the time the pipe is removed from the bath until it is accepted in place in the trench.

Laying Pipe in Close Quarters.

The construction of the pipe line presented no particular difficulties, as most of the trench excavation was in soil which stood well after the trench had been opened. The depth of cutting for about one-half the length of the line was under 12 ft. and for the remainder the cutting ran from 16 ft. to 22 ft. In the more shallow excavation the latter was made by hand, and in nearly all of this part of the work no shoring was required; shoring was employed, in fact on a very small percentage of the total amount of trench that has been opened.

A steam shovel mounted on a traveling platform is being used in making the excavation for the deeper sections of the trench, on which work is nearing completion. This platform, which is about the size of the platform on which a regular 20-ton Vulcan steam shovel is mounted, carries a boiler and a hoisting engine to operate the crane and dipper arm. The platform is carried by four 18-in. I-beams, 30 ft. long, two of which are placed across the trench under the front end of it and the other two under its rear end. These beams have truss rods connecting their ends, the latter resting on rollers on plank runways laid on both sides of the trench. These runways are back 2 ft. from the top of the trench and distribute the load on the sides of the latter to such extent that in the soil thus far encountered no caving has been caused by the load of the shovel outfit. The latter was built by the Vulcan Iron Works and removes the principal part of the excavation, the extra space required at the joints between the 28-ft. lengths, and extra trimming being done by hand.

The city of St. Louis operates a standard-gauge electric railway between the low-service and the two high-service pumping stations, which railway parallels the location of the 7-ft. flow line at a distance of 50 to 300 ft. This railway connects with steam railroads in the city, and on it has been delivered over 5,300 tons of the steel pipe required in building the flow line. The pipe was brought in over this line in the cars on which it was loaded at the mills and in a large portion of the trench was unloaded along the section of the trench it was to occupy, so little difficulty was encountered in pipe transportation.

The pipe is handled into the trench by a stiff-leg derrick set between the latter and the electric railway. Each 28-ft. section of pipe is lifted by one line around the center, this line being threaded through a hose to prevent injury to the coating of the pipe. The joints between the 28-ft. sections are made with pneumatic hammers supplied with an under pressure from either of two compressor outfits mounted on four-wheel trucks. One outfit has a 10x10-in. Laidlaw-Dunn-Gordon compressor and the other a 10x12-in. Curtis compressor, each of which is direct-connected to a 50-h. p. motor that receives power from the transmission line of the electric railway. They can be moved readily by one team and have been found very serviceable in this work.

The pipe line is tested, in lengths of approximately 2,000 ft., to a hydraulic pressure of 30 lb. per square inch. This pressure is maintained until all leaks in the entire section under pressure have been caulked and the pipe made tight.

The 25,000,000-gal. storage reservoir to which the 7-ft. flow line delivers at the upstream one of the two high-service pumping stations has only recently been completed. It has buttressed reinforced-concrete side walls and its bottom is lined with concrete. The excavation for the basin was nearly all made in dense limestone rock, the tops of the sides of the basin being about flush with the ground surface. The pipe line terminates in a gate house at the reservoir. A connection is made between this gate house and the reservoir, and a 60-in. hub-and-spigot cast-iron pipe is extended across the later on concrete pedestals, 10 ft. high, to the pumping station. The 7-ft. flow line is also connected through the gate chamber to the brick and masonry conduit from the settling basins at the low-service pumping station.

Mr. Ben C. Adkins is water commissioner, Mr. Edward E. Wall is assistant water commissioner and Mr. Arthur I. Jacobs is engineer of the supply and purifying division of the water department. The flow line is being built by the Parker-Washington Co., the work being under the direction of the St. Louis office of that company. The steel pipe was made by the Carroll-Porter Boiler & Tank Co. of Pittsburgh.

The Key West Extension of the Florida East Coast Ry. has been making rapid progress lately and construction trains are now running over half the distance from Miami to Key West. The more difficult half of the road is unfinished and it may be two years before it is ready for regular operation. There will be about 5¾ miles of concrete arches of a type already illustrated in The Engineering Record. Their spans are 50 to 60 ft. and they will rise about 30 ft. above the water. At one place the track is carried for 10,500 ft. on a succession of these arches.

Science and Engineering.

The relations between science and engineering were discussed in the opening address of the engineering section of the recent convention of the British Association for the Advancement of Science. The address was made by Dr. Silvanus P. Thompson who asserted at the outset that the astonishing development of the material resources of civilization is due to science. Chemistry, physics, mechanics and mathematics have furnished the means for this development, and the profession most potent in using them is that of engineering. The difference between the England of Edward the Seventh and of Edward the Sixth, between the Germany of William the Second and of Charles the Fifth is due more to the progress made in science and its applications than to the changes in politics, art, philosophy and religion. The following extracts from the address cover its leading topics:

In engineering, above all other branches of human effort, we are able to trace the close interaction between abstract science and its practical applications. Often as the connection between pure science and its applications has been emphasized in addresses upon engineering, the emphasis has almost always been laid upon the influence of the abstract upon the concrete. We are all familiar with the doctrine that the progress of science ought to be an end in itself, that scientific research ought to be pursued without regard to its immediate applications, that the importance of a discovery must not be measured by its apparent utility at the moment. We are assured that research in pure science is bound to work itself out in due time into technical applications of utility, and that the pioneer ought not to pause in his quest to work out potential industrial developments. We are invited to consider the example of the immortal Faraday, who deliberately abstained from busying himself with marketable inventions arising out of his discoveries, excusing himself on the ground that he had no time to spare for money-making. It is equally true, and equally to the point, that Faraday, when he had established a new fact, or a new physical relation, ceased from busying himself with it, and pronounced that it was now ready to be handed over to the mathematicians. But, admitting all these common places as to the value of abstract science in itself and for its own sake, admitting also the proposition that sooner or later the practical applications are bound to follow on upon the discovery, it yet remains true that in this thing the temperament of the discoverer counts for something. There are scientific investigators who cannot pursue their work if troubled by the question of ulterior applications; there are others no less truly scientific who simply cannot work without the definiteness of aim that is given by a practical problem awaiting solution. There are Willanses as well as Regnaults; there are Whitworths as well as Poissons. The world needs both types of investigator; and it needs, too, yet another type of pioneer, namely, the man who, making no claim to original discovery, by patient application and intelligent skill turns to industrial fruitfulness the results already attained in abstract discovery.

There is, however, another aspect of the relation between pure and applied science, the significance of which has not been hitherto so much emphasized, but yet is none the less real—the reaction upon science and upon scientific discovery of the industrial applications. For while pure science breeds useful inventions, it is none the less true that the industrial development of useful inventions fosters the progress of pure science. No one who is conversant with the history, for example, of optics can doubt that the invention of the telescope and the desire to perfect it were the principal factors in the outburst of optical science which we associated with the names of Newton, Huygens and Euler. The practical application, which we know was in the minds of each of these men, must surely have been the impelling motive that caused them to concentrate on abstract optics their great and exceptional powers of thought. Had there been no industrial development of the steam engine, is it at all likely that the world would ever have been enriched with the scientific researches of Rankine, Joule, Regnault, Hirn, or James Thomson?

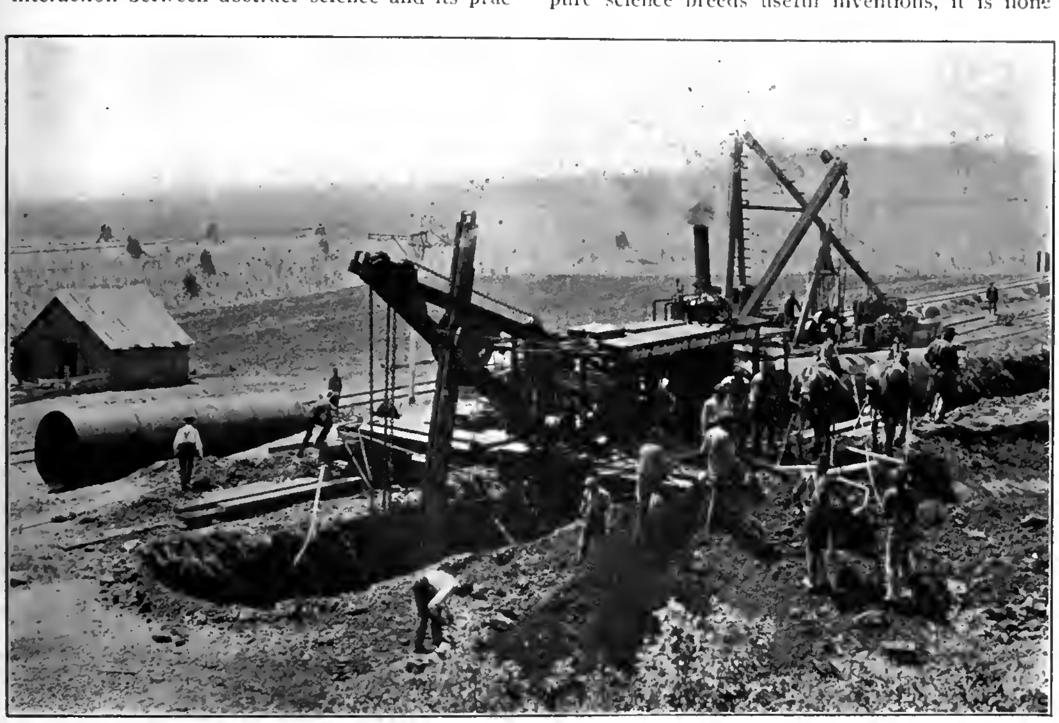
In considering this reflex influence of the industrial applications upon the progress of pure science it is of some significance to note that for the most part this influence is entirely helpful. There may be sporadic cases where industrial conditions tend temporarily to check progress by imposing persistence of a peculiar type of machine or appliance; but the general trend is always to help to new developments. The reaction aids the action; the law that is true enough in inorganic conservative systems, that reaction opposes the action, ceases here to be applicable, as, indeed, it ceases to be applicable in a vast number of organic phenomena. It is the very instability thereby introduced which is the essential of progress. The growing organism acts on its environment, and the change in the environment reacts on the organism—not in such a way as to oppose the growth, but so as to promote it. So is it with the development of pure science and its practical applications.

In further illustration of this principle one might refer to the immense effect which the engineering use of steel has had upon the study of the chemistry of the alloys. And the study of the alloys has in turn led to the recent development of metallography. It would even seem that through the study of the intimate structure of metals, prompted by the needs of engineers, we are within measurable distance of arriving at a knowledge of the secret of crystallogensis. Everything points to the probability of a very great and rapid advance in that fascinating branch of pure science at no distant date.

There is, however, one last example of the interaction of science and industry which may claim closer attention. In the history of the development of the electric motor one finds abundant illustration of both aspects of that interaction.

We go back to the year 1821, when Faraday, after studying the phenomena of electromagnetic deflexion of a needle by an electric current—Oersted's discovery—first succeeded in producing continuous rotations by electromagnetic means. In his simple apparatus a piece of suspended copper wire, carrying a current from a small battery, and dipping at its lower end into a cup of mercury, rotated continuously around the pole of a short bar-magnet of steel placed upright in the cup. In another variety of this experiment the magnet rotated around the central wire, which was fixed. These pieces of apparatus were the merest toys, incapable of doing any useful work; nevertheless, they demonstrated the essential principle and suggested further possibilities. Two years later, Barlow, using a star-wheel of copper, pivoted so that the lowest point of the star should make contact with a small pool of mercury, found that the star-wheel rotated if a current was sent through the arm of the star while the arm itself was situated between the poles of a steel horseshoe magnet. Shortly afterwards Sturgeon improved the apparatus by substituting a copper disc for the star-wheel. The action was the same. A conductor, carrying an electric current, if placed in a magnetic field, is found to experience a mechanical drag, which is neither an attraction nor a repulsion, but a lateral force tending to move it at right angles to the direction of flow of the current and at right angles to the direction of the lines of the magnetic field in which it is situated. Still this was a toy.

Two years later came the announcement by Sturgeon of the invention of the soft iron electro-magnet, one of the most momentous of all inventions, since upon it practically the whole of the constructive part of electrical engineering is based. For the first time mankind was furnished with a magnet, the attractive power of which could be increased absolutely indefinitely by the mere expenditure of sufficient capital upon the iron core and its surrounding copper coils, and the provision of a sufficiently powerful source of electric current to excite the magnetization. Furthermore, the magnet was under control, and could be made to attract or to cease to attract at will by merely switching the current on or off; and, lastly, this could be accomplished from a distance, even from great distances away. How slowly the importance of this discovery was recognized is now a matter for astonishment. To state that Sturgeon



Steam Shovel Used in Trench Work for 7-Foot Steel Pipe Line.

died in poverty twenty six years later is sufficient to indicate his place among the unrequited pioneers of whom the world is not worthy. Six years elapsed and then there came a flood of suggestions of electric motors in which was applied the principle of intermittent attraction by an electro-magnet. Henry, in 1831, and Dal Negro, in 1832, produced see-saw mechanisms so operated. Ritchie, in 1833, and Jacobi, in 1834, devised rotatory motors. Ritchie pivoted a rapidly commutated electro-magnet between the poles of a permanent magnet—a true type of the modern motor—while Jacobi caused two multipolar electro-magnets, one fixed, one movable, to put a shaft into rotation and propel a boat. A perplexing diminution of the current of the battery whenever the motor was running caused Jacobi to investigate mathematically the theory of its action. In a masterly memoir he laid down a few years later the theory of electric motive power. But in the intervening period, in 1831, Faraday had made the cardinal discovery of the mechanical generation of electric currents by magneto-electric induction, the fundamental principle of the dynamo. Down to that date the only known way—save for the feeble currents of thermopiles—to generate electric currents had been the pile of Volta, or one of the forms of battery which had been evolved from it. Now, by Faraday's discovery, the world had become possessed of a new source. And yet again, strange as it may seem, years elapsed before the world—that is, the world of engineers—discovered that an important discovery had been made. Not till some thirty years later were any magneto-electric machines made of a sufficient size to be of practical service even in telegraphy, and none were built of a sufficient power to furnish a single electric light until about the year 1857. In the meantime in America other electric motors, to be driven by batteries, had been devised by Davenport and by Page; the latter's machine had an iron plunger to be sucked by electro-magnetic attraction into a hollow coil of copper wire, thereby driving a shaft and fly-wheel through the intermediate action of a connecting-rod and crank. Page's was, in fact, an electric engine, with 2-ft. stroke, single-acting, of between 3 and 4 h.-p. The battery occupied about 3 cu. ft., and consumed, according to Page, 3 lb. of zinc per horse-power per day. This must have been an under-estimate; for if Daniell's cells were used, the minimum consumption for a motor of 100 per cent. efficiency is known to be about 2 lb. of zinc per horse-power per hour.

An instructive view of the development of electric motors half a century ago can be obtained from a discussion of electro-magnetism as a motive power which was held in April, 1857, at the rooms of the Institution of Civil Engineers. On this occasion the most eminent engineers one and all condemned the idea of electric motive power as unpractical and commercially impossible. Even Faraday, in his lecture on Mental Education, in 1854, had set down the magneto-electric engine along with mesmerism, homœopathy, odylism, the caloric engine, the electric light, the sympathetic compass, and perpetual motion as coming in different degrees amongst "subjects uniting more or less of the most sure and valuable investigations of science with the most imaginary and unprofitable speculation, that are continually passing through their various phases of intellectual, experimental, or commercial development, some to be established, some to disappear, and some to recur again and again, like ill weeds that cannot be extirpated, yet can be cultivated to no result as wholesome food for the mind."

Fifty years have fled, and Hunt, Grove, Smee, Tyndall, Cowper, Joule, Bidder and Stephenson have long passed away. Lord Kelvin remains the sole and honored survivor of that remarkable symposium. But the electric motor is a gigantic practical success and the electric motor industry has become a very large one, employing thousands of hands. Hundreds of factories have discarded their steam engines to adopt electric-motor driving. All traveling cranes, nearly all tramcars, are driven by electric motors. In the Navy and in much of the merchant service the donkey engines have been replaced by electric motors. Electric motors of all sizes and outputs, from one-twentieth of a horse-power to 8,000 horse-power, are in commercial use. One may well ask: What has wrought this astonishing revolution in the face of the unanimous verdict of the engineers of 1857? The answer may be given in terms of the action and reaction of pure and applied science. Pure science furnished a discovery; industrial applications forced its development; that development demanded further abstract investigation, which in turn brought about new applications. It was beyond all question the development of the dynamo for the purposes of electrotyping and electric light which brought about the commercial advent of the electric motor.

Interplay of action and reaction make for progress not only in the evolution of the scientific industries, but also in the development of the individual engineer. In him, if his training is on right lines, pure theory becomes an aid to sound practice; and practical applications are continually calling him to resort to those abstractions of thought, the underlying principles, which when known and formulated are called theories. Recent years have brought about a so much better understanding of education, in its bearing upon the professions and constructive industries, that we now seldom hear the practical man denouncing theory, or the theorist pooh-poohing practice. It is recognized that each is useful, and that the best uses of both are in conjunction, not in isolation. As a result of this better understanding distinct progress is being made in the training of engineers. Of this the growth of the engineering departments of the universities, and of the technical colleges and schools, affords striking evidence. The technical schools, moreover, are recognizing that their students must have a sound preliminary education and are advancing in the requirements they expect of candidates for admission. They are also finding out how their work may best supplement the practical training in the shops, and are improving their curricula accordingly. In the engineering industry, too, Great Britain is slowly following the lead taken in America, Germany and Switzerland, in the recognition afforded to the value of a systematic college training for the young engineer, though there is still much apathy and even distrust shown in certain quarters. Yet there is no doubt that the stress of competition, particularly of competition against the industry and the enterprise of the trained men of other nations, is gradually forcing to the front the sentiment in favor of a rational and scientific training for the manufacturer and for the engineer.

Knowledge, perfected by study and training must be infused into the experience gained by practice; else we compete at very unequal odds with the systematically trained workers of other nations. Nor must we make the mistake here in the organization of our technical institutions of divorcing the theory from its useful applications. In no department is this more vital than in the teaching of mathematics to engineering students. For while no sane person would deny that the study of mathematics, for the sole sake of mathematics, even though it leads to nothing but abstract mathematics, is a high and ennobling pursuit, yet that is not the object of mathematical studies in an engineering school. The young engineer must learn mathematics, not as an end in itself, but as a tool that is to be useful to him. And if it is afterwards to be of use to him, he must learn it by using it. Hence the teacher of mathematics in an engineering school ought himself to be an engineer. However clever he be as a mathematical person, his teaching is unreal if he is not incessantly showing his learners how to apply it to the problems that arise in practice; and this he is incapable of doing if these problems do not lie within his own range of experience and knowledge. Were he a heaven-born senior wrangler, he is the wrong man to teach mathematics if he either despises or is ignorant of the ways in which mathematics enter into engineering. The fact is that for the great majority of engineering students, the mental training they most need is that which will enable them to think in physics, in mechanics, in geometric space, not in abstract symbols. The abstract symbols, and the processes of dealing with their relations and combinations, are truly necessary to them; but they are wanted not for themselves, but to form convenient modes of expressing the physical facts and laws, and the interdependence of those physical facts and laws. When the student looses grip of the physical meaning of his equations, and regards them only as abstractions or groupings of symbols, woe betide him. His mathematics amount to a mere symbol juggling. That is how paper engineers are made. The high and dry mathematical master who thinks it beneath him to show a student how to plot the equations $y = A \sin x$, or $r = b \sin \theta$, or who never culls an example or sets a problem from thermodynamics or electricity, must be left severely on one side as a fossil.

One evidence of the wholesome change of opinion that is springing up concerning the training of engineers is the abandonment of the system of taking premium pupils into works with no other test or qualification than that of the money-bag. Already many leading firms of engineers have been finding that the practice of taking sons of wealthy parents for a premium does not answer well, and is neither to their own advantage nor in many cases to that of the "pupil," whom it is nobody's particular business in the shops to train. Premium pupilage is absolutely unknown in the engineering firms of the United States or on the Continent of Europe. The firms who have abandoned it are finding themselves better served by taking the ablest young men from the technical schools and paying them small wages from the first, while they gain experience and prove themselves capable of good service. Messrs. Yarrow & Co. have led the way with a plan of their own, having three grades of apprenticeship, admission to which depends upon the educational abilities of the youths themselves. Messrs. Siemens have adopted a plan of requiring a high preliminary training. The Daimler Motor Company has likewise renounced all premiums, preferring to select young men of the highest intelligence and merit. Messrs. Clayton and Shuttleworth have quite recently reconstructed their system of pupil-apprenticeship on similar lines. The British Westinghouse Company and the British Thomson-Houston Company have each followed an excellent scheme for the admission of capable young men. Even the conservatism of the railway engineers shows signs of giving way; for already the Great Eastern Railway has modernized its regulations for the admission of apprentices. What the engineering staffs of the railway companies have lost by taking in pupils because of their fathers' purses rather than for the sake of their own brains it is impossible to gauge. But the community loses too, and has a right to expect reform.

A Unit Table for Talbot's Spiral.

The accompanying table based on Talbot's Spiral has been compiled by Mr. G. A. Kyle, principal assistant engineer of the Chicago, Milwaukee & St. Paul Ry., of Washington, for use on the Pacific extension west of Butte, Mont. Professor Talbot's formulas are used, the only departures being in symbols and in the form of the equations for obtaining deflections from points on the spiral other than the beginning or initial point. The unit table is developed to a limited extent in the printed editions of this easement curve, but the table presented here is adapted to any length up to 400 ft. varying by whole feet.

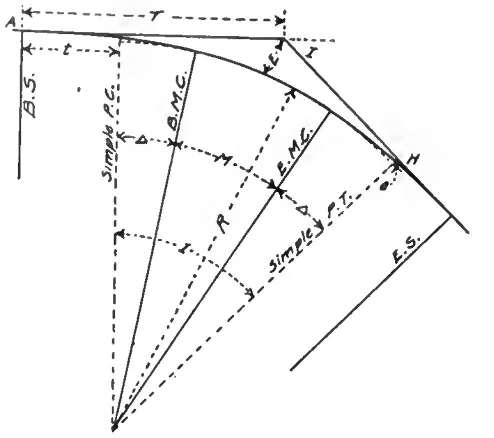


Figure 1.

Most spiral tables are based on a fixed chord length and when a certain chord has been chosen no other points than those tabulated can be set without the use of complicated formulas. With the spiral under consideration, however, the chord lengths can be chosen of any length to suit local requirements, since fractional chord lengths do not involve any extra labor of computation. This advantage is readily appreciated when points are required for trestle bents, or when it is impossible to set stakes at the full chord points.

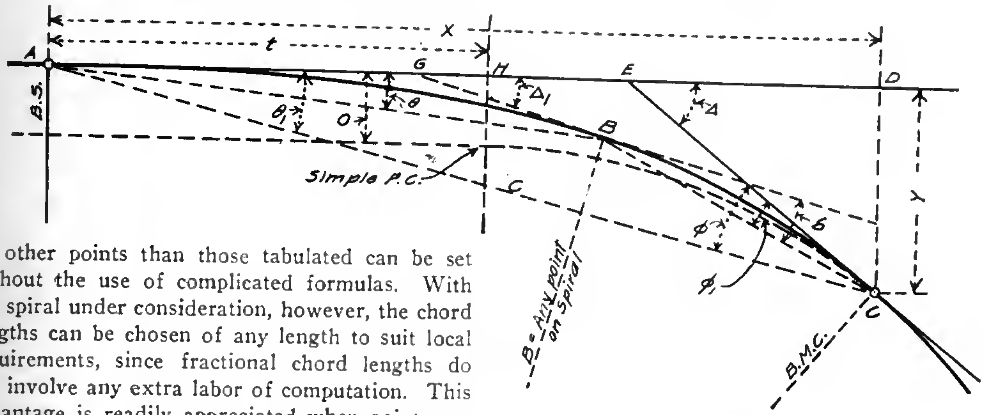

Figure 2.

Attention is called to the use of the terms B. S., beginning of spiral, B. M. C., beginning of main curve, E. M. C., end of main curve, and E. S. end of spiral. There are a number of minor departures from Professor Talbot's notation, and a new symbol, δ, is introduced, indicating a deflection angle turned from the tangent to the spiral at any point, except the B. S., to the B. M. C. For this angle a special formula has been derived which is used instead of the general equation—

$$\phi = \tfrac{1}{2}\, a\, L^1\, (L - L^1) \mp \tfrac{1}{6}\, a\, (L - L^1)^2$$

where L is the distance along the spiral from the B. S. to the point to be located, and L^1 is the distance from the B. S. to the point where the instrument is set up. The equation for ϕ_1 is also a special case of the above general equation, and it will be noted that if it be desired to set points between the B. S. and an intermediate point on the spiral at which the instrument is set up, that the equation for ϕ_1 may be used by merely assuming that the instrument point for the time being is the B. M. C. The angles δ, ϕ and ϕ_1 are always between a tangent to the spiral at the point considered and a chord to some other point on the spiral. To get on tangent at any point on the spiral when the B. S. can be seen it is only necessary to turn off the angle ϕ, backsighting on the latter point. The quantities A, d and d_1 are also original with this table.

The equation for the length of the spiral was evolved by Mr. Kyle in a modified form in 1900, while he was division engineer on the Northern Pacific Ry. at Tacoma. The equation is

$$L = V\,E$$

where L = length of spiral in feet; V velocity of the train in miles per hour; and E = elevation in track in inches for speed V. This formula is explained by its author as follows:

"Before spiral curves were used it was a common and almost uniform practice on Western roads to attain the difference in elevation of rails on curves by an approach usually on the tangent but sometimes one-half on the tangent and one-half on the curve, allowing 60 ft. in which to attain 1 in. difference in elevation, the maximum speed being assumed at 45 miles per hour. Then, to find the distance required to attain 1 in. difference in elevation of rails at any other speed, allowing the same time to attain a fixed elevation, the procedure was as follows:

Let E equal difference in elevation of tracks in inches on main curve.
V^1 " maximum velocity in miles per hour assumed in raising 1 in. in distance D^1.
D^1 " distance assumed in which to raise 1 in. at V^1 miles per hour.
V " velocity of train in question.
D " distance required to raise 1 in. at V miles per hour.
L " length of incline required to attain elevation E at V miles per hour—assumed to be the correct length of spiral curve.

Then, to find the distance D required at any speed V to attain 1 in. difference in elevation of rails we have,

$$D = D^1\, V \div V^1 \qquad (1)$$

inserting the assumed values of D and V, we have

$$D = 60\, V \div 45 = 1\tfrac{1}{3}\, V$$

and to attain the whole elevation E

$$L = 1\tfrac{1}{3}\, VE \text{ or } L = D^1\, VE \div V^1 (2)$$

Later it was found that this gave an excessive length of curve and the original assumptions were changed so that the maximum speed should be 50 instead of 45 miles per hour, and the distance required to attain 1 in. in elevation at 50 miles per hour was taken as 50 instead of 60 ft.

Inserting the above figures in the formula

$$L = D^1\, VE \div V^1 \text{ we have } L = V\,E \qquad (3)$$

The formula now in use is theoretically correct, assuming that the constants and distance in which to raise 1 in. are based on the proper

(Continued on page 260.)

usage. It takes into account the constant time function required to attain a fixed elevation, and the mechanical difficulties for the trucks to assume their radial position on the main curve.

The elevation E on curves is represented by the formula

$$E = G v^2 \div 32.2 R$$

in which G is the gauge of track, 4.71 ft.

E equals elevation main curve in inches.

v equals velocity of train in feet per second = $1.4667 V$.

V equals velocity of train in miles per hour.

R equals radius of main curve in feet equals $5730 \div D$ (approximately), equals degree of main curve.

Substituting values of $V^2 R$ and G in the above equation.

$$E = (4.71 \times 1.4667^2 V^2 D) \div (32.2 \times 5730) = 0.00005491 \; V^2 \; D \text{ (in feet)}$$

Reducing by multiplying last half of equation (3) by 12

$E = .00005491 \; V^2 \; D \times 12 = .00065892 \; V^2 \; D.$

Substituting value of E in equation $L = V \; E$.

$L = .00065892 \; V^3 \; D$ (4)

in which the length of spiral curve varies as the cube of velocity and as the degree of curve."

This equation $L = V \; E$ is also used by Mr. J. R. Stephens in "The Six-Chord Spiral," as the proper length of spiral curve.

A study of the formulas here given will explain the use of the unit table, which has been so named because it gives quantities computed for a value of a, the rate of change of the spiral per station, of unity. All the elements of the curve are functions of a, and to use the table for any particular case it is merely necessary to multiply the tabulated values by the a, or square of the a, selected for the case in hand. The quantities D, θ, ϕ, Δ, Y and O vary directly as a, and X, c, t, U and V vary as a^2 The quantities in the correction columns for the latter group must therefore be multiplied by the square of the a selected.

The use of the various corrections tabulated are evident from an inspection of the formulas. To obtain x or c the corresponding correction is subtracted from the spiral length from B. S. to the point to be located, the t correction is subtracted from half the length, the U correction added to 2/3 the length, and the V correction to 1/3 the length, the length being expressed in feet. It will be noted that these corrections all vary as the square of a.

The table here given takes the place of the dozen or more tables usually necessary for using any spiral, and embodies all possible spirals varying by whole feet up to 400 ft. Any length of spiral or any rate of change can be used, and the only operation necessary is a simple multiplication.

An additional table also presented here gives the values of a and the lengths of spiral used by the road for different speeds and degrees of curvature. The instructions issued with the table give the following rules: "The maximum speed on main line will be 50 miles per hour generally, excepting on mountain grades, sharp curves or points on line where instructions direct speed to be reduced.

"The maximum elevation is not to exceed 6 in. except in sags or at points where speed may be higher than the maximum speed above indicated. (See instructions for elevating on curves.)

"The table gives the nearest even lengths of spirals and their respective values of a for different speeds and degrees of curvature which will be made the standard and will be used by all engineers. For any other degree of curvature the length of spiral will vary as the degree of curvature and for any other speed will vary as the cube of the speed. In all cases leave a

(Continued on page 262.)

minimum length of tangent 60 ft. between spiral curves of opposite directions.

"The last length of spiral in each column is the maximum to use for the speed at the head of the column. For less speeds use next column to left. The table will be found sufficient for all general cases and any special case can be figured by formula $L = V E$."

Abbreviations.

D_1 = degree of main curve.

D = degree of curve at any point on spiral.

a = rate of change of spiral per station = degree of spiral curve 100 ft. from B. S.

A = deflection in minutes to point on spiral 100 ft. from B. S.

θ = deflection angle at B. S. to any point on spiral.

ϕ = deflection angle at B. M. C. from tangent to the spiral to B. S.

ϕ_1 = deflection angle at B. M. C. from tangent to the spiral to any point on the spiral.

δ = deflection angle from tangent at any point on spiral to B. M. C.

Δ = total angle in spiral at $E = D\ E\ C$. (Fig. 2.)

Δ_1 = angle in first portion of spiral from B. S. to any point on spiral, as from A to B at $G = D\ G\ B$.

Δ_2 = angle in second portion of spiral from any point to B. M. C., as from B to C at F_1.

L = total length of spiral in 100-ft. stations.

d = distance from B. S. to any point on spiral in stations.

d_1 = distance from any point on spiral to B. M. C. in stations.

c = long chord from B. S. to B. M. C., as $A\ C$.

X = distance along tangent to any point as $A\ H$ or $A\ D$.

Y = offset from tangent at any point on spiral as $D\ C$.

U = first tangent of spiral, $A\ E$.

V = second tangent of spiral, $E\ C$.

t = distance from B. S. to point where main curve produced is parallel to tangent as $A\ H$.

T = distance from P. I. to B. S. or E. S. as $I\ A$ or $I\ X$.

E = distance from P. I. to center of main curve.

M = main curve angle.

I = total intersection angle between two main tangents $= M + 2\ \Delta$.

O = offset distance between main tangent and a tangent to main curve produced at H.

Formulas.

When quantities are required for any point on spiral, insert d for L in equations.

$a = 0.269 \sqrt{(D_1^3/O)} = D_1/L$.

$D = a\ d \quad d = D/a$.

$A = a/6 = D_1/6\,L$.

$D_1 = a\ L \quad L = D_1/a$.

$\Delta = \frac{1}{2}\ a\ L^2 = \frac{1}{2}\ D_1\ L = D_1^2/2a = 3a\ L^2$.

$\Delta_1 = \frac{1}{2}\ a\ d^2 = \frac{1}{2}\ D\ d$.

$\theta = \frac{1}{3}\ \Delta = \frac{1}{6}\ a\ L^2 = \frac{1}{6}\ D\ L = D^2/6a = A\ L^2$.

$\phi = 2\theta$ for whole spiral.

$\phi_1 = A\ d_1\ (3d + 2d_1) = A\ d_1^2\ (3d/d_1 + 2)$.

$\delta = A\ d_1\ (3d + d_1) = A\ d_1^2\ (3d/d_1 + 1)$.

$\Delta_2 = (\Delta - \Delta_1)$.

$Y = 0.2909\ a\ L^3 - .00000158\ a^3\ L^7$.

$X = 100\ L - .000762\ a^2\ L^5$ X Cor. $= .000762\ a^2\ L^5$.

$O = .0727\ a\ L^3 = .0727\ D_1\ L^2 = \frac{1}{4}\ Y$.

$L = 3.714 \sqrt{(\sigma/D_1)}$.

$t = 50\,L - .000127\ a^2\ L^5 = 50\,L - \frac{1}{6}\ X$ Cor.

$c = 100\,L - .00034\ a^2\ L^5$ (in feet).

$U = X - Y \cot \Delta = X - V \cos \Delta = \frac{2}{3}\ L + \frac{1}{3}\ X$ Cor.

$$V = \frac{Y}{\sin \Delta} = \frac{100}{3}\ L + .000244\ a^2\ L^8 =$$

$\frac{1}{3}\ L + \frac{1}{3}\ X$ Cor.

$T = t + (R + o) \tan \frac{1}{2}\ I$.

Forests and Run-Off.

It is a matter of dispute whether the removal of forests always affects the amount of run-off from watersheds, for records of certain European districts indicate that deforestation has not been followed by increased floods and erosion of the soil. In examining the subject in detail, however, it has been observed repeatedly that where the removal of the forests has been followed by agricultural work which opens up the pores of the soil, assuming the latter to be somewhat coarse grained, the run-off and soil erosion may not be materially affected. This relation of forests and agriculture to run-off and soil erosion is pointed out in an exhaustive bulletin on the Potomac River basin recently issued by the U. S. Geological Survey, from which the following notes are taken.

If the rain-fall is all absorbed, as by a coarse, sandy soil, there is no run-off and no erosion. As the soil becomes finer in texture, more compact, and correspondingly less pervious, the rain is not absorbed as fast as it falls. The impact of the raindrops loosens the fine particles of soil, and unless absorption takes place the drops gather into small streams and rivulets, transporting with them, by a system of natural elutriation, the finest particles of soil and leaving behind the larger and heavier grains. At first this is entirely due to the hydraulic action of the impinging raindrops, but no sooner do the rivulets gather power, either by the added volume of water or by increased gradient, than they likewise begin cutting loose and transporting the soil.

The capacity of a stiff soil for water is in practice 35 to 50 per cent. of its volume, or for ordinary farmed soils 4 to 5 inches of rainfall to the surface foot. In spite of this capacity, the greater part of a heavy shower will usually not be absorbed. The coarse structure of a sandy soil permits the rainfall to be absorbed as rapidly as it falls. In a clay soil, unless in a high state of tilth, the pores are smaller and there is less open cellular communication between them, and absorption must largely take place through cracks, worm holes, and root holes, and when there are few of these absorption is largely retarded until the air can be expelled. In the extreme case, that of a raw clay soil with its surface puddled by a previous heavy rain, the result is, as King points out, "that when a heavy rain falls, the close structure and feeble granulation result in the surface pores of the soil becoming so quickly closed that the soil air has little opportunity to escape, and yet only so fast as it does escape can rain enter the soil, and hence during heavy rains the water accumulates quickly and extensively upon the surface."

The greater portion of the tilled soils of the Potomac basin, especially of the lower part, are of heavy type and close texture, and the run-off from them indicates failure to absorb. But were they well granulated and in good tilth they, as well as the more permeable sandy soils, could readily absorb, without undue accumulation of surface water, a much heavier rain than commonly falls at one time on the Potomac basin.

The porous condition or granulation of a heavy soil necessary to effect absorption is best procured by the addition of humus.

There is room for a large storage of storm water in farming soils, and more rational farming methods must ultimately lead to this. The effect of such storage would be reflected in a diminished run-off of flood water, especially of heavy midsummer rains. Little of the water thus accumulated would normally pass off as seepage to spring and river flow. The improved growth of the crops would utilize such stored water, and give a more constant and available amount of soil moisture.

Any additional storage, either transient, tending to prolong or distribute a flood crest, or deep seated, tending to increase the amount of the dry-season flow, can be secured only in the forest soil. Storage in forest soil, except in sandy phases, takes place very largely through the medium of humus. The amount of water which is actually retained by a thin humus is small, in fact, a thin humus is usually far more litter than humus and has a very low retentive capacity; but the chief function of humus, except where it has accumulated to a great depth, are (1) to maintain the volume and depth of the soil by preventing erosion; (2) to secure the porosity of the soil; (3) to promote the absorption of rainfall by the soil in retarding the run-off of heavy showers until the water can be absorbed, as the air is gradually expelled from the soil; (4) to act as a mulch and lessen the evaporation of soil moisture.

On coarse, deep sands of low gradient the office

of humus is at a minimum. There is no surface flow of storm water and no soil transportation; evaporation of soil moisture is low both from the surface of the soil and from transpiration by the xerophytic flora, and the larger part of the rainfall passes as percolation. With an increase in the clay component, greater radient, and a decrease in soil depth, humus becomes more essential in supplementing the water-absorbing and water-carrying capacity of the soil, its functions in this respect attaining a maximum on heavy, shallow clays of mountain slopes.

Where the humus is thick, however, it possesses a high storage capacity. While there is some doubt in regard to the exact amount of water humus is capable of holding, the quantity is relatively large. The lowest estimates by Ebermayer place it at considerably more than its own weight, and Wiley's investigations of Florida mucks give it about the same capacity, while Wollny places it at about four times its weight, and Henry's laboratory experiments tend to confirm Wollny's high limit. The capacity of humus must vary, however, not only with the state of decomposition, but with its origin as well, since the pore space is the final determinant of its water-bearing capacity. The undecomposed litter, which covers the humus and from which humus is formed, does not exhibit the characters of humus toward water. It protects the humus, as humus does the underlying soil, from excessive transportation by surface water and in addition from excessive evaporation, acting as a mulch.

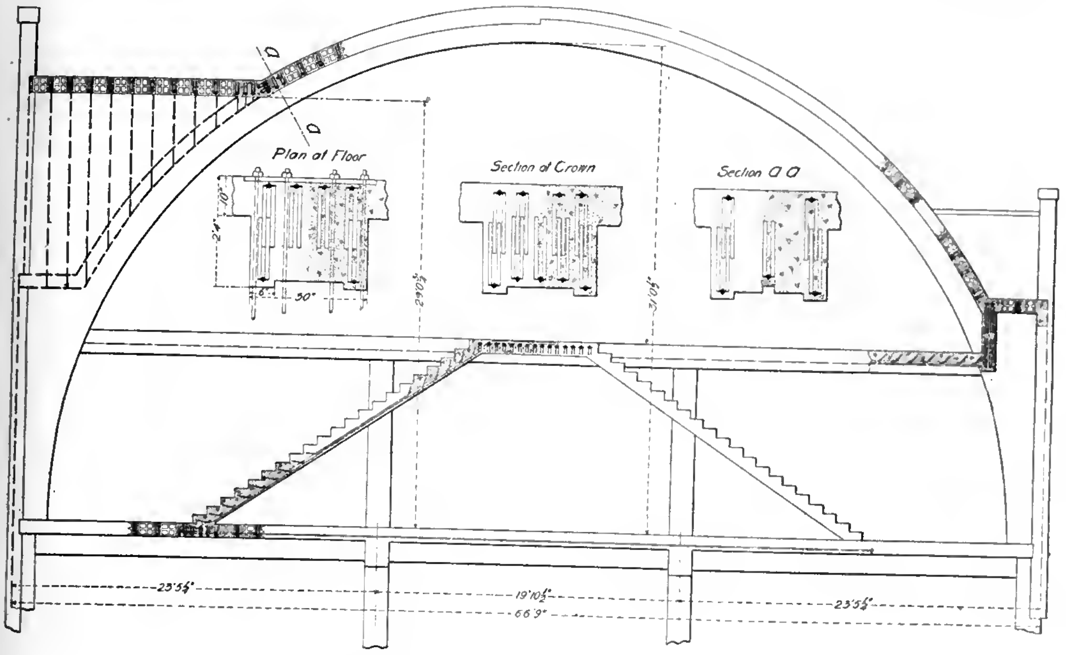
The accumulation of humus on forest soil depends, if it has neither been disturbed nor destroyed, on the kind of species forming the forest and to some extent on the soil, the destruction of humus proceeding rapidly on loose, porous soils, which permit freer circulation of air and afford the condition best suited for bacteriological activity, and since many species of trees, especially the white oak and chestnut, have a wide range of soil adaptability, their capacity to accumulate humus is modified both by their rate of growth on the soil and by the oxidizing capacity of the soal on which they happen to be growing.

The Bosphorus Bridge linking Europe to Asia is a project that Sultan Abdul Hamed has long had under consideration. The last bridge was that built by Darius for the use of his army long before the Christian era. The plans for the Turkish bridge were accepted years ago and call for short suspension spans between a succession of granite towers, of which the foundations are now being built.

The New Manufacturing Plant of the George N. Pierce Co., Buffalo, N. Y.

By Howard S. Knowlton.

One of the latest industrial plants to be completed in Buffalo is the new automobile manufacturing establishment of the George N. Pierce Co., located on the site of the Pan-American Exposition grounds. The company employs about 1,600 men, and it has been building the well-known Great Arrow car. The group of buildings which comprise the plant are all of reinforced concrete, the engineers and architects for the work being Messrs. Lockwood, Greene & Co., of Boston, with Mr. Albert Kahn, of Detroit, as associate architect. The designs and plans for the reinforced concrete work were made by the Trussed Concrete Steel Co. The office or so-called "welfare building" was designed by Mr. George Cary, of Buffalo.

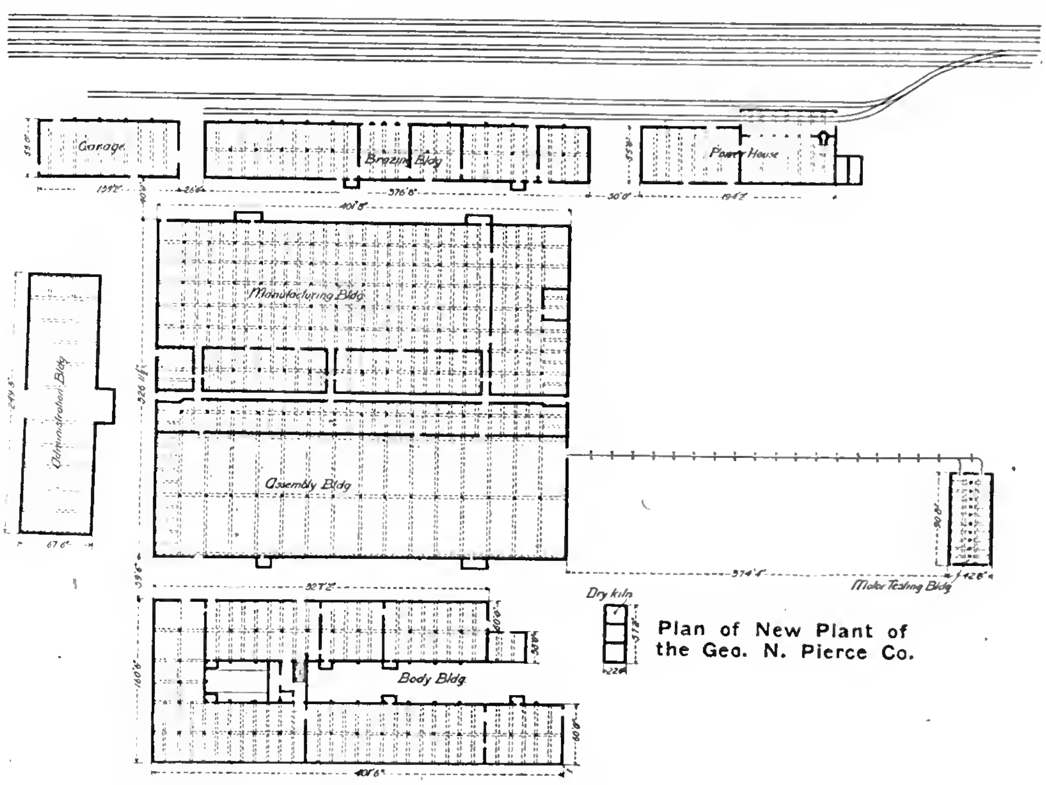


Cross Section of Administration Building.

Administration Building.—The plant occupies part of a lot of land fronting on Elmwood Ave., and is located beside the New York Central & Hudson River R. R. with special siding facilities for the receipt of materials and the shipment of products. The area of the property is about 15 acres, the lot being nearly rectangular, 997.3 ft. long and 655.2 ft. wide. There are eight buildings in the establishment at present. At the Elmwood Ave. entrance of the works, near the centre of the property, stands the Administration or Welfare Building, which is about 252 ft. long by 70 ft. wide, and three stories in height, with a barrel-arch roof. This building is the main entrance to every department of the plant. In the basement are provided lockers, bicycle and wash rooms for the employees, and from this basement the main manufacturing building is reached by underground passages. On the first floor are located the administrative and general offices of the company with a club room for department heads. The second floor is devoted to welfare work and its principal feature is a large restaurant for the use of employees.

The unique feature of the building is the barrel roof, carried by arches spaced 30 ft. on centres at the end spans and 20 ft. for all other spans. The ribs are approximately 30 in. wide by 26 in. deep, and are reinforced by nine 1¼x3¾-in. Kahn bars, five in the intrados and four in the extrados, at the crown. Four 1⅛-in. round rods run between the springing lines of the arches imbedded in the second floor. The roof slabs are made of 10-in. hollow tile spaced 16 in. on centres, with a 4-in. concrete joist between each row of tile. The joist has a ¾x2-in. Kahn bar as reinforcement. The first and second floors are of somewhat similar construction.

Shops.—In the rear of the Administration Building are the main shops. These are composed of the Body Building, about 401½x160½ ft.; the Manufacturing Building, about 327x402¾ ft.; the garage, 139¼x55 ft.; the Brazing Building, 376¾x55 ft., and the power house, 194¼x55 ft. There are also a 22x57½-ft. dry kiln, a gas house 26 ft. square, and a motor-testing building, measuring 90¾x42¾ ft. The last is located 374 ft. from the nearest shop to allow for the extension of the works to meet future business requirements.



Plan of New Plant of the Geo. N. Pierce Co.

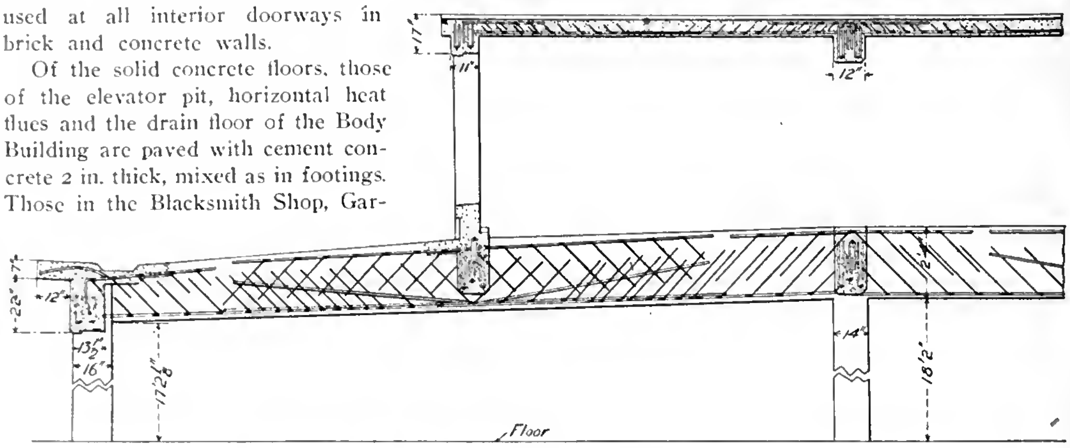
The Body Building is two stories in height, and divided by brick firewalls into the various storage and fitting, paint, lumber, filing, gluing, varnishing, trimming, pattern and blacksmith shops necessary in the production of the automobile body. The manufacturing building is one story in height and contains stores, tool, inspection, machine shop, experimental and assembly divisions. The assembly department is located

on the side of the building nearest the Body Building and is 402¾x122 ft. It is separated by a brick fire wall from the main manufacturing section. The Brazing Building includes in its single story brazing and tin shops, sand blast, case hardening, nickel plating, chip and receiving rooms. The power house has a coal pocket, boiler room, compressor and pump room, and an engine room. The side tracks have an aggregate length of 2,115 ft., and are three in number. One serves the coal pocket, and the other two serve the engine room, brazing building, and garage. The total floor space in the plant aggregates 280,000 sq. ft. Ground was broken on April 23, 1906, and the last building was turned over to the owners in November.

General Details.—All supported floors and roofs in the plant are built of hollow tile and reinforced concrete on the Kahn system. The beams, columns, footings and stairs are of concrete-steel. The concrete is composed of one part Portland cement, two of sand and four of crushed stone. The stone for footings was not allowed to exceed 2 in. in size, and for all other work ½-in. standard hard burned tile grooved on all sides, was used, and the concrete was all machine mixed. The concrete was designed to resist direct compression and shear up to 30 lb. per square inch. The minimum thickness of the concrete covering on the steel at any point is 1 in. The maximum elastic limit allowed in the steel was 45,000 lbs. per square inch, and the tensile strength of the steel was specified at a minimum of 60,000 lb. with 20 per cent. elongation in 8 in. test pieces. The cold bending test was 180 degrees. The design of the centering was planned to enable the slab forms to be removed first, and then the sides of the beams, leaving the bottom supports of the beams and girders to be removed last. Exposed faces of beams, girders and columns were finished smooth.

Floors were tested after the centering had been removed one month, to twice the nominal safe live load, uniformly distributed over the panels. The maximum specified deflection allowed was 1/400th part of the span, with return to normal position after removal of the load. The reinforced concrete work was designed for the following unit stresses: For hooped or latticed columns of concrete, 750 lbs.; shearing stresses in concrete and adhesion of concrete to steel, 30 lbs.; beams, slabs and girders in direct compression, 500 lbs.; tensile stress in steel, 16,000 lbs.; compression in steel, 12,000 lbs. The tensile strength of the concrete was not considered, and the ratio of the moduli of elasticity of concrete and steel was 1:12.

Girders and beams were designed with top reinforcement over the bearing to provide for continuous girder action; and the diameter of columns was taken at a minimum of one-sixteenth the total height. Footings were built of 1:3:6 concrete, and were laid in 5 in. layers, each layer being started before the previous one had commenced to set. The foundation walls were built of concrete mixed in the same proportions as for footings.

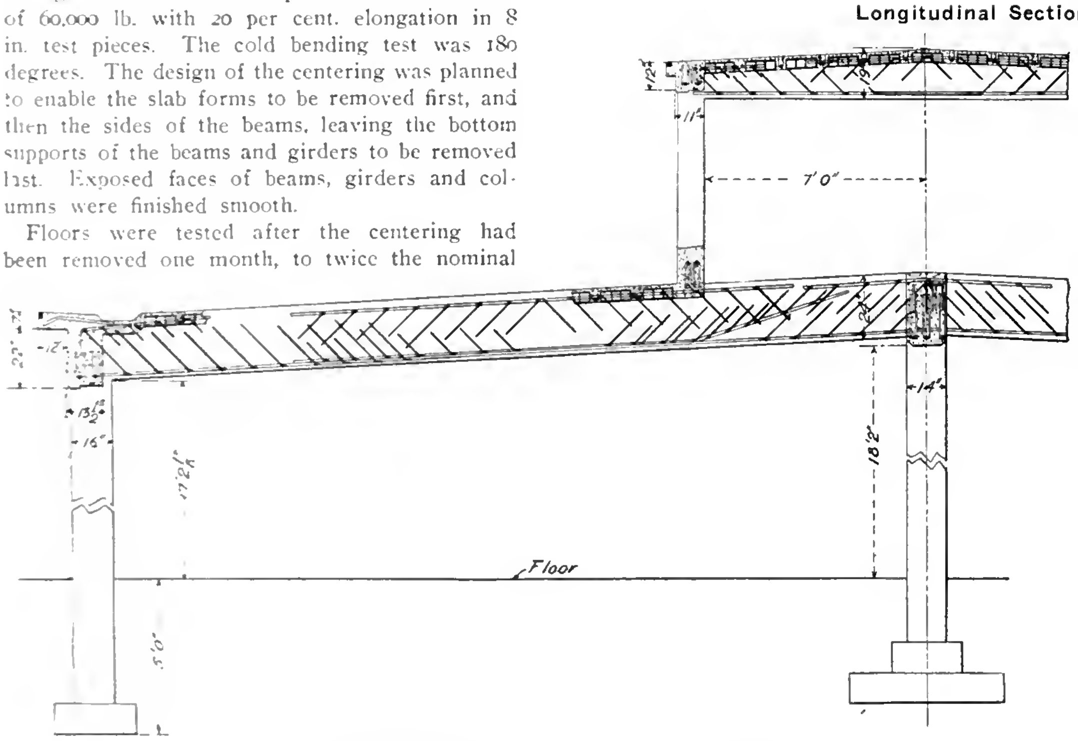


Longitudinal Section of Brazing Building.

Brickwork was employed in various interior walls, all fire walls being thus made; in the walls of buildings, where the spaces between columns are not occupied by windows; for certain footings, and in filling in the gaps between adjacent windows and the horizontal reinforced concrete wall columns. The tunnel from the power house to the Body and Manufacturing Buildings is provided with walls and roofs of reinforced concrete, the floor being plain concrete. Window sills are reinforced, and in the floor of the garage are built pits with sides and bottoms of cement concrete. Cast iron sills are used at all interior doorways in brick and concrete walls.

Of the solid concrete floors, those of the elevator pit, horizontal heat flues and the drain floor of the Body Building are paved with cement concrete 2 in. thick, mixed as in footings. Those in the Blacksmith Shop, Garage and Brazing Building are laid with a 5 or 6-in. base of cement concrete and a 1 in. wearing surface of Portland cement mortar. The floor of the Testing Building is laid with a 3½-in. cement concrete base, with a 1-in. Portland cement mortar wearing surface. The roof of the Body Building is covered with dry cinders, with a top layer of 1-in. concrete, drained to sumps formed in the latter. Earth floors were used in pipe pits. Water-closet floors are reinforced concrete covered with rock asphalt ⅞ in. thick. Tar concrete floors 4 in. thick are used in the first story of buildings with plank wearing courses.

Partitions in the Manufacturing, Garage and Brazing Buildings are of metal and plaster, 2 in. thick, braced with 3-in. channels running to the beams, and one side of the studding is covered with steel lath and plastered. Where hollow tile partitions are used, the tile are laid in 1:3 cement mortar, the tiles being wet. The under sides of all hollow tile floors and roofs are plastered with two coats of cement mortar.



Transverse Section of Brazing Building.

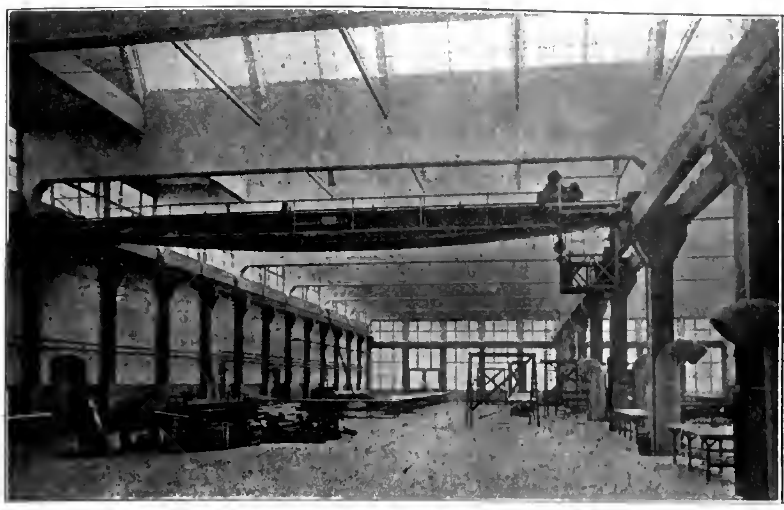
The entire skylights, except the ends and space occupied by the sash are of reinforced concrete. The ends are hollow tile, and the fronts have wood frames anchored to the concrete for securing the sash. The sashes are of 2¼ in. cypress stock, and are glazed on the outside with ¼ in. ribbed glass in one length and on the inside with clear glass. The concrete work in front and the tile work at the ends are covered with 16 oz. copper. The roof, columns and beams of monitors on the Blacksmith, Garage and Brazing Buildings are reinforced concrete and the monitor sashes are glazed with ½-in. ribbed glass. The skylights over the Testing Building and the sand blast rooms in the Brazing Building are framed with heavy galvanized iron with condensation gutters which discharge on the roof. These are glazed with ¼-in. plate glass 18 in. wide. The backs of all saw tooth skylights and roofs are covered with five-ply asphalt and slag roofing.

Brazing Building.—The Brazing Building is designed with a single row of columns, one every 25 ft. This is considered to give the most economical arrangement, because of the wide spacing of columns affords large unbroken floor areas. Because of the necessity of good ventilation this building is built with a monitor its entire length. Sashes 13 ft. 4 in. high on each side of the monitor give a quick means of ventilating the entire building.

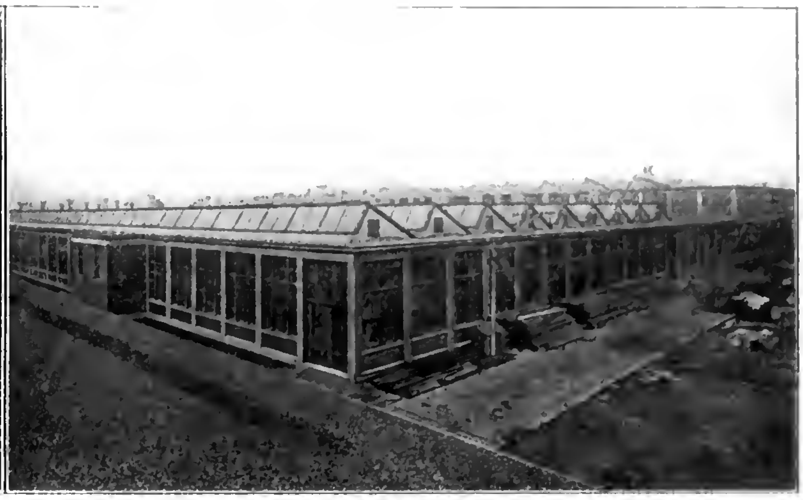
The transverse beams in this building are 12x24 in., reinforced with two 1¼x3¾ in. bars and one ¾x2-in. bar. One 1x3-in. compression bar is also used. The top continuity bars over the supports are 1x3 in. The main horizontal girders are 14x28 in. reinforced with three 1¼x3¾ in. and two ¾-in.x2-in. bars. As these girders were not of T section, it was deemed necessary to put in two 1x3 in. compression bars and also a 1x3 in. continuity bar over all columns. The transverse beams are supported alternately on columns and by the longitudinal girder. The interior columns are 14x14 in., reinforced with four ¾x2 in. bars. The exterior columns are 16x16 in., being made that size for architectural effect. The corners of all columns and beams are chamfered.

The roof of this building is constructed of 4-in. tile 16 in. apart on centres, with 4 in. concrete joists between the tile courses. Each course is reinforced with ½x1½ in. Kahn bar. One inch of concrete is spread over the tile in order to give a fastening for the waterproof roofing.

Manufacturing Building.—In the Manufacturing Building the columns are spaced 25 ft. apart lengthwise and 20½ ft. 6 in. crosswise. The minimum headroom from the finished floor to the under side of the beams is 16½ ft. The saw-tooth skylight beams are spaced every 12½ ft., one coming over every column and one midway between columns, with a 4-in. tile slab rein-



An Aisle in the Assembly Building.



Manufacturing and Assembly Buildings.

forced with ½x1½ in. bars. The inclined beams are reinforced with two 1x3 in. bars and one compression bar, together with the top reinforcing bars. The pitch of the roof is about 30 degrees, while the windows are inclined at an angle of 60 degrees.

In order to carry the large amount of shafting and machinery in this building, a system of 8-in. I-beams is used, spaced 8 ft. 4 in. apart on centres. A stiffening is run from the roof to the centre of each I-beam to prevent vibration. The construction of the roof itself depends in no way upon these steel beams, which are put in only to facilitate hanging shafting.

The main girders of this building have 25 ft. span and are 14x26 in. reinforced with two 1¼x3¾-in. and one 1x3-in. bars and two ¾-in.x2-in. compression bars. In all valleys of the roof of this building, concrete saddles were formed to provide for the drainage, the downspouts being approximately 50 ft. apart. The columns are 14x14-in., reinforced with four ¾x2-in. bars.

This building is at the present time filled with machine tools of every description, most of them to be used for turning out small pieces of work requiring careful execution and inspection. The employees prefer to work in the interior of the building rather than at the wall benches, as the light is better and more constant 200 ft. away from the walls than it is next the outside windows.

Assembly Building.—The Assembly Building section is divided in the centre by a row of 24x24-in. columns. Two 3-ton cranes travel the full length of the building, and the single row of columns was arranged to give these a large area of action. These are two bays 62 ft. wide and 401 ft. long, so the sawtooth construction was faced east, and the 62 ft. span taken care of by a reinforced concrete girder 16x84-in. in section.

The crane girders are reinforced concrete throughout, no steel beams of any description being used. The girders fastened to the centre row of columns span 25 ft. and are 12x22 in., reinforced with 1x3-in. bars, together with a compression bar and a top reinforcing bar at every column. The rails are fastened directly into the concrete, ⅝-in. bolts being used, which together with iron clamps used to hold the rail in position, are bedded in the concrete. The crane girders in the sides of the building are 12x16 in., reinforced with two ⅜x2 in. bars and one 1x3-in. bar, together with one ¾-in. compression bar and one ¾-in. top reinforcing bar. These girders are designed to carry a 5.5-ton wheel load on a 10-ft. wheel base. In tests recently made a centre load of 28,000 lbs. was placed on one of the beams, and a deflection of a scant 1/16 in. resulted.

The centre row of columns in this building are 24x24 in., reinforced with four 1x3 in. Kahn bars, and four 1¼x3¾ in. unsheared Kahn bars. Owing to the necessity of having proper clearance for the cranes, brackets have been provided on these columns where the crane girders are attached.

For all outside windows ⅛ in. ribbed glass was used. The lower and upper sashes are provided with Taber fixtures, which permit the windows to swing out and also to be raised and lowered. About ten sashes are operated from a point.

Body Building.—The floors of the Body Building are designed to carry a live load of 150 lbs. per square foot. The roof is designed and built as strong as the second floor so that another story can be added at any time. The pitch of the roof is furnished by cinder fills. Each wing is arranged with a row of columns down the centre longitudinally, a column occurring every 25 ft. The floor slab, which has a span of 12 ft. 6 in., is composed of 10 in. hollow tile 16 in. on centres between 4 in. concrete joists reinforced with one ½x1½-in. bar. The cross beams carrying this floor are 14x30 in., reinforced with three 1¼x3¾-in. and two 3¾x2-in. bars. One 1x3-in. compression bar is also necessary. Every other beams rests on the columns while the beams between the supported at the centre of the longitudinal girder. Longitudinal girders are 18x36 in., reinforced with five 1¼x3¾-in. and two ¾-in.x2-in. sheared bars, and three ¾x2-in. unsheared bars.

The centre row of columns in each wing in this building are 24x24 in., carrying the second floor, and 20x20 in., carrying the roof or future third floor. The reinforcement of the lower columns is four 1¼x3¾-in. and four ¾x2-in. Kahn bars and four 1x3-in. unsheared bars. The columns above are reinforced with four 1x3-in. sheared bars and four 1x3-in. unsheared bars.

The footings for this row of columns demonstrate the elasticity of the application of rein-

First Floor of the Body Building.

Shafting Supports in Manufacturing Building.

forced concrete design. Figuring this footing as carrying two floors and the roof, a size of 12 ft. 0 in.x12 ft. 0 in.x30 in. deep, reinforced with 28—1x3-in. bars is necessary. The columns rest directly on a small cap 3 ft. 4 in. x 3 ft. 4 in. x 18 in. thick. Owing to the way in which the property previously had been cut up by the Pan-American Exposition, and also because of the poor quality of the clay, it was necessary to design the footings of all buildings at a very low bearing value, averaging between 3,000 and 4,000 lbs. per square foot. In many cases, owing to the way in which the ground was broken up by old foundations, sewers and other works, it was necessary to make a great many changes in the footings. With reinforced concrete this was very easy to do, as bad portions of the ground could be arched over or beams put in, spanning the weak spots. In many cases the outside curtain walls are not carried on a footing of their own, but a reinforced concrete sill was put in, and the walls carried on this. A great deal of time and expense was saved in this way, as in some cases it would have been necessary to go down 10 or 12 ft. below grade for proper footings.

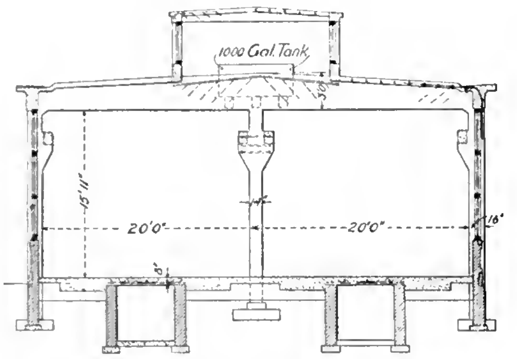
In one section of the second floor it was found desirable to construct a slatted platform at the same level as the finished floor, so that the unfinished bodies could be placed on this portion and washed down. This was arranged by dropping the concrete slab a little, making it flush with the ceiling below and building over this depressed portion a hard pine drain floor.

roof to 40 in. at the wall columns. The construction and reinforcement of the building is in the main similar to that of the Brazing Building.

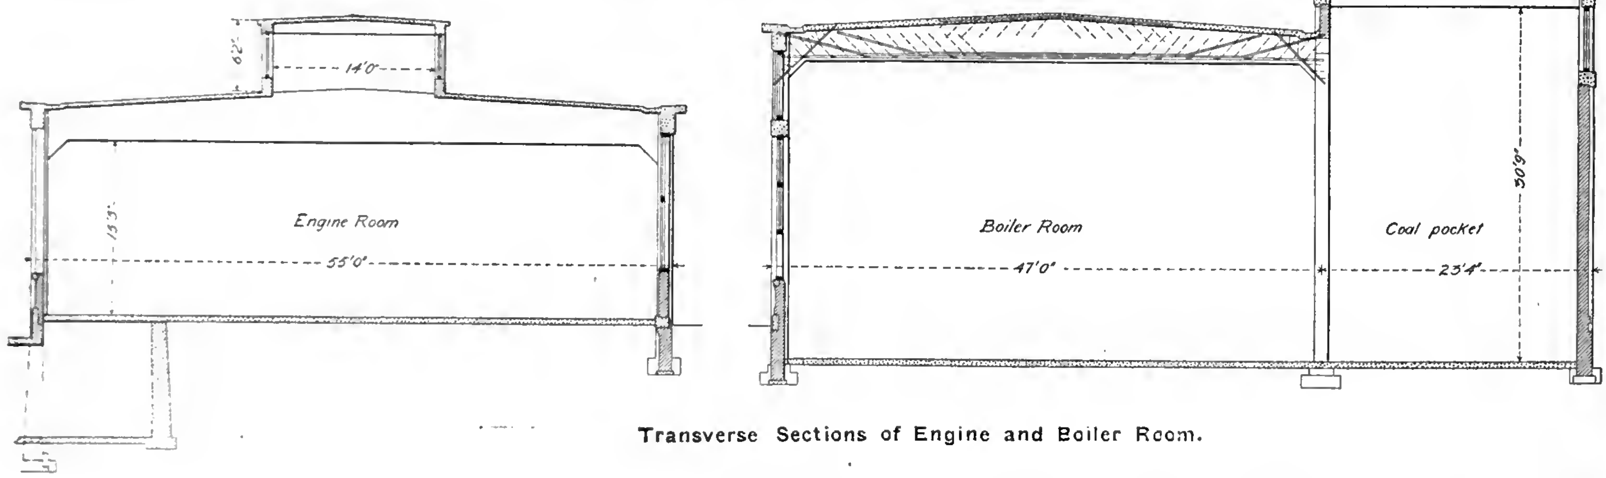
Power Plant.—The power plant supplies the different buildings with electricity for lighting and motor operation, compressed air, filtered city water, Acme gas, live and exhaust steam for heating purposes. The coal pocket is located on the side of the boiler room nearest the railroad tracks and it is 89 ft. 3 in. long, 21 ft. 6 in. wide and 30 ft. 9 in. high. A spur track enters this pocket on a trestle at a height of 13 ft. above the floor and coal is dumped into the pocket by gravity, whence it is delivered to the boiler room stokers by hand. The boilers are equipped with Jones underfeed stokers.

The boiler room is 89 ft. 3 in. long by 45 ft. wide and 25 ft. 3 in. high. It contains at present two batteries of horizontal return tubular boilers, aggregating four units, with space for a fifth, supplied by the Skinner Engine Co., of Erie, Pa. Each boiler is 84 in. in diameter and 18 ft. long, and contains 104 4-in. tubes, with Tupper grates, 84x60-in. and a 6-in. steam outlet. Each boiler discharges into a round breeching carried along the front at the top of the drums, and increasing in diameter from 30 to 54 in. From the breeching the gases are delivered to a Green economizer mounted at the end of the boiler room parallel to the longitudinal axes of the boilers, a by-pass connection being provided from the breeching directly into the chimney. The economizer is supported on columns and beams of reinforced concrete, and contains 352 4-in. tubes 10 ft. 2¼-in. long installed in two sections.

The chimney is reinforced concrete mounted on a reinforced concrete foundation. Its inside diameter is 6 ft. and its height 157 ft. It was built by the Weber Steel Concrete Chimney Co., of Chicago. Owing to the fact that the stack intersected a row of beams in the end of the building, it was necessary to carry cantilever beams to carry the roof up to and around the chimney. This construction did away with the necessity of putting in small columns, and it also keeps the stack clear of the building and the column footings independent of the stack footing.



Transverse Sections of Testing Building.



Transverse Sections of Engine and Boiler Room.

A special feature of the coal pocket is the provision therein of a reinforced concrete shavings vault 6 ft. wide, 9 ft. long and 22 ft. 6 in. high over all into which shavings are discharged by a 12-in. pipe leading from the Body Building wood working division. The boiler nearest the pump room is served almost exclusively with these shavings.

The pumps for feeding the boilers are mounted in the boiler room at the side of the battery nearest the engine room and consist of two 6x4x6-in. horizontal duplex units. Near the pumps is mounted an Otis feeder water heater. A 3-in. Penberthy injector is also available for boiler feed. The boiler room floor level is 3 ft. 3 in. lower than the engine and pump room floors.

The pump room, between the boiler and engine rooms, is 52 ft. 4 in. long by 18 ft. wide, and it contains at present one 1,000 gal. Knowles underwriter fire pump and two air compressors. One of the latter is a 12x16¼x12-in. Ingersoll-Sergeant machine and the other a 14¼x10-in. compressor of the same make.

The engine room, 79 ft. 3 in. by 52 ft. 4 in., contains space for five units. Two 200-kw. sets, a 125-kw. and a 35-kw. set are now in place, with room for another 200-kw. unit in the future. The engines were all supplied by the Skinner Engine Co., of Erie, and the generators are of Westinghouse make. One of the 200-kw. generators is direct-driven by a 15x20x20-in. engine, tandem compound type; the other 200-kw. generator is direct-connected to a 19x20-in. simple engine, and the 125-kw. generator is run by a 15x16 in. engine. The 35-kw. set has a 10x12 in. engine. The two large machines are 440-volt alterators; and the others are exciters. The switchboard is 6 ft. from the north wall, and it is 20 ft. long. It is separated by a special railing from the rest of the engine room.

The power house service is supplied to the different buildings through an 8x8 ft. concrete tunnel which leaves the engine room basement near the pump room. There are two live steam mains in the boiler room, each of which increases from 10 to 12 in. in the run past the boilers. At the end nearest the pump room the two mains are cross-connected by a 12-in. pipe which equalizes the steam pressure in the mains and provides a flexible method of securing live steam on either side. One of the mains passes into the engine room, where it delivers steam to the engines by loops dropping down to the cylinders, and the other feeds the fire pump, the two air compressors, and the buildings, via the tunnel. The tunnel line starts as a 10-in. pipe, decreasing as the different building branches are taken from it. This main line is provided with a valve so that all apparatus beyond the fire pump may be cut off.

The fire pump exhaust is a 5-in. line which rises vertically to the roof and terminates in a

In many cases it was necessary to suspend shafting, motors and machinery from the ceilings of this building, and this was done by cast-iron sockets supplied by the Trussed Concrete Steel Company.

The Body Building is separated from the Assembly Building by a court 40 ft. wide. The west end of this court is bridged over to furnish a working floor 50 ft. long by 40 ft. wide. The beams carrying this floor are 18x42 in., reinforced with five 1¼x3¾-in. and five ¾x2-in. bars. The floor construction is the same as in the Body Building. For the finished floor in both buildings 2x3-in. beveled sleepers were laid crosswise of the tile about 16 ft. on centres, the space between being filled with cinder concrete and ⅞ in. maple wearing surface nailed to these sleepers.

Motor Testing Building.—The design of the Motor Testing Building is somewhat similar to that of the Brazing Building, with the addition of two light crane runways. It is connected with the Assembly Building by a covered trolley way.

Garage.—In the Garage Building no interior columns are allowed, as it is necessary to have a large unbroken space in which automobiles can be easily moved around. The entire floor is left clear. Large spans and heavy construction resulted. The roof beams are 16x56 in. at the centre of the building, sloping with the

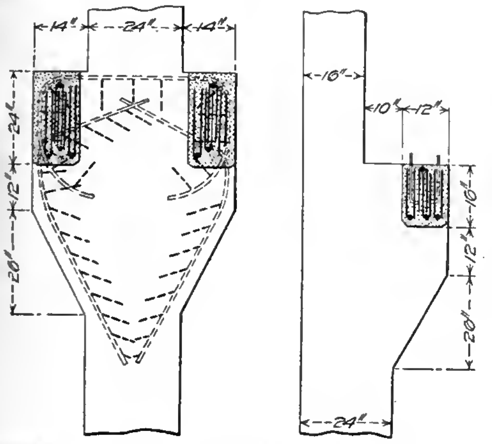
free exhaust head. The engine exhaust is collected in a basement main which reaches a diameter of 18 in. at the end of the engine room nearest the boilers, and it receives the 7-in. exhaust of the air compressors en route to the feed water heater. The heater is by-passed in the usual manner with free atmospheric exhaust.

The air inlet pipes on each compressor are 6 and 12 in. in diameter, respectively. These take air from a 12-in. pipe which runs from a concrete box under the pump room floor through the roof to a screen and hood. From the air outlets of the compressors 6 in lines are run to two receivers in the pump room, long radius bends being used on these lines. The two receivers feed the buildings through a 6-in. pipe which runs through the tunnel. A 5 in. air line also is run through the engine room to the Brazing Building, the pipe being supported on the engine room wall behind the live steam main. The fire pump water supply is drawn from the city mains through a 16 in. connection and 12 in. suction pipe, a blank flange for a second 12 in. outlet being provided for a future fire pump of the same size. The fire pump discharges into an 8 in. line, which connects with the hydrant main serving the various parts of the factory.

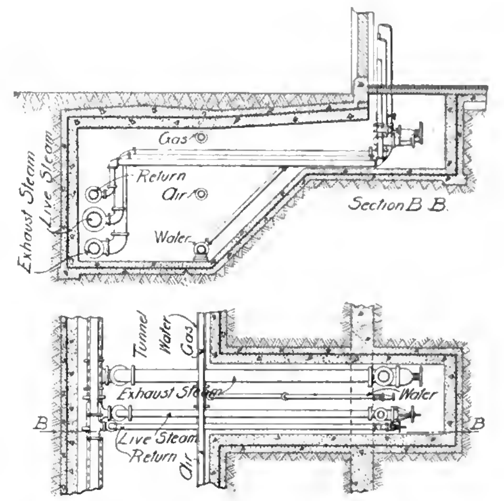
The reinforced concrete tunnel connecting the power house with the various buildings carries live steam, exhaust steam, water, air, gas and return pipes together with electric wires for lighting and power service. All the wiring conduits are carried on the ceiling of this tunnel. Branches are taken off at each building. The top of the tunnel is kept about 2 ft. below the outside grade in order to insure freedom from frost in winter. At the commencement of the tunnel the sizes of these service pipes are: Live steam, 12 in.; exhaust steam, 12 in.; water, 7 in.; air, 6 in.; air to Brazing Building, 5 in.; condensation return, 8 in.; water to Brazing Building, 6 in.; Acme gas, 4 in.; producer gas, 5 in.; water to motor-testing building, 3 in.

Heating.—The method of heating the buildings was devised by the Buffalo Forge Co. In each building a section is partitioned off for a stack of pipes through which exhaust steam is tossed. The air is forced through this heater by an engine-driven fan and discharged through tunnels beneath the floors upward through risers into the rooms. In some cases these tunnels are 6x7 ft. in cross section, and all are built of reinforced concrete. An elaborate system of fire fighting equipment is installed, and the Garage and Body Buildings are provided with an automatic sprinkling equipment because of the value and inflammability of the materials stored in them.

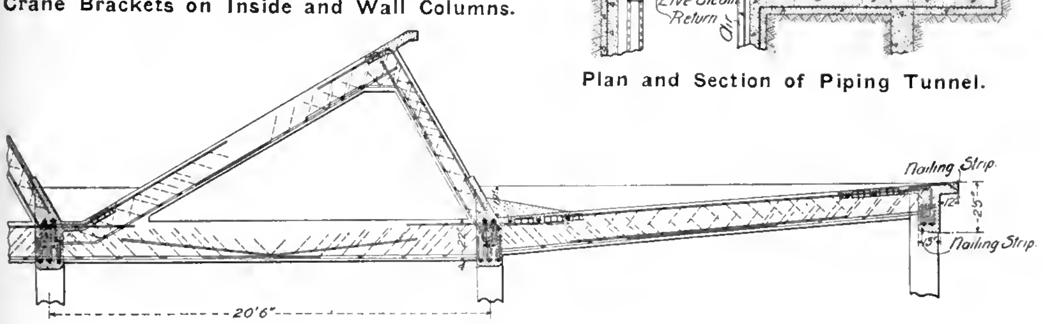
The floor area of the entire plant, including the Administration Building, is approximately 280,000 sq. ft. In the execution of the contract over 1,087 tons of steel and 178,000 sq. ft. of 10 and 8-in. tile were used, together with over 15,000 bbls. of Portland cement. On the completion of the buildings several tests were made. The crane girders in the Assembly Building were tested to twice the working load and the deflection at the centre was less than 1/16 in.



Crane Brackets on Inside and Wall Columns.



Plan and Section of Piping Tunnel.



Roof Section of Manufacturing Building.

At the Body Building a superimposed load of 250 lbs. per square foot was put over a panel, with a deflection of slightly less than 1/32 in. and no permanent deflection was observed.

The buildings were erected in six months by the Concrete Steel & Tile Construction Co., of Detroit. This was about one-third the guaranteed time for either mill construction or steel. The mechanical engineer for the power house was Mr. F. A. Shoemaker, of Buffalo.

THE PACIFIC BUILDING in San Francisco is one of the most important reinforced concrete structures yet undertaken. It is nine stories high, exclusive of a mezzanine floor and basement, and covers an area of 145x195 ft. The reinforced concrete columns are spaced on 16-ft. squares each way. The floors are 4½ in. thick and are reinforced in each direction by 22⅜-in. rods and two sets of four diagonal rods. An interesting structural feature is a spiral staircase of reinforced concrete and another is a cantilever balcony overhanging 6 ft. at the mezzanine floor. The concrete of the wainscoting and baseboards is colored and treated so as to resemble African marble. The facade is faced with terra cotta and glazed tiles in green and brown colors. The ground floor will be used for stores, the basement for a cafe, and each of the eight upper floors is laid out in 64 offices. Dean reversible windows are used throughout, and there are one freight and six passenger elevators.

The Detection of Pollution in Underground Waters.

Extracts from a paper read before the Association of Water Engineers by John C. Thresh, M.D., D.Sc.

The fact of underground water becoming polluted is too often only discovered by a sudden outburst of typhoid fever. Such would probably never be the case were the water submitted to periodical examination. This examination should not be limited to a mere chemical analysis, as from our point of view a bacteriological examination is the more important. If examinations are made systematically, the normal condititon of the water is soon ascertained; and should at any time an abnormal condition be found, its cause can be sought for, and, when detected, it may admit of a remedy. This remedy may possibly prevent outbreaks of disease which sooner or later would have ensued had not the defect been discovered and the remedy applied.

Unfortunately, the cause of the contamination is often very difficult to find, and sometimes one has to admit an utter failure to discover it; but usually this is because the water authority will not go to the necessary expense, or cannot obtain sanction from tenants or landlords to carry out the experiments required. The systematic examinations above referred to often enable the investigator to form some opinion with reference to the character of the polluting matter, and its proximity to the source of the water. For example, a certain well water yielding about a million gallons per day gives unexceptional chemical and bacteriological results save on rare occasions when there is a very heavy rainfall. Within twenty-four hours of a downpour, the number of bacteria present in the water increases enormously. Some of these are of an objectionable type; but they disappear again almost as quickly as they appeared. Chemically the water undergoes a scarcely appreciable change. Here it is obvious that the microbes do not come from any great distance—in fact, their source cannot be far from the well. Their nature indicates that they are derived from manured soil; and an examination of the surrounding area leaves little doubt as to their sources. In another instance certain objectionable bacteria appeared in a spring water supplying a small town; but their appearance was many days after an appreciable rainfall. An examination of the collecting area showed that there were large gravel pits about 200 yards away, and that recently some house refuse had been tipped therein. Experiments were carried out which established the connection between this gravel pit and the spring; showing that it would be exceedingly dangerous to allow house refuse to be tipped therein.

Before making experiments with chemicals, a careful survey of the whole position must be made. The geology of the district must be studied, the depth and section of the well and the length and direction of any adits must be known, as the records of the systematic analysis must be considered and compared with the rainfall and with the height of the water in the nearest ponds or streams. Some information must be sought with reference to the direction of flow of the subterranean water, and as to the cone of depression caused by pumping. The position of the outcrop of the water-bearing stratum may also require to be known, so that it may be examined, if not too far away to be possible source of danger. If evidence can be obtained of the presence of fissures, and of their extent and direction, it may prove of the utmost value in the investigation. All the possible sources of pollution must then be sought out and considered in connection with the knowl-

edge so ascertained. This will enable the investigator to determine which is most likely to be the cause of the trouble, and therefore the one which should first receive attention. If such experiments as will be described shortly fail to show any connection between this possible source of pollution and the spring or well, attention must be directed to the next most probable source, and so on, until something definite has been determined.

It is not always the well with apparently the best surroundings that yields water of most uniform quality, nor the well with doubtful surroundings which yields water of most varying quality. Take, as an example, the well of the Windsor Corporation Waterworks. It is sunk in the chalk on an island in the Thames—and the character of the Thames water is too well known to need description. It would seem almost certain that this well would be affected by the river, and that in times of flood the water would show unmistakable signs of being so affected. Such, however, is not the case. Careful chemical analysis show that there is a decided difference in the same saline constituents of these waters; and the bacteriological examination fails to give any indications of great rises in level of the Thames water. As another example of the opposite character, one may mention a very deep well in the new red sandstone —one of a series of four—which often shows unmistakable signs of contamination with surface water, yet the surroundings are almost ideal; and a probable source from which any polluting matter can be derived has not yet been found.

To ascertain whether a given source of pollution can affect a given well, it is usual to introduce some chemical at the point of suspicion, and then to examine the water at frequent intervals to ascertain whether the chemical selected can be detected in it. For this purpose common salt (sodium chloride), a lithium salt, or a dye named fluorescein have been employed; and recently the author has used ammonium salts, since, in certain cases, it possesses advantages over the others. Sodium chloride is used chiefly because it is very cheap, easily obtainable, quite innocuous, and easily detected and estimated in the water. As all waters contain chlorides, the normal chloride must be first ascertained, then any subsequent increase during the experiment may be attributed to the salt used. Slight variations are often observed in water from the same well. Consequently enough salt must be added to produce a more marked effect than any recorded in the normal water. The quantity must be at least equal to one grain of salt per gallon (=0.6 grains Cl.). Should it prove necessary to add this amount to a large quantity of water, the weight of salt used must be considerable. For example, it may be necessary to add sufficient salt to materially increase the chlorine content of a million gallons of water. To do this would require 1,000,000 grains, or 143lb of salt—an amount which can easily be handled and readily dissolved and passed into the soil. If, however, it is estimated that at least 100,000,000 gallons of water will have to be affected, then six to seven tons of salt must be used—an unwieldy quantity, difficult to deal with. Where anything like this volume of water has to be considered, a substitute for salt would now be used.

One of the best examples of the use of salt is recorded in connection with an outbreak of typhoid fever at New Herrington, Durham, in 1889. The well, when inspected, was found to receive water from various fissures; and one at a depth of 45 ft. from the surface came under suspicion, since the water therefrom contained more chlorides than the water entering elsewhere. From a study of the dip of the strata and direction of the fissures, it was surmised that there might be a connection with a farmyard about three-quarters of a mile away, since the sewage from this farm disappeared down a fissure and was no more seen. Two experiments were made; two tons of salt being used in the first and five tons in the second. This was washed into the fissure with an enormous volume of water. On the following day the chlorine in the water in the fissure inceased from four to six grains per gallon—its ordinary limits of variation—to 15 grains per gallon; and in six days it reached a maximum of 24 grains. A few days later it fell to the normal amount.

Another example quite as conclusive, but in which a much smaller quantity of salt was used, may also be quoted. The *bacillus coli* was frequently found in a public supply derived from a spring in the mountain limestone. The chemical analysis of the water gave uniformly good results, and the chlorine was constant at 1.6 grains per gallon. This low chlorine figure, and its constancy, did not indicate direct pollution with sewage; and a careful survey of the neighborhood led to the suspicion that the polluting matter entered at a fissure in some marshy ground about half a mile away. The soil round this fissure swarmed with the *bacillus coli* and similar organisms, probably derived from a farmyard a little distance above. A little fluorescein was placed in the water which could be seen in this fissure; and it disappeared so quickly that it was obvious that there was a rapid flow of water. It was considered too risky to put a large quantity of coloring matter in. Consequently, at 10.30 o'clock on a Wednesday morning, half a ton of salt was shovelled in, and samples of water were collected at frequent intervals from the spring. The results were as follows:—

GRAINS OF CHLORINE PER IMPERIAL GALLON IN THE SPRING WATER.

	Wednesday.	Thursday.	Friday.
9.00 a.m.	—	—	1.6
9.30 "	—	1.6	—

4.30 "	2.0	—	—
5.30 "	2.0	2.1	1.6

Pumping ceased.

In this case it was obvious that the water from this fissue only entered when the level of the water in the reservoir over the spring was depressed by pumping; and on comparing the levels it was found that such must be the case, as when the reservoir was full the water level was practically the same as the level of the water in the fissure.

A salt of lithium has frequently been used instead of salt. Exceedingly minute quantities of this can be detected by means of the spectroscope. A crude lithium sulphate, which answers every purpose, can now be purchased at 4s. per lb. About one part of this salt in 1,000,000 of water may be detected—1 grain in 14 gallons —and inasmuch as lithium is not a normal constituent of potable waters, its detection after the use of salt is positive proof of direct connection between the point where the lithium has been placed and the source of the water. Unfortunately, the detection of such minute traces in a considerable amount of deposit left by the evaporation of the water is very tedious and troublesome; and to use any quantity of the substance very expensive. For these reasons lithium salts are now rarely employed.

The author has recently used ammonium chloride—sal ammoniac—in several investigations, with marked success. It is very cheap, free from color, perfectly harmless, and the ammonia, even in great dilution, admits of easy detection and estimation. When 7 lb., costing about 3s. 6d., is dissolved in a million gallons of water, the ammonia can readily be detected. The amount of ammonia present in all good subsoil waters is too trifling to interfere. But certain very deep wells, yield waters and many polluted waters contain very varying quantities of an ammonia salt might not lead to definite conclusions. It must also be remembered that the salt must be put directly into the subsoil water or fissure, as if spread on fertile ground a portion of it might be nitrified by the nitrifying organisms of the soil. Probably, however, in any case, the amount nitrified would only be an infinitesimal portion of the salt employed. On the whole, it may be regarded as much more convenient for use than either common salt or salts of lithium. In one of the experiments already referred to, where objectionable bacteria in a spring water were traced to the deposition of house refuse in a gravel pit, ammonium chloride was the salt used. The records of the experiments are as under:—

December 12th.—Four pounds of ammonia chloride placed in a hole in the gravel pit and water poured in until the salt had disappeared. Samples of water collected and examined daily until January 15th. On December 26th the water contained a distinct trace of ammonia; on no other day during December was ammonia discovered.

On January 14th the ammonia again suddenly appeared in marked quantity; but next day no trace could be discovered. The rainfall was as under:—

Dec.	12	0.02	inch
	13	0.36	"
	14	0.08	"
	15	0.19	"
	16	0.30	"
	17 to 23	0.00	"
	24	0.07	"
	25	0.31	(3½ in. snow)
	26	0.06	as snow
	27	0.15	"
	28	0.13	"
	29	0.00	
	30	0.22	snow and rain
Jan.	1	0.35	snow melted.
	2	0.13	
	3 to 5	0.00	
	6	0.01	
	7 to 9	0.00	
	10	0.20	
	11 to 18	0.00	

The heavy rains from December 13th to the 16th apparently affected the spring water on the 26th; and the rain and melting snow on January 1st and 2nd also carried the ammonia from the gravel pit to the spring, affecting it on the 14th. There is no doubt that water from the gravel pit reached the spring in from ten to fourteen days, after a heavy rainfall. Ammonium sulphate would probably answer equally as well as the chloride, and as it was manufactured on a large scale for use as an artificial manure it is much cheaper. It may, however, contain large traces of arsenic, which renders it necessary to examine the sample before deciding to use it.

Another substance of an entirely different character, which is of special importance in such investigations as the above, is a coloring matter called fluorescein. Many of the aniline dyes possess enormous colorific power; but most of them, when in very dilute solution, are colorised by filtration through soil, and others are too expensive or are objectionable in other respects. Fluorescein appears to be unaffected by passage through chalk, sand, surface soil, &c., and when dissolved in water by aid of an equal weight of caustic soda it can be easily detected by its fluorescence when the dilution is 1 in 100 millions. Under very favorable conditions 1 in 200 millions may be detected. In other words, 1 lb. of fluorescein will distinctly color 10 million gallons of water. As the demand for this substance has increased, the price has gone down, until it can now be purchased at 7s. 6d. par lb. in quantities of 10 lb. and upwards. The rel-

ative cost of these various substances used in sufficient quantity to affect one million gallons of water would be fluorescein; 9d.; common salt 2s.; ammonium chloride, 3s. 6d.; and lithium sulphate, 40s. Fluorescein is, therefore, much the cheapest; it is the easiest to apply, and far the easiest to detect. There is only one possible objection to it, and that is that, if used incautiously, it may so colour the whole of a water supply as to cause alarm on the part of the consumers. For this reason it is in most cases preferable to use salt or ammonia chloride in the first instance; and if, when used in moderate quantities, these give no definite results, to employ fluorescein. This dye has been largely used for tinting underground streams to trace their course, and to a certain extent for determining the direction and rate of flow of subsoil water, and one case is recorded where it unexpectedly made its appearance in a public water supply, and caused considerable astonishment and some alarm. More recently it has been applied for the special purposes dealt with in this paper, and some recent experiments carried out on a somewhat large scale near Cambridge may be cited as examples.

In 1905 a series of cases of typhoid fever occurred at the County Asylum near Cambridge, and the Local Government Board instructed Dr. Monckton Copeman to investigate it, and more especially to report with reference to the risk of pollution of underground water supplies by the sewage of the asylum. A detailed description of the geology of the district is given in Dr. Copeman's report. The asylum sewage was disposed of by a crude system of broad irrigation on land, which consists of a thin layer of loamy soil covering the chalk. The well supplying the asylum is about 60 ft. deep, and some 1200 ft. to the west of that portion of the irrigation area selected for experiment, and about 2500 ft. east from a well, 70 ft. deep, which furnishes the chief supply to the city of Cambridge. A hole was dug to the chalk on the irrigation area and 0.5 kilos. of fluorescein dissolved by aid of caustic soda was washed into the chalk and samples of water from pits and wells around afterwards collected for examination. The resullts not being conclusive a further experiment was made, using 5 lb. of fluorescein. The experiment was started at 11 a. m. on October 18th, and at 3 p. m. the color appeared in a pit 200 ft. N. N. E.; at 9 a. m. on the 20th it was found in a pit 700 ft. E. N. E.; at 4.30 p. m. on the 21st it was seen in a pit between the sewage plot and the pit in which it was observed on the previous day; on October 22nd it was found in the water of the asylum well; and on October 27th it was found in the water of the Fulbourne well. It had therefore taken 103 hours to travel about 1200 ft. westward, and about nine days to travel 2500 ft. to the eastward. The wide diffusion is an interesting point, as the wells both to the east and west were affected. At no time previously had these waters come under suspicion, and neither bacteriological nor chemical analyses apparently had ever indicated contamination. Dr. Copeman therefore adds: "It does not, of course, necessarily follow, because the fluorescein should have proved capable of detection at various points, inclusive of the asylum well, at so great a distance in different directions from the point at which it was introduced, that bacteria, harmful or otherwise, would be equally capable of transmission for so considerable a distance, but, nevertheless, the results of these experiments are decidedly instructive and important."

The Asylum Committee were advised to make some arrangement for dealing with their sewage which should remove all risk of the effluent contaminating either of these sources of water, and the author was requested to report upon the best method of securing this desirable result. A study of the geology of the district had led him to infer that, beyond a certain line, the underground water would be travelling in a direction away from these wells; and to prove this a hole was bored on the site, and 2 lb. of fluorescein dissolved and suitably diluted, was poured into the bore. It quickly disappeard; but although all the pits, walls, springs, &c., around were watched, no trace of the coloring matter was ever again seen. A further experiment on a larger scale was therefore decided upon, and carried out in the following manner:—Two bore-holes, 30 ft. deep, were made at opposite sides of the field selected. They were 110 yards apart, and both yielded water freely. A trench was cut from a point six yards north of the south bore to a point six yards south of the north bore. This trench was 96 yards long, 1 ft. wide, and 6 in. deep. Water was pumped from the south bore at the rate of 25,000 gallons per day; but it filtered through the trench so rapidly that a pump had to be placed in the north bore. When the second pump was started the whole of the trench could be flooded, and also a shorter trench cut at right angles and communicating with it. Pumping was kept up for three days to thoroughly saturate the ground before the fluorescein experiment was commenced on March 8th. A tub was mounted at each end of the long trench; and in each was placed 1 lb. of the dye. While pumping was continued the solution was allowed to dribble into the water as it entered the trench. The time taken in running in the solution was, on an average, four hours. Four pounds were put in on the 8th, 4 lbs. on the 9th, 2 lb. on the 10th, and on the 12th 1 lb. was run directly into the north bore-hole.

The amount of dye used would have distinctly coloured about 150 million gallons of water. Watch was kept at seventeen different points. At no time did any colour appear in the south bore-hole; but in the north bore-hole the water was tinted seven hours after the commencement of the experiment. No trace of colour appeared elsewhere until nine days later, when the water in a chalk pit 300 yards N. N. W.; on March 31st, the color observed in a well water 1200 yards further N. N. W.; and on April 7th it was detected in the marsh water near the river Cam, about 3000 yards away, still in the same direction. At no other points has any trace of color been detected. The second experiment, therefore, not only confirmed the first in so far as it showed that water from this locality did not travel towards either of the wells, but it also proved that the colored water travelled in a definite direction, which, fortunately is quite away from the sources of supply. The depth of color observed has never been greater than that produced by 1 part of the dye in 130 million parts of water, save at the north bore-hole, where it was much more deeply tinted.

To do away with any doubt as to whether bacteria can be conveyed from any given point to a deep source of water, it has been suggested that certain easily recognized bacteria should be introduced into the soil at the point where pollution is suspected to arise, and to examine the water repeatedly for the special bacteria. Experiments of this kind have been recorded, and it has been shown that bacteria can be washed by very heavy rain through a few feet of soil into collecting trenches beneath, but they have never been traced any considerable distance. The author's experience with this test, using the bacillus *prodigiosus*, has not led him to regard it with any favor, nor would it justify him in recommending it, though one can conceive cases in which such a test would afford information of some value. Some time ago, the author commenced a series of experiments in a brick channel about 36 ft. long, 1 ft. wide and 3 ft. deep. A little shingle was placed along the bottom, and the trench was filled up with fine sharp sand, such as is used by builders. At intervals of a yard glass tubes 2 in. in diameter were inserted 2 ft. into the sand, and water was run in until the water level was about 1 ft. from the surface. Water was then allowed to flow away slowly from the bottom of the trench at the opposite end to that at which the water was being introduced, and a condition of equilibrium maintained. An emulsion of the *bacillus prodigiosus* was then placed in the tube nearest the water inlet, and samples of water were collected from the other tubes and also from the outlet. In every experiment the bacillus was detected in the outlet water in a few hours, but it was never discovered in the water in the tubes. Apparently the microbes were first carried downwards into the shingly layer and then carried forward to the outlet. The results merely showed that polluting matter on a collecting area may pass downwards, get into a stratum of greater porosity, and then travel a considerable distance.

Afterwards the same organism was used in connection with the gravel pit referred to in the ammonium-chloride experiment, but the bacillus never showed itself in the spring water. As there is undoubtedly a connection between this gravel pit and the spring, as was proved by the ammonium-chloride test, possibly one might conclude that it was not of such a character as to permit of objectionable bacteria going into the spring water.

The difficulty and trouble in carrying out such a test are very great, and the instances in which it is desirable are very few. Possibly in every case a comparatively simple experiment with fluorescein, together with a series of ordinary bacteriological examinations, would give more valuable and reliable information.

ANOTHER POLAR RAILWAY is contemplated by a leading Russian engineer and contractor named Knorre, who has recently received the concession for the Polar-Ural R. R. He has been over the entire route and says that it is perfectly practicable, with an easy grade over the Ural Mountains. This road is intended to help the development of agricultural western Siberia. It will be the outlet and inlet for the splendid water freight routes of the Yenesei and Ob rivers and of the Irtish, the great tributary of the Ob. It will more than double their importance, because it will do away with the difficult, dangerous and uncertain navigation of that part of the Arctic Ocean called the Kara Sea. The railroad that will now be built will start from Obdorsk on the Ob River at the Polar Circle and extend northwest across the tundra to Bolvansk Bay, the southern part of Pechora Bay, about 266 miles. As compared with the Kara Sea route the railroad will shorten the distance between the Siberian rivers and the ports of western Europe by about 1,000 miles, as by the route now used vessels have to travel far north to circumvent the Jalmal Peninsula. Pechora Bay is open for commerce more than four months in the year, and the navigation season on the great rivers of western Siberia is still longer, while in the great grain region of the southwest on the upper Ob and the Irtish it is six and a half months. All the large trade centres of the southwest, as Tobolsk, Pavlodar, Semipalatinsk, Tomsk and Barnaul are on the Ob and Irtish highways leading direct to the railroad, whence the journey will be safe and easy to all the leading ports of northwest Europe.

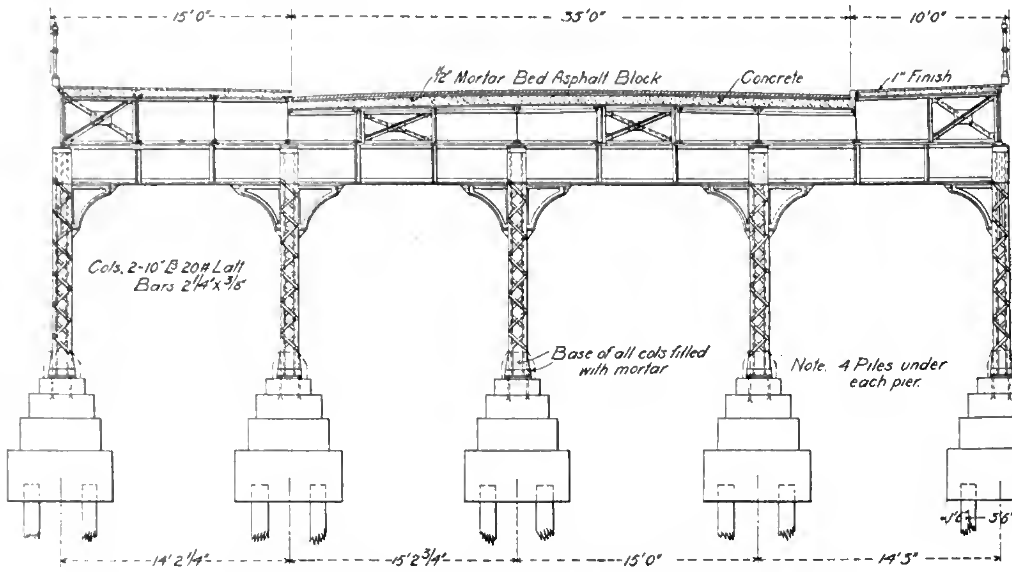
Elimination of Grade Crossings in New York Central Electric Zone.

The frequent train service inaugurated in connection with the electrical operation of the New York Central & Hudson River R. R. has made it necessary for the safety of the public and the efficient movement of the traffic that all grade street crossings within the Electrical Zone in New York City be abolished. This is being accomplished at some points by means of overhead bridges and at others by carrying the street under the elevated track. At the High Bridge and Morris Heights stations the former plan has been adopted. At these stations the four tracks of the Hudson division and the two tracks of the Putnam division occupy a strip on the east side of the Harlem River parallel to the river's general course and 150 to 300 ft. from the water's edge. The tracks are a little higher than the wharves along the water front. The station buildings at High Bridge and Morris Heights have their main street entrances on the second floor, which is at the same elevation as a steel girder bridge 10 ft. wide which in each case extends along the front of the station across the railroad tracks. This bridge connects at its west end with an incline leading down to the area along the water front and at its east end with one or the other of the streets mentioned in the title. In construction and design the structures over the railroad tracks afford no features of special interest. Their east approaches are formed by earth fill between dry rubble masonry walls. The construction of the west approach in each case, however, involves heavy concrete work which has been handled by efficient methods.

At the Depot Pl. or High Bridge station the approach to the west end of the bridge over the tracks consist of a straight ramp about 525 ft. long which extends southward parallel to the railroad track and the bulkhead line close to the former. This ramp, which is on a 4.3 per cent. grade, consists of an earth fill between plain concrete walls having the maximum and minimum sections shown in an accompanying illustration. The clear width between the coping courses is 23 ft. 2¾ in. Of this, 5 ft. along the river side is devoted to a bluestone flag sidewalk and the remaining width is occupied by a granite block pavement on a sand foundation with a single gutter along the sidewalk curb. The wall concrete is a 1:3:6 mixture of Lehigh Portland Cement, sand and gravel and the coping concrete is a 1:2:4 mixture of the same materials. Tongue-and-groove 2-in. pine plank forms in 2½x16-ft. units are used and a 1-in. finishing coat of 1:2 cement mortar is applied as the wall concrete is laid by means of thin sheet-steel finishing plates.

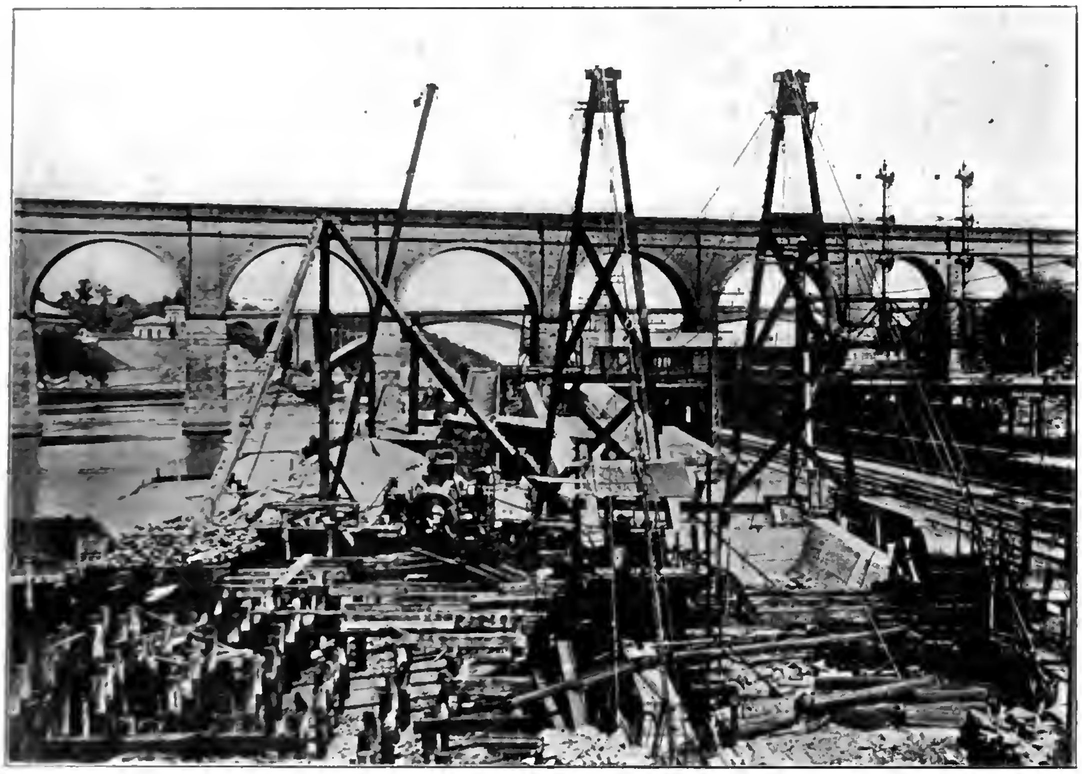
The wall footings are about 6½ ft. below mean high water and rest on piles, 20 to 55 ft. long, whose tops are embedded 1½ ft. in the footing concrete. These piles are placed in three longitudinal rows where the over-all height of the wall exceeds about 24 ft. and in two rows where the wall is lower. The spacing of the piles in each line varies from 3 to 4½ ft. according to the weight supported.

The two walls have been carried forward from the lower toward the upper end of the ramp in 59-ft. sections, the work alternating from one wall to the other. Expansion joints are formed with one thickness of heavy tar paper placed as shown in accompanying sketches. Wooden sheet piling is used and two Cameron steam pumps, sizes 9 and 11 have been employed to keep the water down while the footing concrete was placed.



Section of Steelwork of Morris Heights Approach.

Near the south end of the ramp the roadway is carried over an old abandoned canal, the bottom of which is above low tide, with a plate-girder and reinforced concrete bridge. There are three 42½-in.x36-ft. girders placed 13 ft. ⅝ in. on centers carrying 15-in. 42-lb. I-beam floor beams on about 6-ft. centers. The 13x6-ft. panels thus formed are covered with a continuous 7-in. slab of concrete reinforced in a direction parallel to the course of the canal with ¾-in. round steel rods on 12-in. centers and in a direction parallel to the center line of the ramp with the same size rods on 6-in. centers. This canal formerly served an entrance to a neighboring coal yard, but it was abandoned long ago.



Approach to Bridge over Railroad Tracks at High Bridge Station.

Sand and gravel is delivered alongside the work on lighters holding about 600 cu. yd. each. Each lighter is loaded with both materials, the proportions being the same as required for the concrete. The boats are unloaded by shoveling the material into 1-yd. buckets which are delivered to storage piles near the mixer on shore or to the mixer itself by a stiff-leg derrick placed at the water's edge on the north side of the canal and operated by a Lidgerwood hoist. The 1-yd. Smith mixer is placed near the derrick on a slightly elevated platform and delivers to 1-yd. buckets which are conveyed to the proper point along either wall by two cable-ways, one over each wall. One of these cableway outfits was made by the Lidgerwood Mfg. Co., New York City, and the other by W. A. Crook & Bros., Newark, N. J. The cableway engines are mounted one on the extreme south end of each wall and the guyed A-frames forming the towers are placed on the south abutment of the canal bridge and beyond the north line of the bridge over the railroad tracks, as shown in an illustration. Steam is supplied to the various engines and pumps by a 60-h.-p. Erie boiler and a 40-h.-p. locomotive boiler formerly used on the New York elevated railroad. These boilers are in a shed about 100 ft. north of the old canal and close to the west wall of the ramp. The cableway conveyors are being used to deliver the filling material which is brought alongside the work on scows and placed between the walls before the coping courses are built.

For the convenience of the users of the water front at the High Bridge station, pending the completion of the permanent improvements, a timber incline has been built just outside the west line of the west wall connecting at its upper end with the bridge across the track.

At the 177th St. or Morris Heights station the bridge over the tracks will be extended westward about 141 ft. by a similarly designed elevated steel structure 60 ft. wide, carried by five longitudinal lines of latticed columns spaced 34 ft. 8 in. center to center in each line. The longitudinal floor

girders are spaced in general on about 5-ft. centers, thus dividing the floor into long panels about 5 ft. wide. The 9-in. reinforced concrete floor carrying the 35-ft. roadway, rests on the longitudinal girders and is reinforced with ½-in. round rods, those parallel to the girders being on 12-in. centers and those perpendicular to them being on 6-in. centers. A 15-ft. cement sidewalk extends along the north side of the bridge roadway and a similar walk 10 ft. wide is on the south side. These sidewalks and the roadway slope downward on a 4 per cent. grade to the extreme west end of the steel structure where they meet a concrete and earth fill incline U-shaped in plan, as shown in accompanying illustrations.

In general, the concrete walls of this plant have the same sectional form as those at High Bridge and are built of the same materials in the same proportions. The high transverse wall at the east end of the earth fill, however, has a much heavier section than the other walls since it serves as an abutment for the west end of the steel

structure. The pile supporting these walls are 20 to 53 ft. long.

Sand and gravel is delivered at Morris Heights in lighters, as at High Bridge. During the early stages of the work these were unloaded with 1-yd. buckets handled by a small stiff-leg manually-operated derrick. The abutment and the center and north walls were constructed first. While this work on these was in progress, the mixer, a 1-yd. Smith machine, was placed on a slightly elevated platform near the middle point of the center wall on its south side. Sand and gravel was hauled from the lighters to storage piles near the mixer in dump wagons and the mixer was served from the storage pile by wheelbarrows. The mixer delivered to 1-yd. buckets which were handled by a stiff-leg derrick with an 85-ft. boom, placed between the center and north walls about 80 ft. west of the abutment wall and operated by a Lidgerwood hoist. Later during the construction of the west and south walls the mixer was placed in the corner formed by the south and west walls on an elevated platform, the small derrick was replaced by one with a 70-ft. boom operated by a Lidgerwood hoist, and the large derrick mentioned before was mounted at the west end of the center wall from which point it could reach the mixer and the forms for the west and south wall.

In handling the water encountered at Morris Heights, two Cameron steam pumps of the same sizes as those at High Bridge were used. Steam was supplied to the pumps and hoists by a 60-h.-p. Olney & Warren boiler placed near the east end of the south wall.

The structures immediately over the railroad tracks were built by the New York Central & Hudson River R. R., and the approaches are being constructed by the City of New York. Mr. Josiah A. Briggs, chief engineer of the Borough of the Bronx, New York City, exercises general supervision over the work which was planned and is being executed under the immediate supervision of Mr. S. C. Thompson, principal assistant engineer of highways. The approaches at High Bridge and Morris Heights are being constructed under one contract, Mr. J. C. Rogers being the contractor. The construction work which is now in charge of Mr. Chas. Gartensteig, assistant engineer, was begun by Mr. R. H. Gillespie, assistant engineer, who resigned last May to take up other work. The American Bridge Co. will fabricate and erect the steel structure at Morris Heights.

RAILWAY STATISTICS from advance sheets of "Poor's Manual" show that the average receipts per passenger-mile in 1906 were 2.011 cents, as against 2.028 cents in 1905. The average revenue per ton-mile in 1906 was 0.766 cent, as against 0.784 cent in 1905. At the close of the year there were 222,635 miles of railway.

Sewage Disposal Results at Berlin, Ont.

A sewage disposal plant, comprising two septic tanks, two storage tanks, a pumping station and

TABLE 1—AVERAGE RESULTS OF TESTS TO DETERMINE EFFICIENCY OF SEWAGE DISPOSAL PLANT AT BERLIN, ONT.

Description.	No. of Specimens Examined.	Parts per 100,000 — Free Ammonia.	Parts per 100,000 — Albuminoid Ammonia.	Parts per 100,000 — Chlorine.	Percentage Removal by Septic Tanks and Beds of Albuminoid Ammonia Over Raw Sewage.	Percentage Removal by Each Bed of Albuminoid Ammonia from Septic Tank Effluent.
Raw sewage	19	2.935	1.406	29.13	....	....
Septic tank effluent	20	2.450	0.723	27.08	48.5	....
Beds 1 and 2	13	0.594	0.172	20.23	87.7	76.2
Beds 3 and 4	10	0.982	0.169	21.08	87.9	76.6
Beds 5 and 6	11	0.798	0.133	20.78	90.5	81.6
Beds 8 and 11	7	0.5735	0.1159	20.40	91.8	84.0

Bed No. 16	10	1.176	0.131	24.44	90.6	81.8

14 acres of intermittent sand filters in 16 beds was placed in operation at Berlin, Ont., in 1905. Since then samples of sewage from various parts of the plant have analyzed by the chemist and bacteriologist of the provincial board of health of Ontario from time to time to determine the efficiency of the plant. The average results determined by these tests are given in the accompanying table. From these results it may be seen that the average removal of albuminoid ammonia from the raw sewage by the septic tanks and filters was 91.8 per cent., and the average removal of albuminoid ammonia from the effluent of the septic tanks was 84.14 per cent. On no occasion was the effluent from the filters putrescible.

This sewage plant and the conditions governing its design and operation were fully described in The Engineering Record for Dec. 23, 1905. Briefly, the combined capacity of the septic tanks and storage tanks is 500,000 gal., which is approximately the average daily sewage flow. Of this flow nearly 200,000 gal. is trade wastes from a brewery, a woolen factory, a gas works and four tanneries. Formerly these wastes rendered the sewage particularly difficult to treat, but a series of experiments conducted prior to the construction of the disposal plant demonstrated that they could be made much less harmless by simple treatment of different kinds before being turned into the sewers. Provisions have been made for the preliminary treatment of these wastes so that their influence on the activities of the septic tanks and filter beds is much reduced.

The disposal plant was designed by Mr. Wm. Mahlon Davis, consulting engineer, of Berlin, Ont., who has supplied the data concerning the results obtained by it.

A TURBINE TEST of a 1,000-kw. Allis-Chalmers unit was recently made at the power-house of the Kokomo, Marion & Western Traction Co. by Mr. Paul Diserens of Purdue University and representatives of the owners and builders. The turbine was designed for 1,000 kw. at 1,800 r.p.m., using dry saturated steam at 140 lb. at the throttle and 28-in. vacuum at 30-in. barometer. The auxiliaries include a motor-driven exciter, a steam-driven exciter, two small circulating pumps, and a standard Allis-Chalmers turbo-jet condensing apparatus. The average load during the test was 553.3 kw. and the run was 4 hours. The steam pressure at the turbine throttle was 136.4 lb. and at the turbine inlet 61.9 lb. The vacuum was 26.59 in. with the barometer at 28.98 in., equivalent to a vacuum of 27.66 in. with a 30-in. barometer. The turbine ran at 1,800 r.p.m. The water used was 55,662 lb., the drip 450.6 lb. and the boiler leakage 5,344.6 lb. The moisture in the steam was 2.82 per cent. by calorimeter. Dry steam supplied to the turbine per hour 12,115 lb., and the actual consumption 21.9 lb. per kilowatt-hour, the guarantee at half load being 24 lb. with a 28-in. vacuum.

A Method of Tunneling High Railroad Embankments for Culverts.

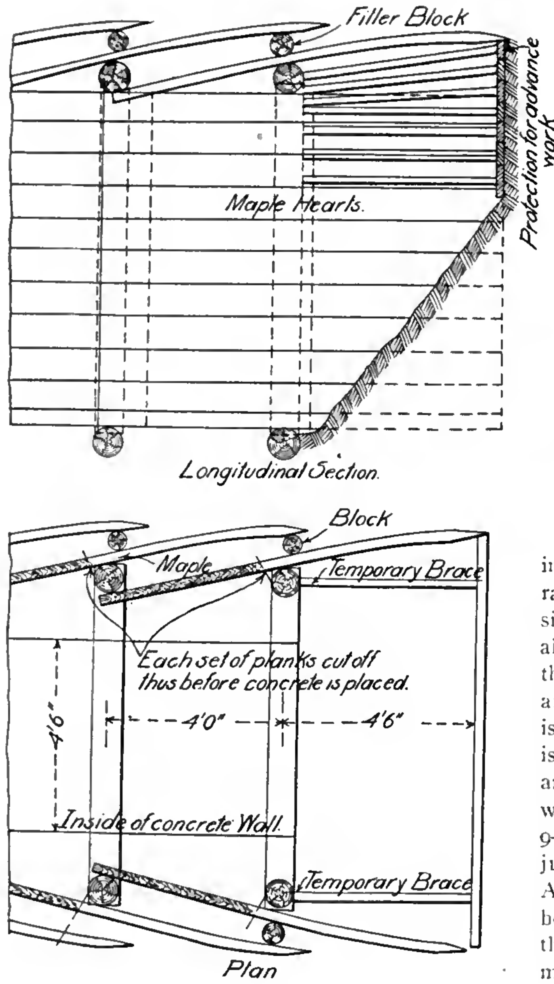
A wooden-box culvert and two cast-iron pipes which have failed under high embankments of sand on the Lake Superior & Ishpening Ry. are being replaced by reinforced-concrete culverts built in tunnels driven through the embankments. A flat-top reinforced-concrete culvert, 190 ft. long, 4.5 ft. wide inside, 4 ft. high at the sides and with a curved invert, giving it a clear inside height of 4.5 ft. at the longitudinal center line, is being built to take the place of a 60-in. cast-iron pipe which failed under an embankment 65 ft. high. A concrete culvert, 284 ft. long and 3x3 ft. in cross section inside, replaces a 36-in. cast-iron pipe under a 95-ft. fill, and one 150 ft. long and 4x4 ft. in the clear in cross-section will supersede the wooden-box culvert which is under a sand fill, 50 ft. in height.

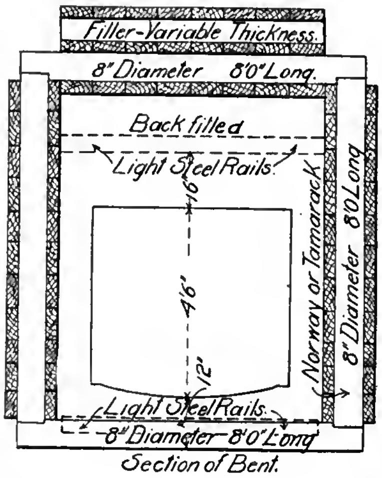
One of the embankments through which these culverts are being constructed was made eleven years ago, when the road was built and the other two, seven years ago, at the time a cut-off from the original line was built. Their height and the material in them precluded any possibility of constructing the culverts in open cut, so a tunnel had to be built through each of the embankments. The comparatively small cross-section required in these tunnels, the character of the sand through which they were to be driven and the necessity of avoiding settlement that would interfere with the heavy traffic on the track carried by the embankment necessitated the adoption of a method of tunneling which would insure both safety and economy.

The tunnel for the largest culvert is 6x7.5 ft. in the clear inside the timber lining, and those for the two smaller culverts are of proportionate size. The method of excavating and timbering the three tunnels is practically the same, so one description and the accompanying illustration will suffice for all. The timbering consists of framed bents of Norway pine or tamarack logs, at least 8 in. in diameter, and 3-in. hard-maple planks for sheeting on the sides and top. The bents are spaced 4 ft. apart on centers, each bent having a bottom sill, two vertical posts and a cross brace connecting these posts at the top, these pieces all being in 8-ft. lengths. The sheeting is driven as closely together as possible and is arranged so a double row of it with a space between the rows, is provided on both sides and the top at all places.

After a start has been made in the side of the embankment by setting two bents in their regular positions and driving the sheeting, the excavation and timbering is carried forward through the balance of the tunnel by the following method: The face of the excavation is closely sheeted with horizontal planks placed against the front side of the last bent erected in order to hold back the fine sand; these planks extend from the bottom of the tunnel to the sheeting at the top so as to prevent the sand from running into the tunnel and undermining the embankment. When this seal has been placed in a manner that will be explained, 3-in. planks in 9-ft. lengths are driven over the top brace of the foremost bent, against which the seal rests. These 9-ft. planks are driven with a slight inclination upward so when they have penetrated until their rear ends are under the second foremost bent, their front ends are over the site of the next bent to be placed and clear the top brace of that bent 8 in. to 1 ft. The planks of the seal across the end of the excavation are then removed one at a time, beginning at the top, and as they are taken out the sand is excavated under the roof sheeting which has been driven ahead of the foremost bent. The planks forming the side sheeting are driven one at a time as this excavation progresses. These side planks are slanted upward to correspond with the slope of the roof planks, and are also pointed so they diverge outward from the center line of the tunnel. They are in 9-ft. lengths in order to form the double row of sheeting on the sides, their arrangement in regard to the bents being the same as in the roof planks. That is, the rear end of each plank is against the inside of the vertical post of one bent; midway, the plank is against the outside of the vertical post of a second bent, and at the forward end is 8 in. to 1 ft. clear of the third bent, each set of planks extending past three adjacent bents.

As the planks forming the seal at the end of the tunnel are removed, the excavation is carried ahead to the site of the next bent to be placed, the material being shoveled into cars, which are pushed out by hand. When necessary, as it usually has been in this work, a seal for the new face is started at the top of the tunnel and carried to the bottom of the latter as the excavation proceeds, the planks being braced temporarily against the bent already placed. After the excavation has been carried forward to the next bent in this manner, the side sheeting driven and the new seal completed, the bent is built up in position. Filler blocks are placed meanwhile between the two rows of sheeting where the latter pass the bent, in order to prevent the projecting part of the outer planks from breaking when the excavation advances further. The cycle of operations is then repeated in this manner until the tunnel has been finished.





Timbering for Tunnels under Embankment.

The sheeting planks could scarcely be driven by hand in the limited room available, and through the hard driving encountered, so a simple battering-ram device that has been improvised for driving them has proved particularly advantageous. A 12x12-in. timber, 12 ft. long, is fitted with a hook near the middle, by which it can be hung from a chain; the chain is attached to the rear one of two pieces of 2-in. pipe placed across the tunnel about 3 ft. apart, near the roof, and just back of the point where work is in progress. A handle is attached on each side of the ram so two men can swing the latter back and forth and drive the plank. As the plank advances the ram is moved forward to the second pipe. The planks are driven quite rapidly and easily in this manner.

Four or five men work in the tunnel while the excavation and timbering is in progress, one man frames the bents and timbering outside the tunnel and a foreman is in charge of the work. With this force an average of about 4 ft. of tunnel is completed each 10-hr. shift.

The construction of the culvert was not started until the tunnel had been finished. The invert of the culvert is 18 in. thick at the sides and 12 in. thick at the middle. The sills of the bents are imbedded in the concrete and two pieces of light rails are placed horizontally between each two sills as reinforcement. The top of the culvert is also reinforced with light rails. In construction, the invert is built first for a considerable length, after which the side walls and the top are finished at one operation. The concrete of the sides is extended back to the outer row of sheeting, and in order to accomplish this the inner row, which is formed by the rear half of each set of 9-ft. planks, is removed by cutting off the planks just back of the middle bent covered by each set. As the culvert is finished, back filling is rammed between the top of it and the sides and roof of the tunnel lining, so settlement of the embankment will be prevented when the timbering decays, as it may do eventually.

The concrete materials are delivered along the track on the embankments in a special form of quick-dumping car, so very little delay is occasioned to train movements. A concrete mixer is set up at the mouth of the tunnel, the materials being delivered down the side of the embankment in chutes to storage piles at the mixer.

The cost of the tunneling, including all labor charges and the cost of timbering, was about $7 per foot for the 8x8-ft. tunnel. Laborers were paid $2.25 and the foreman $3 a day. The 3-in. maple planks used for sheeting were rough heartwood, costing $12 a 1,000 ft. The timbers for the bents were Norway pine or tamarack in logs, except that they were cut at each end for framing. The cost of the concrete culverts is not available at this time, but is probably at least no more expensive than such work done in the open, as no outer forms were required.

This work is being done under the direction of Mr. R. C. Young, chief engineer of the Lake Superior & Ishpeming Ry., to whom this journal is indebted for the information from which these notes were prepared.

Book Notes.

Every few weeks an inquiry reaches this journal for information concerning plunge baths, particularly their heating. A little book that answers these questions in much detail has just been written under the title of "Swimming Pools" by Mr. John K. Allen. It describes their construction, water supply and heating, and gives detailed directions for the selection of apparatus for the latter purpose. A number of installations of different types are illustrated and altogether the book is a decidedly good one. (Chicago, Domestic Engineering, 50 cents).

A large number of tables in regular use by the engineering department of the Trussed Concrete Steel Co. have been published with explanatory text under the title of "Kahn System Standards." Although some of the pages are trade arguments, the volume is esentially a handbook of the practical calculation and application of reinforced concrete, of marked value to those using this system of reinforcement. The beam and girder tables are based on the following assumptions: (1) A section plane before bending remains plane after bending. (2) The tensile strength of the concrete is entirely neglected. (3) There are no initial strains in the beam. (4) All shearing strain is provided against and there is no slipping between the concrete and steel. (5) The modulus of elasticity in concrete is constant. The tables are extended to include T-beams and also beams in which the design is limited by the compression of the concrete and the full tensile strength of the steel is not developed. Reinforced concrete floor slabs and the floors composed of tile and reinforced concrete are covered by the tables, and there are special beam tables of safe loads uniformly distributed which are arranged like the tables of steel beams issued by rolling mills. The tables of column strength relate to hooped and unhooped types, and those relating to footings are unusually extensive. The book also contains the tables of earth, grain and coal pressures which are used by the company's engineers, a digest of part of the requirements of the building codes of New York, Chicago, Philadelphia, Boston and San Francisco, and drawings and tables of standard highway and railroad culverts and arches. At the end there are some excellent rules for construction and tables of the amount of material required for mortar and concrete of different proportions. (Detroit, Trussed Concrete Steel Co., $1.50.)

A complete description of the new water works of the Swedish capital, written by Major F. V. Hansen, gives an account of an undertaking containing many features of design and construction different from those usually adopted in the United States. The title of the book is "Stockholm's Nya Vattenledningsverk vid Norsborg," and it is pubished by K. L. Beckman, of Stockholm. The supply is drawn partly from wells and partly from a large lake. The well water is treated to remove the iron it contains and the lake water is filtered, slow sand filters roofed over with steel trusses and skylights being employed. There is a pumping station connected with the works, a long tunnel, a covered reservoir, inverted syphons, a reinforced concrete aqueduct and many less important features of interest. Their details and cost are stated quite completely and the text is illustrated with many engravings and plates.

The second section of the third part of the cyclopedic "Handbuch fuer Eisenbetonbau," published under the editorial direction of Dr. F. von Emperger, is particularly useful. It opens with an explanation of the theory and design of reinforced concrete reservoirs and vats, underground, surface and elevated, for holding water, wine and other liquids. So many elevated towers are now being considered that the portion of the book outlining the steps to be taken in computing their parts is likely to prove useful to a large circle of readers. The author, Mr. Richard Wuczkowski, of Vienna, also describes many completed structures, a number of them being in the United States. The next division of the book, by Mr. Fr. Lorey, of Bernburg, is a description of the design, construction and test of reinforced concrete pipes, conduits and aqueducts, ranging in size from small sectional pipe carried in stock like vitrified clay sewer pipe to large ornamental aqueduct bridges. Mr. B. Nast, of Frankfort, contributes a short chapter on the uses of reinforced concrete in mine shafts, tunnels and large subways, and Mr. A. Nowak, of Vienna, continues the subject, closing with a description of some unique snowsheds and avalanche galleries. The book is profusely illustrated. (Berlin, Wilhelm Ernst & Sohn, 15 marks).

The voluminous paper on "Elevating and Conveying Machinery in Steel Works and Rolling Mills," read by Prof. G. Stauber at the annual meeting of the Society of German Iron Masters last May, has been reprinted in pamphlet form for sale at 4 marks by August Bagel, Dusseldorf. The illustrations are profuse and cover a great range of machinery, particularly heavy apparatus like special cranes, machines for handling ingots and the like.

A small handbook of the principles governing the design of water power and water supply works, apart from machinery and reservoir details, has been written by Mr. Ferdinand Schlotthauer under the title "Ueber Wasserkraft—und Wasser-Versorgungsanlagen." Its methods are those well known through the famous "Huette" pocket-book and the "Handbuch der Ingenieurwissenschaften." There is nothing particularly novel in the contents, but it explains clearly the steps to be taken in designing small power canals, weirs, penstocks, aqueducts, syphons, and systems of street mains. The engineer who is not looking for details of theory and the design of large works where the minor points are so important that the engineering work becomes complicated, will doubtless find this little book sufficient for his needs. (Munich, R. Oldenbourg).

Students of mill architecture will find a large amount of valuable information on the 25 plates of details in Mr. H. W. Morton's "Details of Mill Construction." This is a quarto volume of drawings for actual mills or sketches made from measurements of existing structures. All the text is lettered directly on the plates with the exception of a few general statements which the author gives in his preface. All drawings have been endorsed by the Boston Board of Fire Underwriters as being in conformity with their requirements. Some of the details call for much less expense than others, so that the reader has quite a range of choice in the designs for the same purpose. The sketches are useful to designers of stores, warehouses, power stations and stables as well as mills. (Boston, Bates & Guild Co.).

Messrs. Henry C. Horstmann and Victor H. Tousley have written a pocket-book entitled "Electrical Wiring and Construction Tables" which seems to be well adapted for the use of foremen on work. It gives direct and alternating current wiring tables and diagrams and an explanation of their use, a chapter on methods of obtaining the utmost economy in laying out wiring jobs, numerous conduit diagrams and a large amount of miscellaneous information relating directly to wiring. The book is small enough to be carried readily in the pocket and is bound in limp leather. (Chicago, Frederick J. Drake & Co., $1.50.)

The U. S. Forest Service of the Department of Agriculture has recently published two books of general interest to those who appreciate the importance of greater care in the use and maintenance of our timber resources. These books show how many advantages will eventually result from the system of federal control over the important timber tracts now known as national forests. Some people have the idea that these lands are great restricted picnic grounds into which the public may intrude only in fear and trembling, prohibited from breaking a branch or culling a posy. As a matter of fact, the homeseeker can travel all through a national forest, pick out the agricultural land he desires, settle there and live for the rest of his years on this tract. The policy of the Forest Service is to encourage such settlement, for it enables more men to be secured promptly to fight forest fires. prospecting and mining go on just as before, and uncontrolled lumbering alone is stopped. The timber is not made useless, however, for not only is it given away to the home-builder and to the prospector, but it is sold for commercial purposes as well, provided the trees may be felled at the time without interfering with sound forestry principles. All these things are explained in considerable detail in the "Use of the National Forests," a well illustrated handbook which contains also considerable information regarding the location, extent and character of the various reservations. The reader who desires to become familiar with all the regulations issued by the Department of Agriculture to govern forest reservations will find the complete text in the "Use Book," which is an annotated collection of these rules and instructions showing every detail of the conditions under which the public may make use of the national forests.

The water, gas and drainage piping and fixtures that are used in buildings are governed generally by the rules of the local building department. These rules are necessarily drawn up to insure sanitary conditions when the job is done with the cheapest materials in the least exensive manner possible to satisfy a minimum hygienic standard. This grade of work and materials is not that desired by most owners, and for this reason it is not possible for them to rely on the specifications of the building department or the inspection of its employes. It is therefore desirable to have the specifications for such work prepared by somebody who is thoroughly familiar with the various grades of installations and to have the job under constant competent inspection as it progresses. This is likely to save money and future annoyance to the owner in the long run, and the reason it has not been done better in the past is the fact that only a sanitary specialist, plumber or fitter really knows where to look for intentional or careless or ignorant mistakes. In order to supply just such information Mr. William Paul Gerhard has prepared a book entitled "The Superintendence of Piping Installations in Buildings," in which he gives the results of an experience covering more than 25 years in planning and supervising such work. The book is prepared so as to be equally useful to architectural superintendents, plumbing and health inspectors, plumbing superintendents and the owners who wish to assure themselves that the sanitary work done on their property is properly executed. The book takes up the superintendent's responsibilities in the order in which they come to him, starting with the sewer, gas and water connections from the street and passing through the rough work and the setting of

fixtures to the tests and the preparation of final records and plans. There is a very general need for such a book and this one answers the requirements admirably. (New York, McGraw Publishing Co., $1.00).

The American Society of Mechanical Engineers, 29 West 39th St., New York, has reprinted the presidential address of Mr. F. W. Taylor on the "Art of Cutting Metals," and is selling it bound in cloth at $3. The demand for this address has been very great, and the number of "Proceedings" in which it first appeared was exhausted directly after the last annual meeting.

The West Virginia Geological Survey has issued a special report on the topography, geology and mineral resources of Ohio, Brooke and Hancock Counties. It is written by Prof. G. P. Grimsley, assistant State geologist, and is sold at $1.50 at the Survey office at Morgantown.

The nature of matter has been a fascinating subject for the philosopher and physicist, the thinker and the worker from the days of Democritus and Lucretius down to the present hour. And, indeed, it may safely be said that at no time in the history of scientific discovery was greater activity displayed in the study of problems relating to the constitution of the ultimate forms of matter than in recent years. Were proof needed, it would be afforded by every one of the 230 pages of Dr. Oliver Lodge's "Electrons." This volume shows a clearness of exposition which leaves no lingering doubt in the mind of the reader. The author has done pioneering work in the electronic field and has discussed proposed solutions of outstanding difficulties with the leaders of scientific thought at home and abroad, so that this latest work of his is sure to command at once the confidence of the reader, even when dealing with the more speculative parts of the subject. That the "electron" has opened up not only a new chapter, but also a vast domain in general physics will be evident from a glance at some of the titles of the successive chapters: Nature of chemical and molecular forces; increase of inertia due to rapid motion; the electron theory of conduction and radiation, etc.

Though several good works on that smallest of entities, the electron, have recently appeared, no student of physical theory can afford to be without this volume. (London, George Bell & Sons, 6s.)

Letters to the Editor.

Railway Topography.

Sir:—In your number of August 24 a correspondent who signs himself "Transitman" makes some interesting observations on the subject of topographical work on railway surveys. He very properly lays stress on the fact that the aim should be to secure the topography with the desired accuracy at a minimum cost, which leads him to the opinion that the methods followed in open prairie country are not applicable in the mountains. With this opinion a good many of us who are engaged most of the time on location will probably agree, yet there are two things to be considered which your correspondent did not mention. The first of these is the very rough nature of considerable location, made for companies of limited resources or for the consideration of directors who have no intention of ordering construction for some time to come except under rather unlikely conditions. The second thing that must be considered is the difference in men, for I have seen a few "natural" topographers whose skill was so great that it is safe to say one of them with a single assistant will map as much topography as an average four-man party and with equal accuracy. The first man of this type I saw was engaged on a party in western Iowa which was trying to locate a line now a part of the Burlington system. The country was the worst I ever traversed, although it did not look particularly bad, and I have often wondered if the Burlington engineers who have been engaged of late years in the improvement of those old lines leading to the Missouri have the same feeling of respect for the twisting gullies of that district that I have maintained for a generation as the result of early experience there. The country is much worse than real mountainous districts, because, until it is all covered by a topographical survey like those of some States where the U. S. Geological Survey has been active, it may be questioned whether it is really possible to know just what is the best location. In mountainous districts, the salient peaks and passes furnish a guide that enables the possible lines to be reduced speedily to a few.

Where the country is difficult, your correspondent is perfectly correct in stating that of all field positions that of topographer requires more experience and greater exercise of judgment than any save that of locating engineer or chief. The late A. M. Wellington once wrote that "in country at all rough the topographer fills the most responsible position on the party below its chief, and should so rank." If he is not competent the map will be of little value, or it will be extremely costly on account of the time put on the topographical work by members of the party engaged for other work. In consequence of this fact, I have always endeavored to obtain permission to use my judgment regarding the detail of topographical work, so that where a poor man is employed on it the amount taken in easy country shall not be so great as to hold back the whole party. This sounds like makeshift work, yet on some surveys it is entirely proper. Where directors will not furnish funds for engaging thoroughly competent men, but demand results on a certain date, they cannot expect these results to be as detailed and as accurate as those obtained on the excellent railway surveying lately done by two great companies in the district from which your correspondent writes.

It seems to me that in a good deal of mountain country in which I have worked there would be no call for such a large force on topography as the writer of the letter advocates. Some mountainous districts are not at all difficult to map expeditiously, for while the slopes are steep, they are uniform and not covered by such a growth of brush that there is any difficulty in seizing upon their contour. In many such districts two men trained in the work are certainly enough. There is no use in getting results to a greater degree of accuracy than will be clearly shown on the map, and I have noticed quite often lately that this unnecessary accuracy seems to be considered essential. Paper locations are extensively made, and some companies are stated to make their final location practically a topographical proposition, the maps of the preliminary party being sent back to a main camp where the final line is plotted on them and then at once run in on the ground. I know nothing about this method, and have never even talked with anybody who has been on work where it is employed, although great claims for its speed and economy have been made. It demands special skill on the part of the topographical men, for they must be both speedy and accurate in order not to delay either of the field parties, and I should like very much to learn more about the working of the method.

There is a feature about topographical work that possibly is overlooked at times. The permanent addition to a party of every extra man means more than the wages of that man, for his subsistence and quarters have to be considered, and the fact that every extra man means so much more delay in getting about. Everybody who has lived in the field for a number of years knows that small parties accomplish more per man than large parties. It is for this reason that I should much prefer to have two good men on topography in difficult country than four of average ability. I have rarely found it necessary to put transitmen on topography where the regular topographer was really skilled, although at times I have had the transit party run lines near both the uphill and downhill sides of the strip so as to reduce the distance the topographer had to work out from a surveyed line. This is equivalent to sending help to the topographer from other members of the party, but it gives him help in such a way that he is not made to appear slow in his work, and the instrumentmen are thereby taught that the work done by the topographer must be borne in mind by them. A very little of such double-line running is necessary with a good topographer, and I believe its cost is far below that of a permanent extra man in the organization, except where the country is broken. Possibly this opinion may be due to the unwillingness of old men to change their views, but it is nevertheless the result of a lifetime of experience in railway surveys and associated work.

Very truly yours, Richard Lea.
Los Angeles, Aug. 26.

The Power Plant of a Small Flour Mill.

Sir: My attention has just been called to an error in an article with the above title in your issue of July 20th, describing improvements made in the power plant of a flour mill at Washington, Mo., which are stated to have resulted in a fuel saving of 120 per cent., a truly astonishing result. The data for this article were prepared in my office and it is possible also that the 120 per cent. figure was made here. The original coal consumption was 43.5 lb. per barrel of flour; after improvements, 19.6; saving, 23.9. This is 122 per cent. of the final and not the original consumption. The saving over the original consumption was 55 per cent., which is, of course, the figure which should have been used. That the statement should have been made in this shape, and was furthermore overlooked when I read the proof, is one of those inexplicable occurrences which sometimes tend to our confusion in spite of the greatest care and watchfulness.

Very truly yours, William H. Bryan.
St. Louis, Aug. 28th.

Graphite Lubricants.

Sir: In your number of July 22 you print the following: "The United States Graphite Co., Saginaw, Mich., has developed a lubricating graphite in which the graphite is held in suspension in oil sufficiently long for it to perform its purposes when fed through oiling pipes. Amorphous graphite reduced to an impalpable powder is used, one teacupful of it being mixed with about a pint of oil."

This gives the reader a wrong impression of the lubricating graphite which we prepare. This differs from the ordinary flake graphite in that it is an impalpably fine powder, air floated and gritless which, when mixed with lubricating oils in the proportion of one teaspoonful graphite to the pint of oil will feed through lubricator tubes without clogging and remain suspended in the oil sufficiently long to perform its functions.

Your notice states that a teacupful should be mixed with a pint of oil whereas the correct proportion is a teaspoonful. And should any of your readers try to use the same in the way you recommend, the results would be very disastrous to them and would tend to hurt the sale of this lubricant.

Very truly yours,
United States Graphite Co.

THE ENGINEERING RECORD

Published Weekly by the

McGraw Publishing Company

James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.

MAIN OFFICES:

239 West 39th Street, New York.

BRANCH OFFICES:

Chicago: Old Colony Building.
Philadelphia: Real Estate Trust Building.
Cleveland: Schofield Building.
San Francisco: Atlas Building.

London Office: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico	$3.00 a year
Canada	$4.50 a year
Foreign subscription	$6.00 a year
25 shiltings. 25 marks.	31 francs.

Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of The Engineering Record on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

Remittances.—Remittances should be made by check, New York draft, or money order, in favor of The Engineering Record.

Changes of Address.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

Back Copies.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.

Date on Wrapper indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

Club Rate.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. The rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 14,250 copies are printed. Total circulation for 1907 to date 538,000 copies, an average of 14,541 copies per week.

TABLE OF LEADING ARTICLES.

The Growth of Electric Motive Power.

Prof. S. P. Thompson's presidential address before the Engineering Section of the British Association, extracts from which were printed on September 7, contains a most interesting abstract of the history of electricity as a motive power. It is immensely difficult to set one's self back in viewpoint a half century and to look on the electric motor and its possibilities as they were then seen. In 1857 the machine was no novelty; it had in fact been known for at least a quarter of a century. At the beginning of that epoch there was precious little popular interest in electricity. It was unfamiliar to all save a few savants, and to them it was mainly of theoretical interest. But a few years later the advent of the telegraph waked the world to some appreciation of things electrical. The commercial needs of the growing art brought about the invention of improved batteries, and the study of the principles of electro-magnetism. An immense amount of active experimenting went on and so it came to pass that at just about the period mentioned by Prof. Thompson, that is, in the "fifties," there was in progress an active "boom" in electrical work, checked only by the lack of adequate sources of electrical energy. A great deal of clever invention work was being done, so much that many an incipient patent of to-day has received its quietus from the work of Page and his contemporaries. And it is worth noting that since that period there have been but few and slight improvements in the electric battery.

Lacking the dynamo, however, it is small wonder that even the most far-sighted should look upon the electric motor as of questionable practicability. There were those who even then held firmly to the belief that electricity would supersede steam as a motive power, yet the sounder judgment was of those who held that its chances were small on account of the uneconomical source of energy. Although to-day a million horsepower and more of motors are in regular use, the doubters of 1857 were essentially in the right. The steam engine is no nearer to being pushed aside now than it was then. The battery stands just where it did then—it was and is incomparably more costly as a source of power than the steam engine. Lord Kelvin, the sole survivor of the brilliant group that discussed electro-magnetic engines on the occasion referred to by Prof. Thompson, need not, fifty years after, retract a word of his early opinion. His contingent possibility has come to pass, that is all. It was a decade later that the beginnings of the dynamo were in evidence, and a score of years before the electric motor in the modern sense of the word made its appearance. And up to the present time the motor has been chiefly an immensely useful intermediary between the steam engine and its point of application. This statement points out the vast economic loss that is still part of our every day life. Although an electric motor of moderate capacity may have an efficiency as high as 95 per cent., mankind is still condemned to furnish it energy from a prime mover with an efficiency of only 10 or 15 per cent.

Electricity direct from coal is as far distant as it ever has been. The few carbon-consuming batteries devised have failed of any commercial usefulness and there have been no cheap batteries invented in the least able to compete with coal and engine. Perhaps the most interesting possibility in this line is the thermo-regenerative battery, thus far of only theoretical interest. This is merely a primary battery of which the current producing reaction is reversible by heat, just as in the storage battery it is reversible by electrolysis. Heat the battery and it goes back to its initial state ready for a new task. Perhaps some chemist may solve the problem and enable the heat of coal to be applied at an efficiency enormously greater than is possible with a steam engine, an efficiency perhaps as great as that of our present boilers. It will take some such revolutionary discovery as this to put the steam engine in some form out of business. The internal combustion engine we have, of course; but great as are its possibilities it has not yet pushed the steam engine hard in actual economy in spite of the fact that it has double the thermo-dynamic efficiency. The next few years should show great strides in the use of gas engines in large sizes, and also some material improvements in steam practice which will probably keep the steam engine still in active work. The electric motor is still the intermediary, though it has been pushed into use to an extent that even a dozen years ago seemed scarcely possible. The advent of the alternating current motor in its various forms has been the strongest recent stimulus in the art. If the great experiments in traction by alternating motors result favorably, the first important inroad on the absence of the steam engine as a working motor will have been made, but behind the motor and the dynamo will still be the engine and boiler, in spite of all. The engineers of the "fifties" were not so far wrong in their chief premises, after all; they merely failed to appreciate the importance of the flank movement which actually took place. And, truth to tell, it is often the flank movements in engineering that enable important positions to be carried in cases where a frontal attack might miserably fail. It is trained resourcefulness that counts.

Power Plant Instruction Books.

The complex operating problems present in many of the electrical industries demand clearly worded and carefully printed instructions in the form of small handbooks for the use of employees. Particularly in transportation service has this necessity become recognized, and the preparation of special books covering the operating exigencies of electrified terminal service is an outgrowth of the new conditions in the field of heavy electric traction. In the work of the New York Central in the vicinity of the metropolis, special instruction books have been prepared in connection with the operation of the high and low tension distribution systems, the maintenance of the third rail and its auxiliaries, and the operation of the new electric locomotives. The New Haven locomotives have also been made the subject of treatment in a small pocket book issued by the latter company. The detailed operation of power plants has not received this sort of treatment to any extent, though in the case of the New York Central sub-stations the printed instructions are very carefully worked out with reference to the maintenance of continuous service.

It is a question if the handling of very large power plants could not be considerably facilitated if the instruction book idea were applied to installations of high capacity and great responsibility of output. The operation of power plant machinery is, of course, a regular business or group of occupations in itself, and to a large degree men employed by a company for power house service are supposed to know the details of their work before they take an active hand in the operation of the equipment. But the facts usually are that the conditions in no two plants are alike, and especially in isolated installations supplying a great variety of service, perhaps including heating, ventilation and refrigeration, it is a matter of no little time for a new man to feel sure of his ground in the rapid handling of valves and switches. It would certainly be a distinct help if some equivalent of an instruction book or at least a type-written set of data expressing the main physical features and operating peculiarities of the system could be kept as a part of a complicated plant, being a sort of mechanical and electrical inventory of the equipment and its arrangement.

Small plants would not need anything like the fulness of instruction desirable in high-powered stations. The latter contain as a rule much more auxiliary apparatus; the exact responsibility and duties of each employee are more essentially specified, and in the case of very valuable machinery, the handling of it should become a matter of established routine, both in normal and emergency conditions as far as they can be antici-

pated. A clear statement of the functions of different main and auxiliary switches and valves, of the order of operations desirable in starting up a large generating unit and in shutting it down, of the proper sequence of moves in starting rotary converters and other apparatus, the routine of handling storage batteries—these and many other points carefully considered in a small instruction book would certainly save time in the breaking-in of new men, and in the maintenance of a higher mental efficiency on the part of more experienced employees. Amended from time to time such a book would represent the kernel of the best operating knowledge in that particular installation. No instruction book can take the place of an alert and intelligent employee at the switch or throttle in times of crisis, but if stripped of the dead wood of long-winded descriptions of standard machinery and packed full from cover to cover of practical operating points it would be a most valuable aid to high efficiency of personal service in large and complicated installations.

The Cause of the Quebec Bridge Failure.

Up to the present time nothing has been discovered which in any way adds any essential information regarding the condition of the wrecked Quebec bridge to the statement published in the news section of this journal last week, nor has the inquiry by the coroner developed any facts not given then. It is not at all surprising that this is the case, for the nature of the accident was such that the wreckage cannot be expected to contribute any definite information save that the material and workmanship were of the highest character. Engineers who visited the wreck agree fully on this point. In view of the special care taken in testing, fabricating and inspecting the material any other conclusion is untenable, and those acquainted with this work are fully convinced that the examination of the twisted and distorted ruins will confirm this opinion. While it is desirable that a thorough detailed examination of the fallen portion of the structure should be made, it will be most improbable that the cause of the accident will be discovered there. It is also possible to discard the horrible suggestion that the accident was due to the malicious acts of persons with some fancied grievance against the builders, for it is inconceivable that the structure should have failed as it did if the accident were due to such a cause.

There is little reason to believe, however, that the cause of the accident will remain undiscovered, which would be an engineering calamity greater than the collapse itself, but there is ground to expect that some theories or methods of bridge engineers will be modified. Engineering is not an exact science, but a highly developed craft, so highly developed as to merit the dignity of a profession. It closely resembles medicine in this respect. Thousands of people died from what physicians termed diseases of the alimentary tract before the nature of appendicitis was determined, and knowledge of this disease is so recent that it lends particular emphasis to the point to be made. Nobody lost confidence in the medical profession when it became known that failure to discover earlier the nature of appendicitis had been responsible for great suffering and countless deaths. On the contrary, people rejoiced at the progress that medicine had made. Engineering is precisely like medicine, except that its weaknesses are blazoned abroad while its achievements are overlooked. It is universally known that a physician has to make assumptions in connection with his diagnosis; but it is not so well known that the engineer also has to make assumptions, and that about the only way he can know that these assumptions were wrong is through the results which his works produce. The accident at Quebec demonstrates that something was wrong, and while there is a possibility that this weakness will be found by a search through the ruins it is also possible that it will be discovered by a critical examination of the design. This statement is no reflection in any way upon the work done by the engineers connected with the Quebec bridge, for that structure was the result of the careful study of men widely recognized as careful, thorough and competent. It simply means that in making that design, like the design of every large bridge, many assumptions had to be made regarding the distribution of stresses, and it is possible that these assumptions did not recognize all the features of the details of the design that affected the stresses.

It is noteworthy that among the suggestions regarding the cause of the accident that have been made by structural specialists to The Engineering Record the unforeseen influence of secondary stresses is advanced more often than any other possibility. The letter on the subject printed elsewhere in this issue is an example of these opinions, and this particular letter, it might be added, was written only after a computation had been made and checked to confirm the views stated regarding secondary stresses. There is hardly a subject connected with the design of steel work which is the subject of more controversy than this. In fact the difference in the views held regarding it is well shown by the fact that the eminent specialist whose computations are stated in the letter should reach a result so different from that of the engineers who designed the Quebec bridge. For this reason it would be eminently proper for the American Society of Civil Engineers to follow the precedent it established in the case of the Johnstown dam failure and appoint a committee to investigate the cause of the Quebec bridge collapse. While the engineers who are officially connected with the investigation now in progress for the Dominion government will doubtless discover valuable facts, the kind of an investigation that is most needed is one that can be made only by a very carefully selected committee of the American Society of Civil Engineers acting solely in the interests of engineering. The expense of such an investigation will be considerable, but the Society could do no better work for its members and for the public which relies on its members' abilities than to conduct a thorough examination of this sort. In making this suggestion The Engineering Record repeats that until such a strictly professional investigation is made the cause of the disaster will not be definitely known, and it may not be then. It fully recognizes the importance of secondary stresses, but it wishes to have the most positive and complete data regarding them in this case before accepting them as the real cause of the disaster. As a rule, secondary stresses are much more dangerous in tension than in compression members, which seem to have been the first to give way in the Quebec bridge. The deflection of the lower chord section of the anchor arm near the main pier, which was noticed by an inspector some time before the accident, may have been due to a weakness of some sort rather than to secondary stresses, and it would not be surprising, when all the facts are known, to discover that the failure was due to a cause whose main element was not secondary stresses.

There is one element of the accident which leaves no ground for debate, however, and that is the importance of stopping work and ordering men off a structure as soon as any sign of buckling is seen in a compression member. It is customary for bridge erectors to look upon small deflections without much consideration as to what may be their cause. These deflections are seen so often and so very rarely cause any trouble in small structures that their significance is not appreciated in large bridges. The deflection observed in the lower chord of the anchor arm in the panel next the main pier was probably the result of the final weakening of the resistance of the structure to the forces that produced its collapse, and with this incident as a precedent it is to be hoped that hereafter any such signs will be considered a signal for an immediate investigation of the most thorough nature.

A Matter of Signals.

A curious controversy has recently been vexing the pages of a contemporary, "Science," regarding some questions of physiological optics involved in railway signaling. It had its origin in a so-called "popular" article in the "Century," and has now degenerated into that singularly fruitless academic hair-splitting to which the professional mind seems prone. The main issue has been quite lost in the shuffle and the disputants are too busy hurling citations at each other to hunt it up. Now "popular" scientific articles in the magazines are, as a rule, by no means badly done, although they can seldom withstand the ingenious analysis of the petty controversial mind. It is next door to impossible in matters of physical science to make a definite and unqualified statement in plain intellectual English which is not open to attack for some inconsequential sin of omission or commission. In the case in hand the original author laid down the proposition that on account of the inefficiency of the eye in judging colors in weak light it would be wise to substitute for colored signal lights a system which should show the condition of the track by the position of luminous lines. In other words, since color signals are for certain definite reasons liable to be confused, let us try position signals which are free from the faults under consideration. Whether as a matter of practical railroading the proposed system would prove advantageous one can hardly say offhand, and it is safe to assume that the railroads would not change generally to this or any other improved system save under dire compulsion, because changes cost money.

Unhappily the writer of the "Century" article expressed himself somewhat carelessly and left several possibilities of misinterpretation which a Western professor pounced upon like a hungry cat upon an incautious mouse, and immediately those who were watching the affair found themselves in trouble. Experiments in physiological optics are rather discordant and indefinite at best, and the subsequent controversy, although rich in something very like the "odium theologicum," has been poor in every day facts to which the engineer can pin his faith. Now the matter of dispute, in so far as it concerns signals, is in theory quite simple. The human eye sees color very badly when the source of light is weak, not at all if it be very weak. Whether the "dark-adapted" eye can distinguish color as well, or a hundred times as well, as the "light-adapted" eye cuts little figure when it is notorious that neither sees well enough to work successfully when the source of light is very dim.

If the eye be color blind in the usual form of red-blindness, wholly or partially, the regular red signal light will prove comparatively inefficient and even if one has normal color vision his judgment of a very faint signal light may be tragically wrong. The usual signal-red glass lets through not only red, but orange, yellow and even a little yellow-green, and seen at a distance or through mist the red, even to the normal eye, pales, through the low luminosity of the full red, until the apparent color may change considerably. Thus a red lighthouse flash sometimes loses its

characteristic color long before it ceases to be seen as a light. Any other strongly colored light, if likewise of impure color, is subject to analogous change as the luminosity decreases. That the failure of the color sense in very dim light has caused serious accidents can hardly be doubted. As regards position signals they can, if of adequate dimensions, be seen as long as the lights are visible as lights and long after all color values have disappeared.

The main contention for a position signal as against a color signal as giving better visibility is unquestionably sound. Whether a change in practice is feasible, and if so what should be the form of the position signals, are questions not so readily answered. As the speed of trains has increased there is increasing need of signals capable of being clearly distinguished for a very long distance. The practical trouble is that the necessary distance which is approximately the braking-distance of the train, is very much greater than the penetration of any signal light now in use. In a fog a few hundred feet distance will render the lights totally invisible, whether one or many, white or colored, while to be of much use a signal should be distinct up to at least a thousand yards. It is rather doubtful whether any visual signal can be made effective enough to meet this condition and the final result may well be an entirely different solution of the problem. Audible signals or electrical signals delivered directly in the cab, or even a positive automatic block system may be the final recourse. Any of these offers a far better chance of real safety than visual signaling. In earlier days, when train speeds were usually low and the trains themselves were light, the situation was simpler. Every train, like every electric car, must be considered as carrying before it a dangerous space equal to the braking distance, within which lies peril. For an electric street car this distance may be one or two hundred feet; for a fast and heavy train one or two thousand yards. If warning of danger is not conveyed from ahead of this space, an accident cannot be averted. Most of the recent appalling collisions are due to disregard of this exceedingly simple fact. There is no excuse for neglecting to provide signals of some kind capable of spanning the dangerous space. If lights and semaphores fail, then it is high time to try something else. The frightful casualty list on our American railroads bears witness of the need for immediate action.

Notes and Comments.

THE CITY OF NEW YORK like other bodies of a corporate nature has been suffering during the summer from a serious difficulty in obtaining ready cash. Some contractors have been forced to receive payment in bonds at par which were sold subsequently at a lower rate which made them an unsatisfactory form of payment and seriously reflected on the credit of the city. This condition has been heralded far and wide as indicating the immediate descent of hard times upon the entire country; consequently it is most encouraging to observe that a sale of bonds held this week in New York resulted in a subscription of five times the amount of the issue. The city offered $40,000,000 4½ per cent. gold bonds and for them over nine hundred bids were received, aggregating $207,159,420. Two of the bids were for the entire issue. All the bonds will be sold considerably above par, and the result of the sale, the largest of the kind ever held in the city, shows that the financial troubles of the summer just passed were due to temporary conditions that are now a thing of the past.

AN ENGINEERING FEAT deserving mention has been accomplished by the undergraduate engineers of the Colorado Agricultural College. This was running a line of levels to the top of Long's Peak, which for many years it was thought impossible to ascend. The upper part of the peak is an immense granite boulder, about half a mile long and 500 ft. high. On one face is a precipice of 2,600 ft. The ascent was finally made by starting on the northeast corner and passing completely around the peak, part of the way on a narrow shelf, and finally reaching the top in a crevice on the southeast corner. The students connected with a bench mark of the Union Pacific Ry. in Estes Park, and ran a duplicate level for a total distance of about 16 miles horizontal distance, and nearly 7,000 ft. vertical difference of level. Since then the U. S. Geological Survey has run a double line of levels, one via Longmont and one via Loveland, connecting with the work on the plains, and finally with the line of precision levels of the U. S. Coast Survey. The height of the peak as finally determined, is 14,255 ft. above sea level. The work of the Hayden survey has universally been recognized as being very good. This is shown by the fact that the elevation of the Peak as given by Hayden is 14,274 ft., a difference of only about 19 ft. in elevation. Long's Peak is probably the only peak besides Pike's Peak, where a line of spirit levels has been run to the top. There is no comparison in the difficulty of ascending and running levels over the two peaks.

THE EXCAVATION PROGRESS that is being made on the Panama Canal is decidedly encouraging to those who hope to see the work completed within the time anticipated by those responsible for the adoption of the high-level plan. During the last month the total amount of excavation was 1,274,000 cu. yd., the largest record yet made, and as this volume was excavated during one of the most rainy months of the year, it is safe to assume that a still larger amount will be taken out during most of the other months. Hence it seems fair to believe that the excavation will be carried through to completion in less than seven years from the present time, when all the steam shovels now under construction are delivered and the tracks for spoil are completed. The figures recently received from the isthmus show how completely misleading were the statements sent North by newspaper correspondents a few months ago regarding the demoralization of the working force on account of the administration's determination to place the control of the work in the hands of eminent members of the Corps of Engineers of the army. At the present time the only feature of the work which foreshadows any probability of trouble is the construction of the dam and lock at Gatun, and unless definite unfavorable information is received concerning the condition of the works in question the excellent showing made last month by Colonel Goethals and his staff warrants the public in anticipating that the time of doubt and uncertainty regarding this great undertaking is now past.

THE TWO-CENT FARE LEGISLATION of Pennsylvania received its first judicial setback recently in the Philadelphia Court of Common Pleas, which decided that the law was unconstitutional. Of course this decision was made in a minor court, and until it is settled by courts of final jurisdiction the matter will remain in dispute. Nevertheless it is interesting to see that the law has been rejected, not only as being a violation of the Pennsylvania Constitution, but also as violating the Federal Constitution, in that it is confiscatory in character. If this opinion is confirmed by the highest Pennsylvania court it is safe to say that those of other States will take a similar view of the matter when it is brought before them, except in a few cases where the State judiciary has long been decidedly averse to the fair treatment of capital invested in public service undertakings. It is also necessary to bear in mind that the sweeping general laws regarding rates which were put on the statute books in some States recently may produce a very nice legal situation that was not brought up in the Pennsylvania case. It may be found in a few States where the constitutionality of these laws will shortly be before the courts that some roads have actually benefited by the greater amount of traffic resulting from the lowering of the rates. On the contrary a minor road may show a loss. In view of such a situation, the futility of any general attempt to regulate rates by law will become evident. What has helped one company has injured another, and it is entirely possible that some of the minor companies may be forced into bankruptcy by legislation of this character. The problem is a complicated one, and as it vitally affects a large amount of engineering work held in abeyance until the troubles are settled, it behooves engineers to give it their most careful consideration.

THE FIRE HAZARD of lofty office buildings was the subject of dire prophecy by the president of the New York Board of Fire Underwriters at a recent meeting of the building code revision committee of the New York Board of Aldermen. According to this fire insurance specialist, with the present unlimited height of buildings in the financial center, where the streets are being converted into canyons by the walls of lofty structures, a great disaster exceeding any ever yet experienced is being courted. It was asserted that the San Francisco fire showed that so-called fireproof buildings cannot withstand the attacks of a great wave of flame. Fire underwriters were stated to anticipate that a fire starting in a group of lofty buildings would be beaten across the narrow streets from the windows on the top floors, and no system of sprinklers or fireproofing would avail in the least to prevent the spread of conflagration. Firemen down below in the narrow streets could accomplish nothing. With respect to this utterance, which is not at all unlike those previously made by fire-underwriters, it is necessary to point out in the first place that gentlemen engaged in the insurance business naturally take the gloomiest view of the probability of the spread of a fire. It is their duty as well as their business advantage to preach the utmost completeness in provision against the spread of a fire. In the second place, there seem to be ample reasons for the belief that the protection afforded by a well-built and properly equipped office building against the spread of fire is something generally unrecognized. For example a good many years ago in the City of New York, the Home Insurance Building unquestionably prevented the spread of a serious fire in the downtown business district. The character of the office buildings in respect to their resistance to the spread of a fire is really more under the control of the insurance interests themselves than under that of the city. The building laws formulated by a city must always, of necessity and equity, prescribe minimum requirements consistent with reasonable safety and sanitation. It is out of the question for the city to demand the character of construction which insurance people consider best suited to prevent the spread of such fires as those under consideration. The insurance interests themselves, however, can materially advance the cause they have at heart by an adjustment of their rates which will make it more desirable for building owners to erect structures of the highest resistance to fire.

THE SUBSTRUCTURE OF THE DEARBORN STREET BRIDGE, CHICAGO.

The Sanitary District of Chicago is increasing the width of the Chicago River and the South Branch of that river to 200 ft., and the depth of the main river and this branch to 20 ft. below Chicago datum, the latter being about 1.5 ft. below the mean stage of water in the river. This undertaking has already involved a large amount of difficult and expensive construction work, included in which is the replacement of the old centerpier highway drawbridges with bascule bridges. Eleven of these new bridges have been completed and are in service, and still more remain to be built. A minimum clear channel width of 142 ft. inside protection cribs for the piers is provided at the new bridges, while a bypass back of each pier increases the cross-section of the waterway at the crossings to nearly the same as that of the standard channel width and depth.

The bridge across the main river at Dearborn street, which will soon be opened for service, is one of five bridges which carry the great volume of traffic between the North side of the city and the central business district, and also the crosstown traffic between the North and South sides. This traffic has all been confined to four bridges for two years, since the old Dearborn street bridge was torn down, with the result that all of these bridges have been badly crowded during rush hours. The new bridge will, therefore, greatly relieve the present situation, and particularly so with regard to the provision of an additional outlet for street railways from the central business district. It is a double-leaf Scherzer rolling-lift bascule bridge, having a clear span of 164.5 ft. between the centers of the front bearings, and providing a 36-ft. roadway, with a 10-ft. walk on each side.

Each leaf of the bridge is carried by a heavy reinforced-concrete abutment, which forms the front wall of a large sub-structure containing a by-pass waterway, two pits for the counterweights and a pit for the floor of the leaf. The two sub-structures of the bridge are the same in general design. They are each 48.5x67 ft. in extreme dimensions in plan at the top and rise to a height of 29 ft. above their footings. The abutment carrying the front bearing of the leaf and the front end of the track girders for the counterweight is 8 ft. wide at the top and is battered 1 in. to the foot on both sides. Back of this abutment is a by-pass, 8 ft. wide at the bottom, which extends through the sub-structure, normal to the axis of the bridge. The counterweight and floor pits are separated from this by-pass by a heavy concrete wall, the counterweight pits having an irregular shape in transverse cross-section, corresponding with the shape of the counterweights. The sub-soil conditions at the site were such that it was necessary to build each sub-structure on twenty 6-ft. circular concrete columns carried down to rock, or to material affording a good foundation. Most of these columns extend from 95 to 105 ft. below the mean water level in the river, and are designed to carry practically the entire weight of the sub-structure and the load on the latter.

The river bottom at the site of both sub-structures is soft river silt to a depth of 7 to 14 ft., under which is a soft plastic blue clay that extends down 40 to 45 ft. below the mean water level in the river. This clay has about the same consistency as putty containing a surplus of oil and has very little capacity for carrying loads unless thoroughly confined. Below this plastic clay, are various strata of a stiffer clay, and of hard, brittle clay, until hardpan is found at about 65 ft. below Chicago city datum. From this hardpan down nearly to bed rock is a material generally termed miners' loam, which when dry is hard and brittle, but when wet has much the same nature as quicksand. The bed rock is about 95 ft. below the water level on the south side of the river, but drops away to a depth of 105 ft. below that level on the opposite side. Immediately overlying the rock, between the latter and the miners' loam, is a stratum of quicksand of varying thickness, which contains a large amount of water and is filled with gravel and boulders.

In addition to these peculiarly difficult soil conditions, two brick-lined tunnels for gas mains had been built under the site approximately parallel to the center line of the new bridge and at a depth of 31 to 43 ft. Both of these tunnels are on the same side of the center line of bridge. One of them is 6 ft. in diameter, and the other has an elliptical cross section, with axes of 5 and 7 ft., each tunnel carrying a 30-in. gas main. The location and profile of these two tunnels are shown in an accompanying illustration, from which their proximity to the concrete columns carrying the sub-structures may be seen. The pipes in these tunnels are important feeder mains that had to be kept in service at all times while the work was in progress.

Owing to these local conditions and limitations, the construction of both sub-structures was handled with considerable hazard. After the draw span of the old bridge on the site had been floated away on scows to another location, the center pier and the crib-work protection for this pier were removed and the channel dredged to about the established standard depth of 20 ft. The two rest piers of this span were also taken out, meanwhile, the intention being to build both sub-structures for the new bridge simultaneously. It was considered, however, that the proximity of the protection of the draw span of the Clark street bridge, a block downstream, would interfere with traffic in the river if cofferdams for both sub-structures were built at the same time. Accordingly, a cofferdam enclosing the site of the south sub-structure was built first and the latter completed; this cofferdam was then removed and the one for the substructure on the opposite side built.

Two Views of North Cofferdam Showing Head Hoists, Concrete Mixing Outfit and Other Construction Plant.

The details of one of the cofferdams, which were both generally the same, are shown in one of the accompanying illustrations, each cofferdam unwatering a space 53x64 ft. in plan. The treacherous soil conditions and the location of both sub-structures outside of the dock lines required all four sides of each site to be enclosed. Each of the three sides in the river had on the outside a row of heavy round timber piles, against which was a row of triple-lap Wakefield sheet piling made of 3-in. plank; and on the inside, a second row of heavy round piles, against which was driven a row of Friestedt interlocking channel-bar steel sheet piling. The space between the two rows of sheet piling on the ends of the cofferdam was 8 ft., while on the river side this space was increased to 13 ft. over the tunnels as shown in the plan. The space thus enclosed was filled with clay to make the cofferdam watertight. The round piles were in 30-ft. lengths, and were driven to a penetration of 10 ft., except over the tunnels where care was taken to avoid penetrating the latter. The wooden sheeting was in 30-ft. lengths and was driven to about the same penetration as the round piles. The steel sheeting had been used previously in four cofferdams, but was still in good condition. It was in 40-ft. lengths, which were driven to a penetration of 6 to 8 ft. more than that of the wooden sheeting, except over the

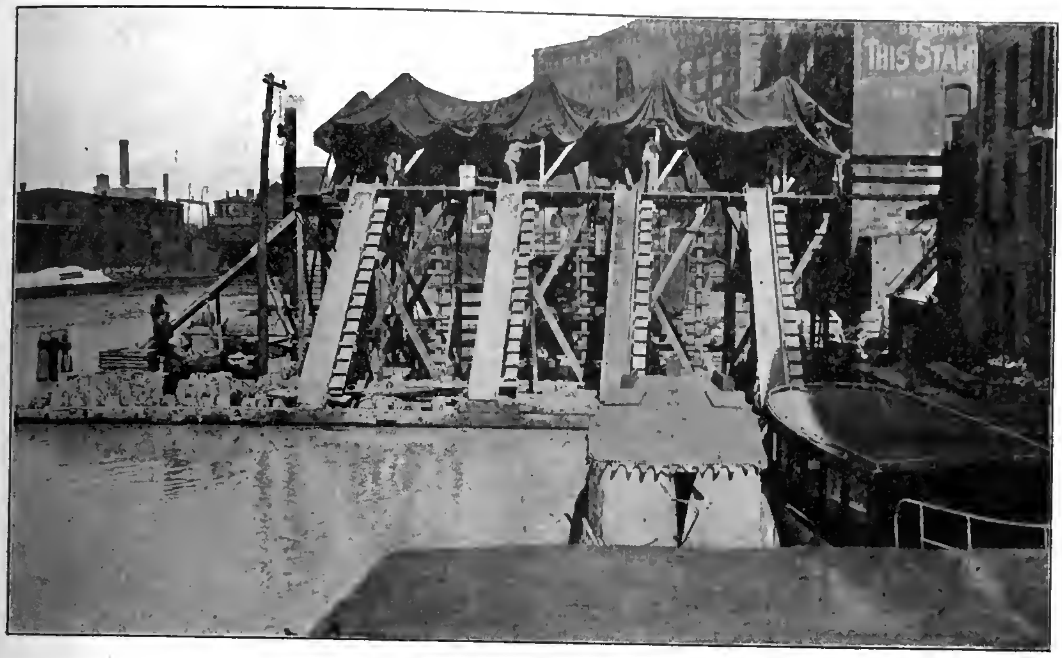
tunnels. The land side of the cofferdam consisted of a close row of heavy round piles, tied together with waling pieces so as to form a footing for the bracing used in the cofferdam.

In building each cofferdam the inner row of piles and steel sheet piling were driven around the three sides in the river with a floating pile driver. After the completion of this work the outer row of piles and sheeting were driven by the same driver and the enclosed space filled with clay by a dredge. The water in the cofferdam was then slowly pumped down, in order that the system of heavy cross-bracing might be placed. This bracing was in four horizontal planes, one just below the top of the piling, and the next three spaced 6, 4 and 3 ft. apart on centers, respectively, from the top down. The bracing consisted of 12x12-in. timbers, placed in regular transverse and longitudinal rows, the sets in the different horizontal planes being braced apart with vertical posts. In both cofferdams the river bottom was considerably higher at the back of the cofferdam than at the front, so in order to permit the bracing to be placed regularly, the excavation was started as soon as any of the bottom had been exposed by pumping. This excavation was made by shoveling the material into buckets and hoisting the buckets out with a turntable derrick crane mounted on one end of the cofferdam. When the cofferdams were pumped out the head of water against the face on the river side was from 20 to 22 ft. The cofferdams stood throughout the work without accident, however, although a portion of the river side of the north one directly over the tunnels was pushed in to some extent, but the steel sheeting prevented a failure at this point. A pulsometer pump was capable of keeping each cofferdam free from water, and during most of the time was not worked to its full capacity.

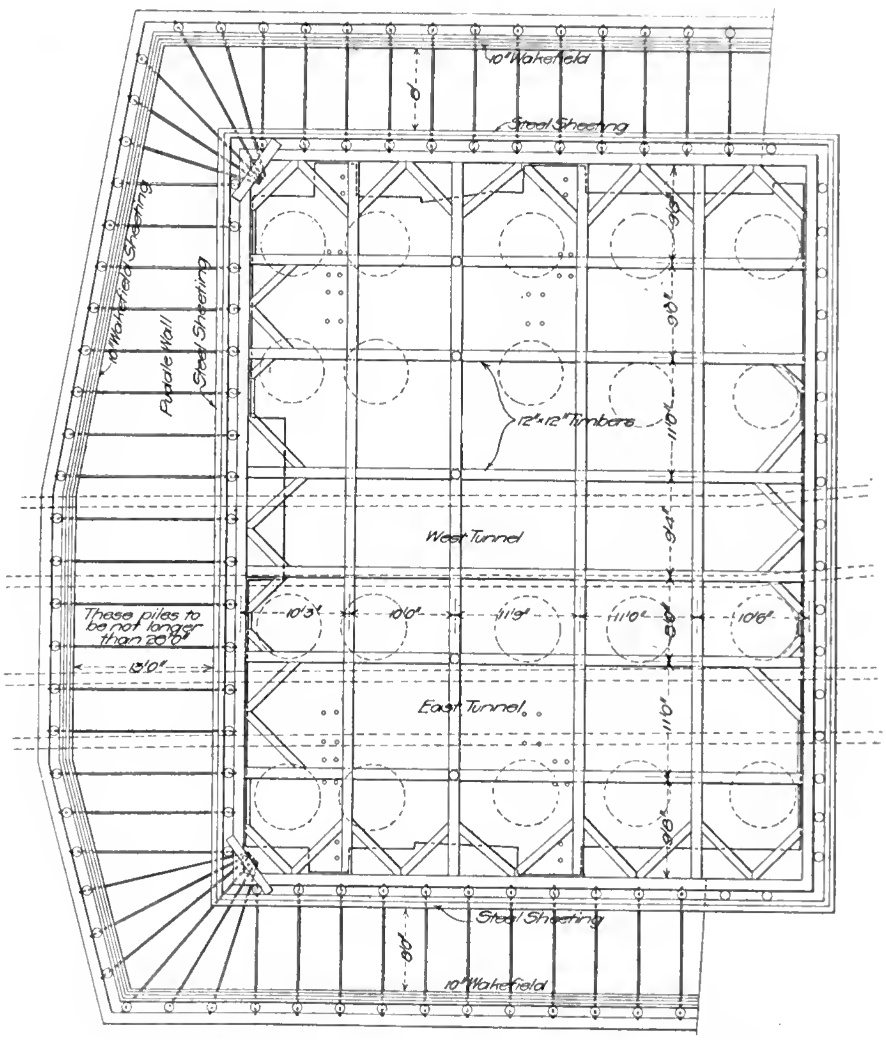
After the material in the bottom of the south cofferdam had been excavated down to a depth of 18 ft. below the water surface in the river, work was started on the excavations for the concrete columns. The latter are in four rows of five each, two rows toward each end of the sub-structure. Each column was built in a separate circular well, according to the same general method employed in building similar columns for footings for large buildings, as is regularly done in Chicago. Five of these wells were opened up at a time, the four inshore ones in the row at one end and the offshore well in the adjoining row being sunk first. The well in the outer corner of the cofferdam was thus left until these first five had been finished and the concrete columns built up in them; this well and the four in the second row were next opened and columns built in them. The same program was then carried out with the ten wells under the other end of the sub-structure.

In the greater part of the wells, 3x6-in. tongue and grooved plank were used for sheeting; 3 and 5-ft. lengths were employed, depending on the character of material, two steel lagging rings being placed to each set of planks. In driving through the sand boulders and water overlying the rock, it was found necessary to use steel cutting shields for a distance of 14 to 17 ft. These shields were each made up in four parts, the cutting section being 5 ft., and the remaining sections 3 ft. long. They were built of 5/8-in. plates, reinforced with two 2-in. angles. The sections were assembled in the well and the shields forced down to rock by means of jackscrews bearing on bulkhead timbers placed across the well. The excavation was all made by hand, the material being hoisted out in buckets.

Five separate, portable head-hoist platforms were built when the excavation of the wells was started, one for each of the wells that had been opened. These platforms were each 10x10 ft. in plan and were placed on a cross and sway-braced four-leg tower, 20 ft. high. A small tripod derrick was erected over each platform. These derricks carried a block at the top, through which a hoist line was passed to a hoisting spool at the base of the derrick. These spools were driven by an endless wire cable, which was driven in turn by a hoisting engine. The cable passed along the row of towers, and through the hoisting spools at each of the latter, the arrangement being such that buckets could be hoisted independently from any one or all of the wells. An opening large enough to pass a heavy bucket was left at the center of each platform, the tower for the latter being set on the top bracing of the cofferdam and directly over one of the wells in which the excavation was in progress. Two men were required on each platform to handle the hoisting line and to dump the buckets when the latter reached the surface. The materials brought up on each platform were dumped from the buckets on a flume leading down to the water just outside the cofferdam, these flumes being steep enough so the clay would slide on them. The materials from the wells were dumped into the river at the ends of the sub-structure in this manner and were later dredged out and hauled away in scows when the cofferdams were removed. After the five wells of the set had been finished, the head hoist plat-



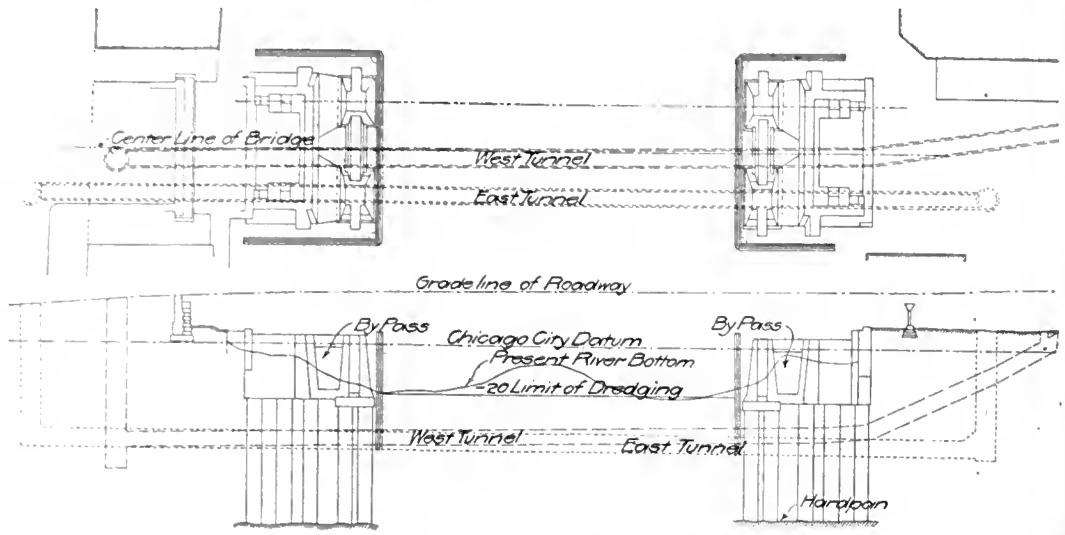
Head Hoists on South Cofferdam.



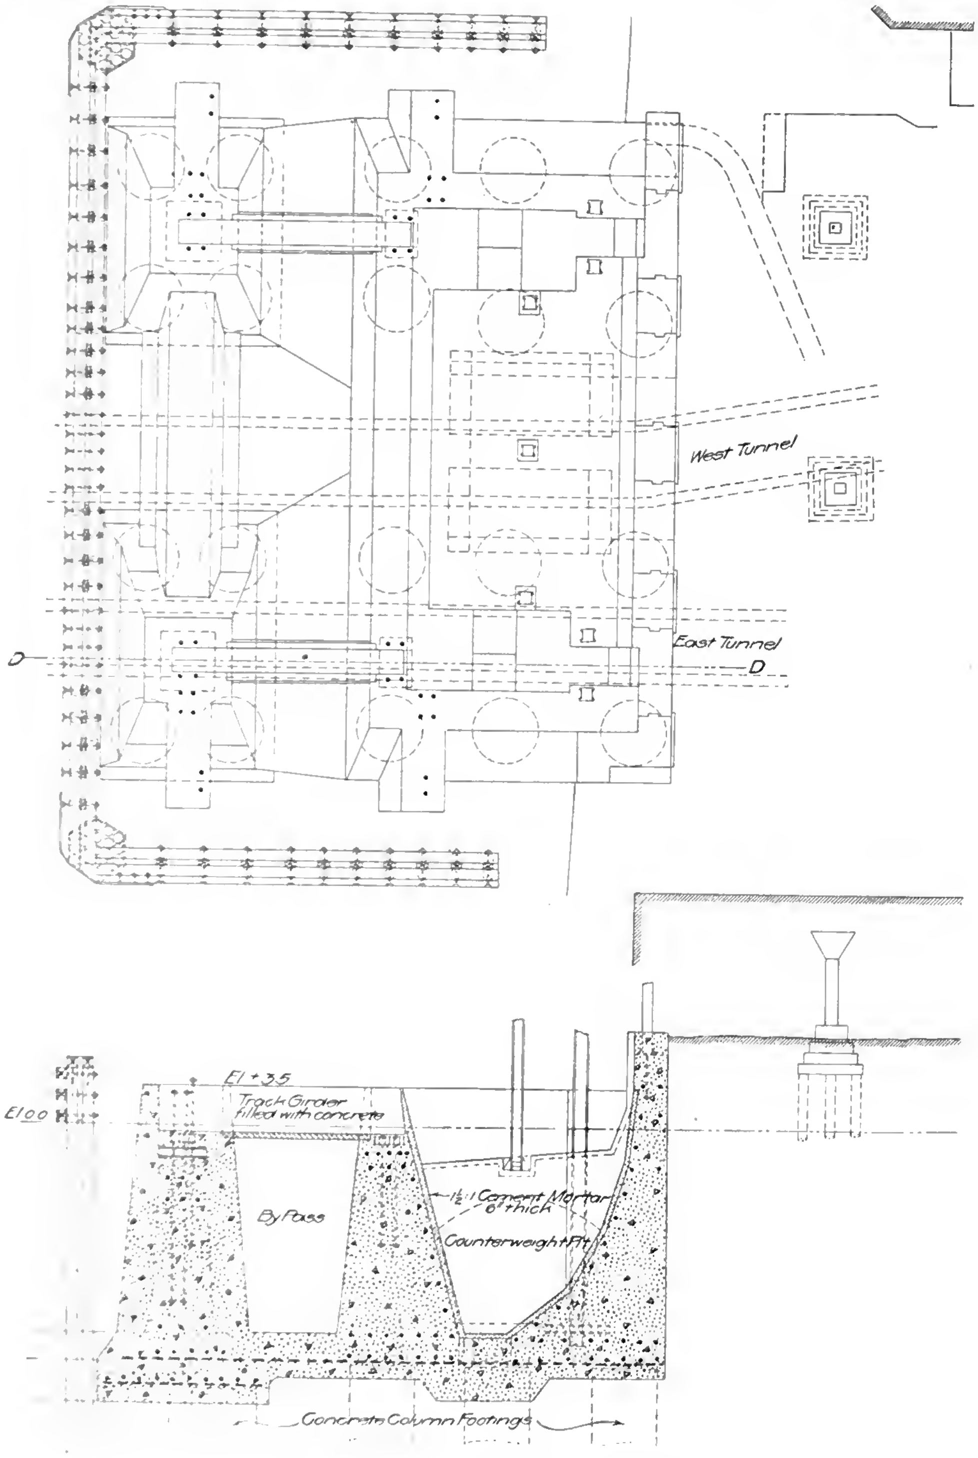
Details of Cofferdam for Dearborn Street Bridge.

forms were picked up by the turn-table derrick crane and moved to the next position, or were moved across the bracing on rollers.

The concrete for the wells and also for the sub-structure was made in the proportions of 1 of cement, 2½ of sand and 5 of broken stone. All of it was made in a pug-mill mixer set up on the fourwheel wide-gauge truck of a turntable derrick. Charging hoppers for the mixer were erected over the latter, a working platform being built around these hoppers. The mixer outfit was brought to the work on a scow and then run out on rails laid on the bracing of the cofferdam. Materials were supplied to it from scows by either of two turn-table derricks, both placed on the ends of the cofferdam. The concrete was delivered from the mixer directly into chutes and pipes leading to the bottom of the wells. As soon as one set of wells was completed the mixer outfit could readily be turned so as to deliver to the next set.



General Plan and Profile at Dearborn Street Bridge.



Plan and Cross-Sectional Elevation of North Substructure.

When the wells and sub-structure on the south side of the river had been finished, the whole construction plant was moved to the other side of the river, where the work was handled in practically the same way as on the south side, and in nearly the same sequence. The wells in the south cofferdam reached solid rock at a depth of from 90 to 95 ft., and, with the exception of considerable water in the quicksand directly over the rock, no particular difficulty was experienced in sinking them. In the wells of the north cofferdam, on the other hand, rock was not found until a depth of in the neighborhood of 105 ft. below the water in the river had been reached. Water was encountered in great quantities in the quicksand at this depth, but three wells were sunk to the rock and filled with concrete. As additional pumping from the wells might have caused damage to adjacent structures the decision was then made to increase the cross-section of the footings of the balance of the wells at a depth of about 64 ft., where hardpan had been found, and to form an elliptical 12x16-ft. base at this level for each column.

The two tunnels for gas pipes which pass under both sub-structures required very careful work in sinking the wells for the concrete columns. One of the tunnels is between two rows of columns under each sub-structure, and the two are so close together under the south sub-structure that there was barely room enough to sink wells between them. The work was completed, nevertheless, without materially injuring either tunnel, although one of them, which was lined with a single ring of brick laid in lime mortar, filled with water after the south cofferdam was flooded. The cofferdam was, therefore, pumped out again and the tunnels were filled with concrete from shaft to shaft.

The plans for the Dearborn street bridge were prepared by the engineering departmnt of the Sanitary District of Chicago, and the construction work was carried on under the supervision of that department. Mr. C. R. Dart is bridge engineer for the District. Mr. R. I. Randolph was resident engineer on the work. The old bridge was removed and the sub-structure of the new one was built by the Great Lakes Dredge & Dock Co.

Run of Mine Coal has been used successfully in the Chicago pumping stations, where formerly it was the practice to employ only lump coal which was supposed to have passed over 1¼-in. screens at the mines so that all pieces under that size were screened out before shipment. This made the coal more expensive, but theoretically it should evaporate more water per pound. By using run-of-mine instead of lump coal the average price was cut down from $2.55 in 1905 to $2.38 in 1906. In 1905 it required at all pumping stations 15.97 lb. of coal to pump 1,000,000 gal. to a height of 1 ft., while in 1906 it required but 15.026 lb. for the same duty, or 0.498 lb. less than in 1905. The total cost of pumping 1,000,000 gal. 1 ft. high in 1906 was 3.89 cents, while in 1905 it was 4.25 cents, showing a saving of 0.36 cent. Of this amount 0.25 cent was due to a saving in coal and 0.11 cent to saving in other causes. The Municipal Division of Tests and Inspection is making the tests.

Completion of the Cross River Dam, Croton Water-Works System.

The contract for the Cross River dam, near Katonah, N. Y., which is to impound about 9,000,000,000 gal. of water for the increased supply from the Croton valley for New York City was awarded, June 23, 1905, to MacArthur Brothers Co. and Winston & Co., for $1,246,211.60. The time limit of 26 months required the completion of the work on August 23, 1907. The time lost by the cessation of work due to an injunction served on the contractors soon after their organization was well completed, and in the reorganization and collection of a large number of employees in a difficult season of the year together caused a delay estimated to be equivalent to five or six months. Notwithstanding this gratuitous interruption, the work is now essentially completed except final touches and auxiliary construction like roads and bridges which do not at all interfere with the service of the dam or the impounding of water to supplement the city supply which was recognized as very inadequate in case of prolonged drouth.

It will be remembered that the need for the dam was so urgent that its construction was classed as emergency work, and the contract was awarded to a high bidder in consideration of experience and available plant assuring the most rapid and efficient progress. The result justifies the unusual action and should be a source of satisfaction to the city of New York, its engineers and the contractors.

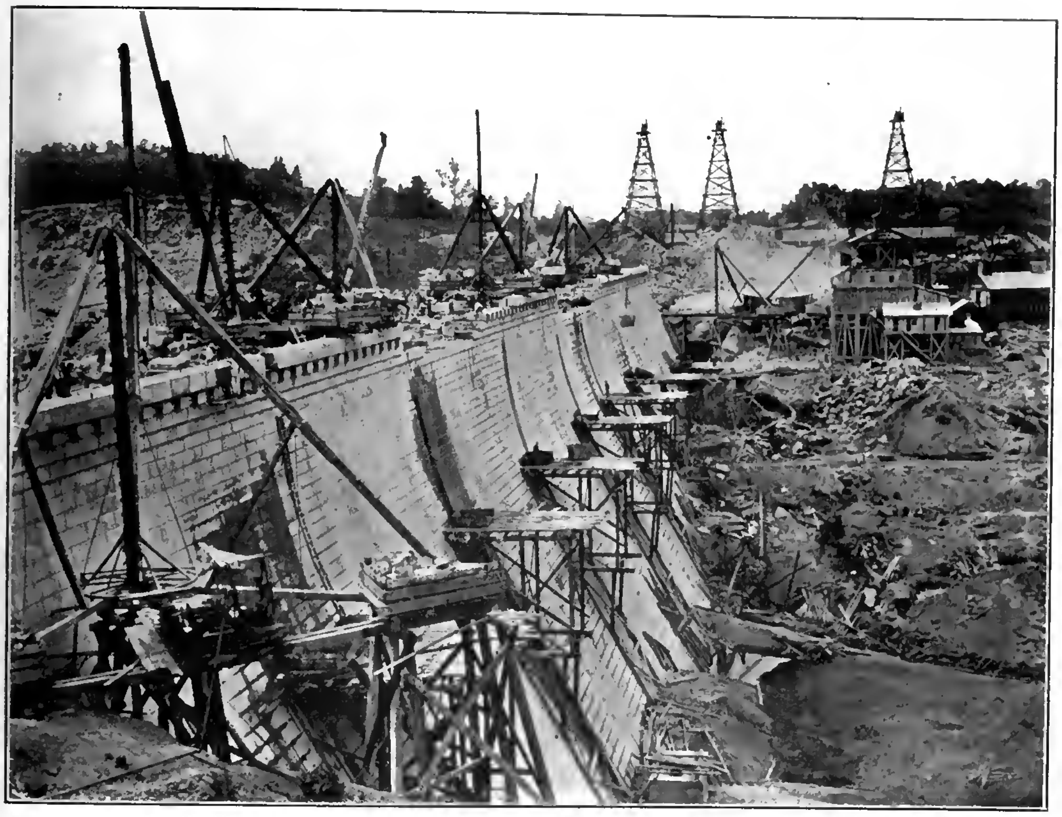
The design of the dam was specially adapted to expedite its construction by the use of moulded concrete blocks instead of cut stone in the face of the dam and the contractors' determination to make good their responsible undertaking installed a combined system of multiple cableways and derricks and provided an equipment far more extensive and expensive than is usually considered adequate for much larger works. With it they have been able to lay masonry at the rate of 18,500 cubic yards per month on a comparatively small area and have essentially completed the main dam, including excavation, diversion work and other preliminaries, in about 20 months working time, inclusive of about six weeks' delay through stress of weather.

The main part of the dam is about 900 ft. long and 170 ft. in extreme height, with a width of 23 ft. under the coping and 115 ft. at the widest part of the base. Its foundations are carried down to solid rock at a maximum depth of 40 ft. below the original low water level of the river. Both faces of the dam are battered except the upper part of the up-stream face which is vertical. It is built of cyclopean masonry faced with large moulded concrete blocks. The principal quantities involved are about 117,000 cu. yd. of excavation and 155,000 cu. yd. of masonry. The details of design, the plant installed and the methods adopted for the execution of the work have been described in The Engineering Record of May 20, 1905, June 16, 1906, and January 5, 1907.

Since these articles were published the design has been modified by the introduction of several horizontal tiers of continuous longitudinal tension bars in the upper part of the masonry to prevent cracking. For this purpose about 106,000 lb. of Thacher bars in 30-ft. lengths are placed in sets of two to six bars in horizontal planes 3 to 5 ft. apart vertically. The hooked ends of successive bars are engaged and special care is taken to bed them thoroughly in the concrete at all points. This requirement operates to limit the size of the cyclopean stone and has made the work somewhat slower.

It has also been decided to carry a 22-ft. roadway on top of the dam, and a 6-in. concrete pavement, crowned 3 in., is laid between the coping stones and is separated from the cyclopean masonry which supports it by a layer of tar paper. The pavement is pitched to five cast-iron catch basins in each gutter, which deliver through transverse 6-in. cast-iron pipes to a 12-in. cast-iron longitudinal pipe, pitched 1:100, which discharges into a cesspool beyond one end of the dam.

In order to handle supplies and machinery as rapidly as possible the contractors built a standard gauge track about 1½ miles long, with heavy cuts and fills and several trestles and bridges, to connect the dam site with the Harlem River Railroad at Katonah. The waters of the Cross River were diverted from the dam site by two earth and rock fill dams across its channels about 1,200 ft. apart. Between the dams the flow of the river was carried in a wooden flume and two 5-ft. riveted steel pipes about 90 ft. long, the latter being built permanently into the dam masonry. Excavation was made by pick and shovel and by blasting, and the spoil was handled successively by wheelbarrows, carts, bottom dump wagons, wooden skips and steel buckets, the latter being hoisted first by derricks and afterwards by cable ways.



Downstream Face of Dam, Showing Derricks, Cableways and Landing Platforms.

Quarries were opened in the hillsides at both ends of the dam, and the larger stones were used for the cyclopean masonry, while the remainder were crushed for concrete, thus utilizing a very large proportion, estimated at 95 per cent. of the total amount of stone quarried. A 700-ft. and an 800-ft. cableway, transverse to the axis of the dam with their towers on opposite sides of the center line were installed to handle the excavated material from the pit and for the back fill, and were moved parallel with themselves several times to command the differet parts of the excavation. Three 1,300-ft, 15 and 18-ton longitudinal cableways with traveling towers were installed on high level tracks on both sides of the valley at the ends of the dam and commanded its entire area. The cables have a clearance of 25 ft. above the finished crest of the dam and, together with nearly a score of derricks have handled all materials.

A power plant was located on the south side, and in it were installed steam boilers of about 1,000 h.-p. capacity, an electric plant and an air compressor plant of about 1,120 h.-p. capacity furnishing power for the operation of all of the machinery. Two stone crushers located on the bank above the south end of the dam receive stone from the quarries, and after it is crushed deliver it by a bucket elevator to a cylindrical screen, from which it passes to the storage bins and thence by a belt conveyor to the concrete mixing machine delivering through 2-yd. steel buckets pushed on narrow-gauge cars to the cableways which transfer it to the required points on the dam. The concrete machinery is contained in a wooden tower and is operated through clutches by an 18x22-in. engine driven with compressed air at 110 lb. pressure. An additional boiler plant was eventually installed to operate the crushers independently.

Water for the steam plant and for the dam was at first provided by two large pumps installed on the river bank below the dam which deliver to an elevated wooden tank. Later, in order to provide an additional water supply at the north end of the dam, a Worthington pump was installed on a raft in the river and delivers through a 2-in. pipe 800 ft. long to a 3,000-gal. wooden stave reservoir tank at elevation 380 which provides an independent supply with a good head for the work most remote from the original water station. A blacksmith shop, machine shop, carpenter shop and saw mill, all well equipped with machine tools, were also provided near the power house and served for maintenance, repairs, and the construction of much of the plant used by the contractors. Buildings were also erected for offices, store houses, commissary, lodging and a number of small cottages for foremen and mechanics.

An area of over 40,000 sq. ft. was levelled on the south hill at an elevation of about 50 ft. below the crest of the dam, and in it were installed forms for casting about 200 large face blocks at once which were constructed at a maximum rate of 65 per day by a 10-man gang, using a rolling overhead concrete platform. This yard was equipped with five boom derricks which handled materials, forms and blocks and piled the latter in storage often to a height of 5 or 6 tiers.

These derricks interlocked and loaded the blocks on cars delivering directly to one of the main cableways which usually transported them out on the dam during the night, leaving it available during the day for delivering stone to the crushers. Normally two of the cables were in constant use in the day time delivering concrete to different parts of the dam, where it and the cast blocks were handled by stiff leg derricks with 60 ft. booms arranged clear of the working face in two rows, one on the upstream and one on the downstream side.

These derricks were at first seated on the ground and afterwards as the work progressed and the elevation of the top of the masonry rose above their effective clearance they were successively lifted up and seated on towers against the faces of the dam. All movements of the derricks were generally made at night when they were handled rapidly and easily by the cableways which transferred them bodily to their successive positions with minimum trouble and often without any interruption of the work. This system promoted the utmost rapidity of construction and although it involved a large amount of plant, has been found very satisfactory.

In the later part of the work this arrangement was somewhat modified by transferring seven of the derricks to the top of the wall. With this arrangement, the six 9-man gangs of masons and the four 3-man gangs of block layers laid 980 cu. yd. in one 10-hr. day. In this masonry the proportion of rock to the entire volume of the masonry varied from 12 to 22 per cent. The output of the quarries was closely regulated by the amount of stone required for the dam and averaged about 2,500 cu. yd. per week. About 580 cu. yd. of concrete was a maximum output for one 10-hr. day.

In order to facilitate the handling of materials from the cableways to the derricks on top of the dam, six 20x30-ft. landing platforms were built at equidistant points on the down-stream face of the dam. The decks were made of 6-in. ties carried on wooden towers with their vertical posts braced on all sides and secured at the feet to inclined timbers resting against the curved face of the masonry and abutting at the bottom on a longitudinal timber sill laid on the surface of the ground. The platforms were at first built at elevation 272 and afterwards as the masonry progressed were raised to elevation 289, 42 ft. below the crest.

The large face blocks of a maximum weight of about 6 tons each were cast in knock-down forms arranged in rows in the casting yard, and after they were at least 2 days old were stripped and later turned over and finally stored in tiers until required in the dam. The concrete was shoveled into them from an overhead rolling platform and as none were cast in cold weather, their manufacture was very much delayed by the late season this spring, so that only about 1,000 cu. yd. were manufactured during the month of May. The weight and dimensions of the blocks are so great that when the work was commenced considerable difficulty was encountered by the springing of the moulds and consequent bulging and convexity of the blocks. This was finally remedied by taking great care to tamp and solidify the ground under the moulds and by reinforcing the moulds themselves.

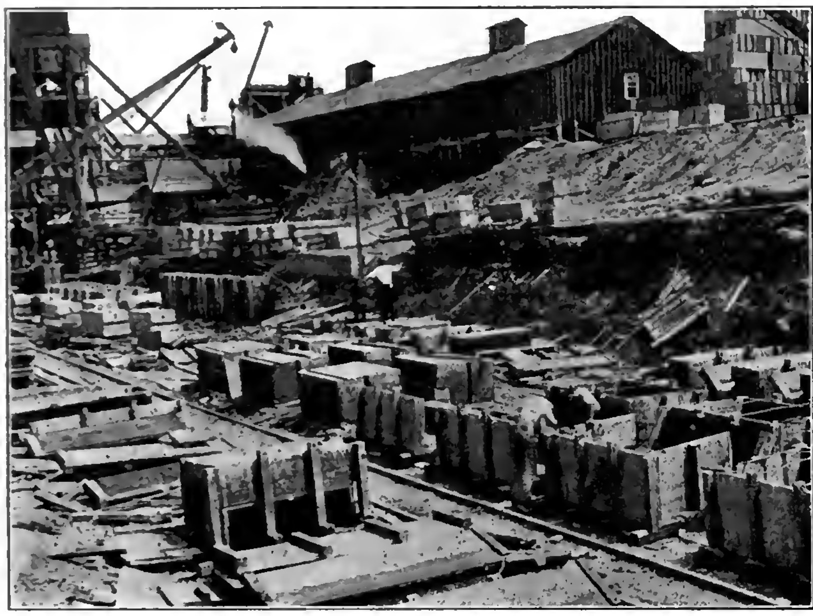
The best results were obtained by casting the blocks with the exposed face downward, and in some cases where two faces were exposed, one side of the mould was inclined slightly from the vertical to give a little pressure of wet concrete against that face. At first dog holes were cored in the blocks when they were cast, but as this was found unsatisfactory, the practice was later abandoned and the holes were cut by hand as soon as possible after the blocks were stripped. A maximum of about 7,000 cu. yd. of molded blocks were stored at once in the yard. The blocks and all other concrete were made with Giant cement and weighed 151 pounds per cubic foot.

All cement was sampled and sealed in bins at the mills and tested at the site. After its receipt at the dam it was held to await the results of 7-days' test before use and usually showed improvement.

The 32½x24½-ft. gate house on the up-stream face of the dam has monolithic concrete face walls cast in position with sliding shutters moved upward in the usual way as the work progressed and arranged to have their lower edges always overlap the finished concrete work and preserve the alignment of the upper part. The 3x6-ft. panels were made of 2-in. tongue and groove horizontal boards with vertical cleats 3 ft. apart and were held in place by ⅝-in bolts 18 in. long threaded at their inner ends to engage nuts and washers permanently bedded in the concrete 12 in. from the surface.

To facilitate the most expeditious construction of the masonry by avoiding the constant movement of derricks and the obstruction of the working surface of the dam, the original designs contemplated the support of a number of, derricks on permanent steel towers built into the concrete masonry. With this system it was intended to deliver stone and concrete by cars on a horizontal service platform alongside the dam. This involved the use of about 160 tons of steel in the towers at an estimated cost of $100 per ton, 1,600,000 ft. board measure of lumber at $40 per thousand and 5,000 lin. ft. of round piles. The use of this system was not obligatory on the contractor and the specifications gave him the option of executing the work in the manner outlined or of adopting any alternative plan which the engineers were convinced would give equal or more satisfactory results.

As the contractor was in a position to cover the work with an unusually large installaton of cableways he was allowed to substitute them for the derrick tower system, and it is considered that the results justified the substitution, and that this plan was the most desirable one both on account of the facilities it afforded for the very rapid movement of all other portions of the plant, such as derricks, platforms, etc., without dismantling them, and because, as the height of the structure increased and the width of the working surface diminished, the vertical movement of materials decreased correspondingly, thus facilitating the rapidity of operations. With the derrick system, on the contrary, the height to which materials were hoisted and the consequent time required to lay a given amount of masonry increased in direct proportion to the height of the structure.



Block Yard, Concrete Tower and Machine Shop.

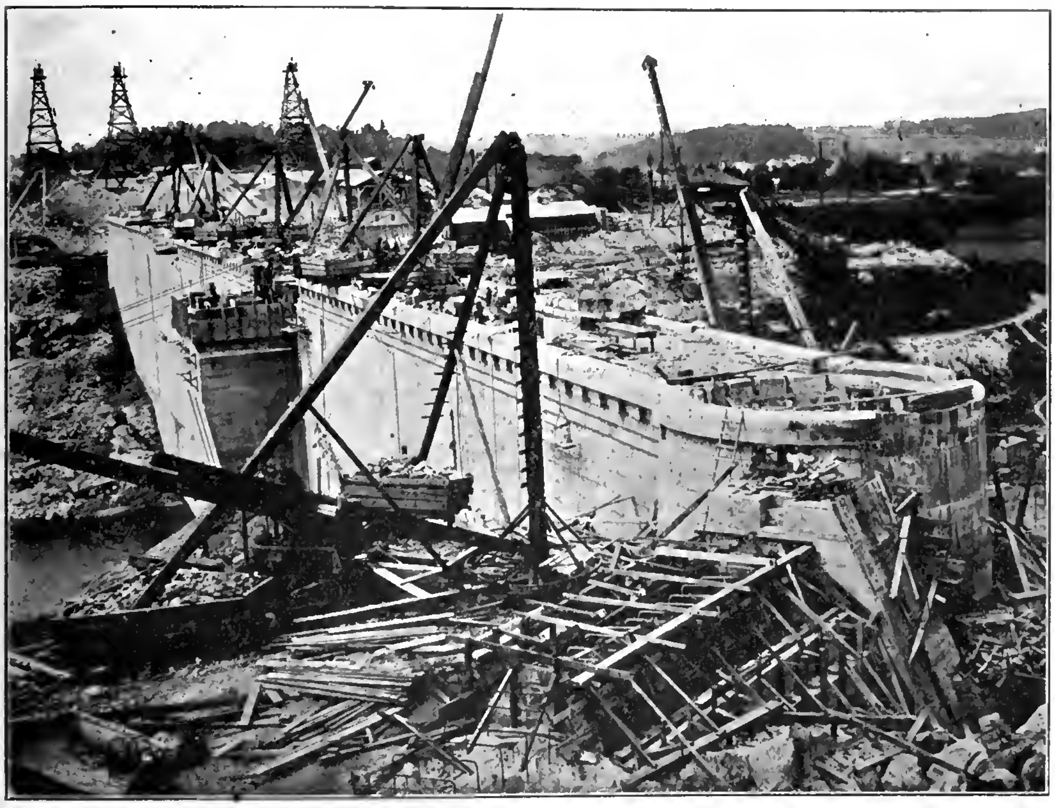
Roadway Foundation and Bars in Crest of Dam.

A cofferdam was built around the upper end of the two 5-ft. steel flume pipes, which carried the flow of the Cross River through the dam during construction, and on July 24th the flow was cut off and during the following night the water level in the reservoir rose 18 in., and the water commenced to flow through the permanent waste pipe at the rate of about 7,000,000 gal. daily, an amount corresponding approximately to the minimum dry weather flow of the river. The flume pipes were immediately closed with rubble masonry very carefully filled in by gangs commencing at the middle and working both ways to the end. The rubble was packed as close as possible, the ends of the pipe were securely closed by heavy dish plates and rubber gas tips bolted on and afterwards all interstices in the masonry were filled by grout forced in under pressure through a full-length perforated pipe.

Besides the construction of the dam the work in progress involves the building of about 1½ miles of macadamized road, 1½ miles of grading, and 5½ miles of gravel road 28 ft. wide. There will be required about 20,000 cu. yd. of open cut at Cross River and 25,000 yd. of cut and 18,000 yd.

of fill at the reservoir and two 40-ft. concrete arch spans across the river and the spillway, involving respectively about 250 and 400 cu. yd. of concrete. The work throughout has been handled as a unit, different portions of it being accelerated or retarded and groups of men shifted from one service to another to maintain a uniform progress and secure the most rapid total advance. A maximum force of about 650 men has been employed and the contractors established a camp large enough to accommodate 600 of them, besides 3-room cattages, boarding hall and dormitory for 60 foremen and mechanics. The camps were supplied with electric lights and water and were carefully cleaned and disinfected twice a week.

Very few fatalities have occurred on the work and there has been no serious accident or epidemic. A regular physician has been retained to care for all cases of sickness and injury without charge to the patient and is paid for out of a fund provided by an assessment of 60 cents per month each on every person employed on the work from the superintendent down. Beds were provided in the New York and White Plains Hospitals as required.



View Looking Downstream, Showing Gatehouse and Bastions.

Mr. W. H. Sears is the chief engineer, and Mr. G. G. Honness is the acting division engineer. Mr. James Winston, of the contracting firm, and Mr. M. J. Look, chief engineer, are in direct charge of the work.

AN UNUSUAL HOT BLAST HEATING SYSTEM has recently been installed in a hospital at Salinas, Cal., in which a furnace heater is used as the source of heat instead of steam coils. The hospital is a 37x90-ft. two-story brick building, and has accommodations for about 30 persons, for which a system with a capacity for delivering about 3,000 cu. ft. of air per min., or the equivalent of about 6,000 cu. ft. per capita per hour, was installed. As there is no steam plant installed, the fan, a 55-in. centrifugal blower, is driven by an electric motor and the air delivered is heated by a large Royal hot air furnace, located in an enlargement of the air casing. The hot blast is distributed by ducts in the basement ceiling with flues rising to each room.

British Power Plant Accidents in 1906.

The annual report for last year of Mr. Michael Longridge, chief engineer of the British Engine, Boiler & Electrical Insurance Co., of Manchester, England, gives interesting information concerning accidents to power plants. The only thing about most of these accidents that is not regrettable is the fact that the information they afford is turned to the use of builders and users of such equipment through these annual reports, which give warning of danger at the expense of somebody else.

The rate of breakdowns among insured steam engines was unusually high during 1906, amounting to 1 in 8.1 of the engines insured, although among oil and gas engines it was lower, 1 in 12.4. The reasons assigned for this difference are that gas engines have fewer parts than steam engines, these parts are generally much smaller than the parts of steam engines of the class insured, and gas engines cannot be habitually subjected to stresses much heavier than the parts were designed to bear. The percentages of the total number of failures of all kinds which were caused primarily by the giving way of various parts first were as follows: Valves and valve gear, 23.3; spur gearing, 12; air pump motions, 9.9; columns, entablatures, bedplates and pedestals, 8.6; air pump bucket and valves, 6.9; cylinders, valve chests and covers, 6.1; connecting rods, straps and bolts, 5.6; main shafts, 5.2, and other parts in smaller percentages. Twenty-eight per cent. of the breakdowns were due to accident or unascertained causes, 36 per cent. to old defects or deterioration by wear and tear, 22 per cent. to the negligence of owners or attendants, and 14 per cent. to weakness, bad design, workmanship or material. In the case of gas and oil engines, the failure is believed to have begun in the valves and valve gear in 28.7 per cent. of the cases; cylinders and cylinder ends 16.7 per cent., main shafts, 15.7; connecting rods and their bolts, 12; govenors and governor gear, 7.4; pistons, 6.5. The unusually high percentage of breakdowns in steam engines on account of wear and tear is attributed to the exceptional activity in the cotton trade, which encouraged spinners and manufacturers to increase their production and consequently their demands for power to the utmost. The increased strain upon the engines found out weak parts which, under rather easier conditions of working, might have remained serviceable. On the other hand the percentage of breakdowns ascribed to weakness, bad design, workmanship and materials was unusually low.

Some of the accidents are described at some length by Mr. Longridge. One of these, interesting as showing the value to power plant owners of the advice of the company's inspectors, occurred to an engine on which more than £300 insurance was refused. It was a horizontal tandem compound engine, with cylinders 19⅛ and 35 in. diameter, by 4 ft. 6 in. stroke, running at 68 revolutions per minute, with a boiler pressure of 120 lb. per square inch. The power, about 450 i. h. p., was transmitted by a rope drum, 24 ft. diameter, grooved for 24 ropes, 1½ in. diameter, and weighing about 21 tons. The peripheral speed at 68 revolutions per minute was, therefore, 5,060 ft. per minute. One morning, while the engineman was filling the crank pin lubricator, he became aware that the engine was gaining speed. As the stop valve was placed between the cylinders, and therefore in a direct line with the rope wheel, he ran to the boiler-house to close the junction valve, but before he could reach it the rope drum burst. All the segments and arms were torn off and broken, leaving the boss only upon the shaft. One of the pieces fell through the boiler-house roof and broke the steam main; other pieces smashed the air pump, condenser, and exhaust pipes, valve and governor gear, and destroyed the engine-house roof. Fortunately, the cylinders escaped. The mill was stopped one month. The accident would probably have been prevented, Mr. Longridge states, by the use of a "knock-off," the absence of which has been reported many times.

Another instructive accident happened to a pair of horizontal tandem tri-compound engines, with high-pressure cylinder, 22 in. diameter, intermediate 35 in. diameter, and two low-pressure, each 40 in. diameter, the high-pressure and one low-pressure piston being coupled to one crank, and the intermediate and the other low-pressure piston to the other crank. The stroke of the pistons was 6 ft., the speed 43 revolutions per minute, and the boiler pressure 160 lbs. per square inch. The power—about 960 i. h. p.—was transmitted by a spur flywheel and pinion, 18 ft. 9 in. and 6 ft. 5 in. diameter respectively. Soon after breakfast one morning a fire broke out in one of the spinning rooms which the engine drove. The operatives at once threw off the machinery and made for the exit, and the engine began to gain speed. The engineman ran to the "knock-off" gear, pulled the trip gear out of action, and began to close the stop valve. While thus engaged, he received an urgent order to start the fire pump, and left the engine-house with the engine slowing down and the stop valve nearly shut. As soon as he had gone, a mechanic rushed in, and, finding the engine still in motion, and no one present, threw the trip gear into action and opened the stop valve as quickly as he could, thinking, in his excitement, that he was closing it. The engines at once began to race, and before the valve could be shut down, had attained sufficient speed to break the cast-iron bell crank levers which drove one of the air pumps. Fortunately, no further damage was done. It is in emergencies like this, Mr. Longridge points out, that such an apparatus as an electric stop motion, which enables anyone to stop the engine by simply pressing a button in the engine-house or in any room in the mill, is useful.

On account of the few instances in which the complete history of broken shafts can be ascertained, the three following cases are important:

The first shaft accident happened to a McNaughted beam engine, with cylinders 20 and

20 in. diameter; strokes of pistons, 2 ft. and 4 ft.; revolutions, 50 per minute; boiler pressure, 75 lbs. per square inch. Power transmitted by spur wheel and pinion. Crank shaft, 23 years old, of wrought iron, with neck 6⅞ in. diameter and 9½ in. long. Bending stress, crank on centre, 7,075 lb. per square inch. Stress due to combination of bending and twisting, 7,920 lb. per square inch. Number of revolutions made by shaft, 193¼ millions. The shaft failed in the neck, the crack being partly longitudinal and then circumferential.

The second shaft accident happened to a horizontal tandem compound engine, with cylinders 17¼ in. and 30 in. diameter, by 3 ft. 6 in. stroke, running at 77 revolutions per minute, with a boiler pressure of 100 lb. per square inch. Power transmitted by spur wheel and pinion. Crank shaft, 19 years old, of wrought iron, with neck 10 in. diameter, by 16 in. long. Distance from centre of bearing to centre line of engine, 19⅜ in. Load on crank pin, about 30,000 lb. in recent years, probably somewhat less in early life. Bending stress with 30,000 lb. load, 6,280 lb. per square inch; combined bending and twisting, 7,400 lb. per square inch. Life of shaft, about 246 million revolutions. The fracture was diagonal for one-third of circumference of neck, and forked at each end.

The third shaft accident happened to a horizontal tandem compound engine, with cylinders 15 in. and 30⅛ in. diameter, by 5 ft. stroke, running at 41 revolutions per minute, with a boiler pressure of 110 lb. per square inch. The crank shaft was of wrought iron, with neck 9⅛ in. diameter, by 15⅛ in. long. The body of the shaft was 10 1-16 in. diameter, swelled to 11 in. to carry the spur flywheel by which the power was transmitted. The shaft broke at the end of the neck farthest from the crank at the junction of the neck to the body. The fracture was circumferential, and practically lay in a plane at right angles to the axis of the shaft, and had extended deeply into the neck all round before the final break. There was no fillet at the change of section where the crack occurred.

The engine was built in 1876 as a simple condensing engine, the low-pressure cylinder being the original cylinder, and worked as such with a boiler pressure of 50 lb. till 1890. The diameter of the cylinder was then reduced by the insertion of a liner to 26 in., and a new high-pressure cylinder placed behind it, converting it into a tandem compound engine. At the same time the boiler pressure was raised to 110 lb. per square inch. In July, 1905, more power was required, and to obtain this the liner was taken out of the condensing cylinder, which was bored out to 30¼ in.

When the alteration was proposed, the Insurance Company strongly advised the replacement of the shaft which had worked for nearly 30 years, but as there was no outward or visible sign of decrepitude the advice was not accepted, and the old shaft was retained. Fourteen weeks later it broke, as described above. The stresses which it sustained are given with fair accuracy as follows:

1876 to 1890; 95½ million revolutions; from bending moments, between 7,600 and 8,450 lb. per square inch; from bending and twisting moments, between 6,800 and 7,200 lb. per square inch.

1890 to 1905; 103½ million revolutions; from bending moments, about 6,800 lb. per square inch; from bending and twisting moments, about 8,700 lb. per square inch.

July, 1905, to October, 1906; about two million revolutions; from bending moments, about 8,150 lb. per square inch; from bending and twisting moments, about 11,000 lb. per square inch. The total number of revolutions was about 202 millions.

Another class of accidents is due to the defective manipulation on condenser plants. A case of this sort was an accident to an inverted vertical two-crank compound engine, with cylinders 12 and 19 in. diameter, by 9 in. stroke, coupled to a continuous current dynamo, giving 700 amperes at 220 volts. Speed, 435 revolutions per minute. Boiler pressure, 160 lb. per square inch. The engine was connected to an independent jet condenser, with an air pump driven by a small electric motor, receiving current from the bus bars on the main switchboard. The set was used for lighting the mill previous to the starting of the main engine at 6.30 a. m. After that hour, the current required both for the lighting and for driving some motors was supplied from a 250-kw. machine driven by the main engine. In transferring the lighting from the smaller to the larger dynamo, the custom was to bring up the voltage of the latter to 220 volts, to switch it on to the bus bars, so as to run in parallel with the pilot dynamo, and then to switch off the latter and stop the pilot engine. During this operation the speed of the main engine had to be regulated by the opening of the stop valve, as the governor would not keep it steady while the load was light.

Under these conditions it is evident that if the steam supplied to the main engine at the moment of switching in the larger dynamo were just sufficient to keep the voltage steady at 220 volts while the dynamo did no work, it would be insufficient to keep the engine up to speed and the voltage of the dynamo up to 220 volts when the load was transferred from the pilot set, or when any of the motors in the mill were started. The maintenance of the voltage would therefore depend upon the manipulation of the stop valve of the main engine by the engineer. If it were not promptly opened, the voltage would fall and the current taken by the motors would increase. On the other hand, if the stop valve of the main engine were opened too quickly or the steam shut off the pilot engine too soon, the pilot dynamo might run as a motor receiving current from the main switchboard. Indeed, the conditions were such as to demand considerable experience and watchfulness on the part of the operator to accomplish the change over without a hitch.

It is not surprising, therefore, that accidents occurred. The first was typical of many others, resulting from the improper manipulation of independent jet-condensing plants. It occurred at 6.30 a. m. one morning on stopping the pilot engine when the main engine had taken the lighting load, and was caused by the attendant switching the current off the air-pump motor, thus stopping the air pump before the pilot engine had come to rest, and before the vacuum in the cylinders was destroyed. The result was that the injection water, instead of being carried away by the air pump, filled up the condenser and exhaust pipe and overflowed into the cylinders, causing the breakage of both cylinder covers.

New covers were obtained during the day, and the engine was started again early the following morning, when another accident occurred, this time through some mistake or want of skill in changing the lighting load over from the pilot to the main dynamo. Exactly what happened could not be ascertained, but the effect of the mistake was that while making the change the voltage suddenly dropped and the current increased sufficiently to throw out the circuit breaker between the main dynamos and the bus bars, and cut off the current before the pilot engine had come to rest. This stopped the motor which drove the air pump for the condenser connected to the pilot engine, and the water again got into the cylinders. The damage on this occasion was not limited to two broken covers. Both cylinders were broken, also the high-pressure piston rod, piston-rod crosshead and guide, and the connecting rod was bent.

Many independent jet-condensing plants are dangerous unless the following rules are observed: 1, Shut the injection cock before stopping the engine. 2, Stop the engine before stopping the air pump. A vacuum breaker arranged to come into action automatically when the water rises above a certain level in the condenser is also a safeguard, so long as it remains in working order, but its adoption should be no excuse for breaking the rules given above.

An accident to an air pump that deserves mention happened to the equipment of a pair of horizontal cross-compound engines, 21 years old, with cylinders 38 and 66 in. diameter by 6 ft. stroke, running at 52 revolutions per minute, with a boiler pressure of 100 lb. per square inch. The power was transmitted by a drum grooved for 40 ropes 1¾ in. diameter, carried on the crank shaft between the engines. The air-pumps, two in number, each 37 in. diameter by 20 in. stroke, were driven by a bell-crank lever from the tail rod of the low-pressure engine.

On looking round the engine one morning, the engineman noticed a vertical crack in one of the air-pump barrels. On closer examination he found several others, which were extending. He at once stopped the engine, and drew the air-pump bucket. He then found the rings very thin, one of them broken in pieces, and the part of the coil spring jammed between the bucket and the barrel. The bucket was said to have been examined six months before the breakdown, but it was quite clear from the worn condition of the rings that no proper examination had been made. The rings were said to be 21 years old. Fortunately the practice of fitting rings into the buckets of vertical pumps has been almost universally abandoned. Besides being a source of danger, they are quite useless, in Mr. Longridge's opinion.

The air pumps usually put in are so large that considerable water leakage may take place past the buckets without materially affecting the vacuum. Not long ago one of the Insurance Company's inspectors found an air-pump bucket, without packing rings, ¾ in. less in diameter than the barrel, yet the vacuum varied from 10 to 12 lb., according to the load on the engine.

Turning to gas-engine accidents it is interesting to observe that the breakages of crank shafts in 1906 were fewer than in 1905, although the number of engines insured was greater. The decrease is no doubt due to the larger diameters which many makers of gas engines have adopted during the last two or three years. Shafts which might have been strong enough five years ago are insufficient for the higher compressions and heavier flywheels now in use, while shafts which were too weak for the old conditions are still more inadequate to-day; calculations of the stresses upon the shafts of gas engines are so difficult and uncertain as to be practically impossible, and makers have to rely to a very large extent on experience, which can only be gained slowly and at considerable expense.

The general practice seems to be to make the shafts and particularly the crank pins, of small engines relatively stronger than those of large. Calling C the diameter of the cylinder, D and d the diameters of the crank pin and shaft journals respectively, l the distance between the bearings on each side of the crank, and r the length of the crank arm, all in inches, the following values of $C^2 (l + d) \div D^3$ and $C^2r \div d^3$ represent roughly the best modern practice. For engines with cylinders below about 12 in. diameter the value of $C^2 (l + d) \div D^3$ varies from 10 to 11, and rises to about 15 for engines with cylinders 20 in. diameter. For small engines, also, the value of $C^2r \div d^3$ is usually 10 to 11, but does not often rise much above 13 for large.

The shafts of some makers give larger constants, and are consequently weaker than those from which the figures given were derived, but in such cases the tendency is to increase diameters. Nevertheless, weak shafts are still being made, and in the keen competition for business the makers of these shafts gain an unfair advantage, for the buyer of a gas engine, particularly a small one, has seldom the fainest idea whether the shaft supplied to him is strong or weak. Mr. Longridge is inclined to think that $C^2 (l + d) \div D^3$ should have a value of about 12 for engines with two bearings and overhanging flywheels, and about 14 for engines with three bearings, and $C^2r \div d^3$ a value of about 10. In any case, large fillets at the junctions of the journals with the crank webs are most important.

Of the shafts that broke in 1906, 77 per cent. had two bearings, 23 per cent. had three or more bearings. Of the shafts with two bearings, 53 per cent. had one flywheel, 47 per cent. had two flywheels. Of the shafts with two flywheels, one broke in one of the crank arms, and one in the body close to the skew wheel for drivng the side shaft. The rest broke in one of the necks, usually the neck at the end which carried the driving pulley.

Of the shafts with one flywheel, two broke in the crank pin, the rest in the neck between the crank and the flywheel. The shafts with three bearings all broke in the neck between the crank and the flywheel.

The breakage of the shaft of the two-flywheel engine close to the skew wheel was unusual. The engine was six years old. It had a cylinder 6¼ in. diameter by 12 in. stroke, and ran at 160 revolutions per minute with town gas. The shaft was of steel 2¼ in. diameter, with two bearings, each 6 in. long. The skew wheel was fixed close to the end of the left-hand bearing, and just beyond it was one of the flywheels. The other flywheel and driving pulley were at the other end of the shaft. The left-hand end of the shaft, with its flywheel, dropped off and careered across the engine-room, and the skew gear was broken. The fracture occurred close to the edge of the skew wheel and between it and the flywheels. It was at right angles to the axis of the shaft, and partly old. Apparently it had started with a skin crack produced by a scriber or by pressure of the sharp edge of the skew wheel, and had then extended across the shaft.

Special attention is called in the report to the fact that the connecting rod bolts give way more often than might be expected; and that flywheels are found loose so often it is probable the keys are not deep enough or are not fitted with sufficient tightness against the driving surfaces of the keyways in contradistinction to the beds. It is also doubtful whether many of the flywheels fit their shafts well enough to be held securely with one sunk key.

One of the most interesting gas engine accidents recorded in the report related to a horizontal gas engine 10 years old, with cylinder 16 in. diameter by 20 in. stroke, running at 160 revolutions per minute with lighting gas from a town main. In November, 1905, the cylinder end fractured, and was replaced. In November, 1906, the new end cracked. The cause was overheating, due to the accumulation of deposit in the water jacket. The owners had been repeatedly advised to keep the water spaces clear, and professed that they were careful to do so. In fact, the Insurance Company's inspector was informed that the jackets had been cleaned five weeks before the crack was noticed, yet when the end was taken off and broken the whole of the heated surface was found coated, and the water spaces round the exhaust-valve chamber completely filled with lime. Pieces of deposit ⅞ in. thick were taken from them.

The case clearly proves the necessity for providing mud holes in the jackets of the cylinders of gas and oil engines, Mr. Longridge states. The company has urged this necessity for many years, but has been met by the argument that, as the water never attained, or ought never to attain, a temperature high enough to cause deposition of lime, mud holes were not required. There is no doubt, however, that hard waters do deposit lime and dirty waters mud, and that provision should be made for removing both. Happily the necessity is now being recognized, at least in the case of large engines. Small ones, however, are still turned out in great numbers without any convenient means of cleaning out the jackets of the cylinders.

In the case of electrical machinery, the breakdowns increased in a somewhat lower ratio during 1906, both in number and in cost, than the number of dynamos and motors insured. In the case of motor-starting switches, however, breakdowns have increased far more rapidly than the number of instruments insured and the cost of repairs in a still higher ratio. The number of breakdowns during 1906 among dynamos was 1 in 16, and among motors 1 in 8.2. Accidents due originally to faults in armatures and rotors made up 44 per cent. of all; commutators and brush gear, 28 per cent.; magnet coils and stators, 14 per cent.; the remaining accidents were too varied to be classified. Of all the breakdowns 22 per cent. were accidental, 11 per cent. were due to age and neglect; 23 per cent. were due to age and deterioration, 9 per cent. were due to bad workmanship and design, and 7 per cent. to overloading.

The inspection of steam boilers and other containers exposed to internal pressure is, in some respects, the most difficult branch of the company's business. While, by the passing of the Factory Act of 1901, Parliament practically, although not explicitly, entrusted the duty of inspection to the boiler insurance companies, it gave them no compulsory powers. It threw the duty of inspection on experienced and responsible bodies, and at the same time compelled those bodies to consult the convenience and necessities of the boiler owners. Most of the demands for increases of pressure by boiler owners and of requests for reduction of pressure on the part of the inspecting companies involve differences of opinion which can only be reconciled by tact and compromise; while the companies have to consider the conveniences and financial necessities of boiler owners on the one hand, they have also to remember that, in the event of anything going wrong, their decisions will be reviewed by a tribunal by training and habit little likely to give purely commercial considerations the importance they have in the eyes of the manufacturer or in the eyes of the insurance companies, which have a more intimate knowledge of his difficulties.

The statutory inspection of boilers under the Factory Act is limited to one thorough inspection every fourteen months. During 1906, 92 per cent. of the boilers coming within the scope of the Act were thoroughly inspected, and over 50,000 inspections were made which were not required by the Act. The serious defects reported during the year were 123 cases of corrosion and grooving, 37 cases of fractures, and five cases where the mountings were out of order or inoperative. Before the end of the year 87 per cent. had been attended to.

THE AVERAGE PERFORMANCE OF STEAM SHOVELS in the iron ore deposits in the Mesabe Range, Minnesota, is about 900 cu. yd. per day of 10 hr. Three shovels together have made a maximum record of 190,000 cu. yd. in a month, a rate per shovel of 1,218 cu. yd. in 10 hr.

The McNulty Building, New York.

The 10-story and basement reinforced concrete McNulty Building, which occupies a 50x95-ft. 9-in. site on the north side of 52d St., between 10th and 11th Aves., New York City, is one of the first small-column reinforced concrete buildings erected in the Borough of Manhattan. The columns, which are of the hooped variety, were designed in accordance with the formula, $P = 1{,}600r^2 + (160{,}000\ Ah \div p) \times r + 6{,}000\ As$, recently developed by the Bureau of Buildings of the Borough of Manhattan for hooped columns. In this formula P = the total working load, r = the radius of the helix, As = the total area of the vertical steel, Ah = the sectional area of the hooping wire, and p = the pitch of the helix. The columns, girders, floor-beams, floors, roof and stairs are of concrete and the walls are of brick and stone. On the sides and rear of the building the panels formed by the wall columns and girders are filled with 12 and 16-in. brick curtain walls above and below the sixth floor, respectively, the exposed outer surfaces of the girders and columns being flush with the surfaces of the curtain walls. The two lower stories of the facade are ornamented with cut limestone and the two top stories with cast cement stone as shown in the accompanying illustration. The intermediate stories of the facade are finished with two shades of red pressed brick and stone window sills.

In plan the various floors are alike, being divided into two longitudinal and four transverse bays by a single line of interior columns placed on the longitudinal center line of the building on about 22-ft. centers. Except in the top story these interior columns are cylindrical in form, and in the basement and in all other stories except the ninth and tenth, they are 27 in. in diameter. In the ninth story the diameter is reduced to 21 in., and in the top story the columns are 12 in. square. Below the fifth floor the reinforcement in each of these columns consist of 2-in. round vertical rods, ranging in number from seven in the fifth story to thirty in the basement, surrounded throughout each story by a 24-in. helix of ½-in. wire with a pitch of 1½ in. Between the sixth and tenth floors the vertical rods are omitted and the diameter of the helix is gradually decreased while the pitch is increased. In the tenth story, four ¾-in. rods, one in each corner of the 12-in. square columns are used.

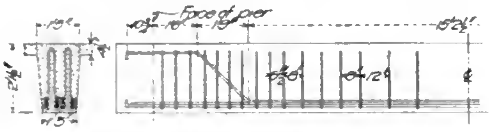
The side wall columns are in general 30x26 in., and carry loads ranging from 48,000 lbs. in the tenth story to 719,750 lbs. in the basement. Below the seventh floor the reinforcement in these columns consist of 2-in. round vertical rods, ranging from three in the sixth story to twenty-four in the basement, spirally wound with 5/16-in. steel wire forming a helix 23 in. in outside diameter with a 2½-in. pitch. Above the seventh floor the reinforcement is four ¾-in. round rods laced with ties of 5/16-in. wire on 18-in. centers. The columns, both wall and interior, rest on cast-iron shoes bedded on solid rock about 2½ ft. below the basement floor.

The main floor girders extend transversely across the building with a clear span of 21 ft. 8½ in. and are 21 in. deep, not including the 5-in. floor slabs. These girders are 15 in. thick at the bottom and 17 in. at the under surface of the floor slabs. Each is reinforced with twelve 1⅛-in. round rods and a large number of 5/16-in. wire stirrups arranged as shown in an accompanying sketch. The method of forming and placing the reinforcement in the columns and girders will be referred to later. The floor beams are placed in general 5 ft. 11½ in. on centers, the floor panels thus formed being about 5⅓x20½ ft. These beams are 15 in. deep, not including the 5-in. floor slabs, and 8 and 10 in. thick at the

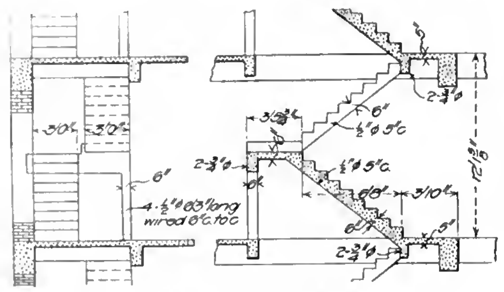
bottom and the under surface of the floor slab, respectively. Each is reinforced with two 1-in. round rods and two 1 1/16-in. round rods and with 5/16-in. stirrups disposed in the same general manner as those in the larger girders. The floor panels are reinforced with 5/16-in. round transverse rods on 5½-in. centers. These rods are cut 13½ ft. long and extend through two panels liberally lapping the succeeding rods at every other floor beam as shown in the floor plan. The side-wall girders have in general a clear span of 19 ft. 3¾ in. and are 2 ft. 2 in. deep including the floor slab and 12 in. and 16 in. wide above and below the sixth story, respectively. The reinforcement in the heavier of these girders consists of four ¾-in. round rods with 5/16-in. stirrups.

The brick work of the facade is anchored to the concrete by suitable anchor bolts and the weight over the windows is carried by cast-iron lintels.

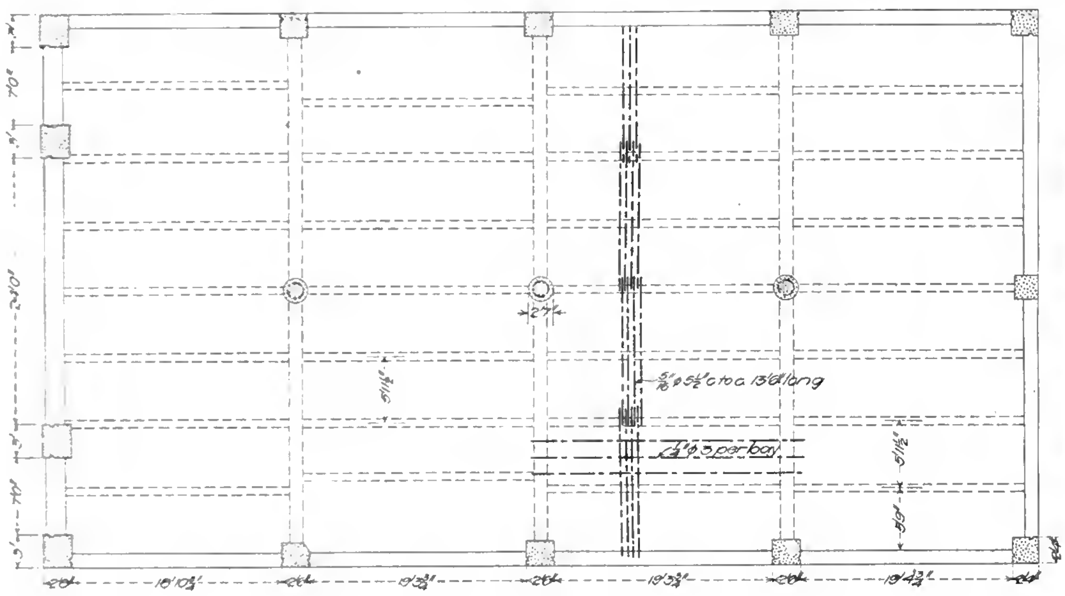
The stairs on both sides of the building are of reinforced concrete with Mason's safety treads.



Floor Girder.



Sections of Stairs.



Floor Plan of the McNulty Building.

The stair slabs have a minimum thickness of 6 in., and in general are reinforced with ½-in. round longitudinal rods on 5-in. centers. Sections of the west stairs on which the reinforcement is indicated are shown.

The reinforcement for all beams and girders was fabricated into units in the shops of the contractor and shipped to the work ready to be put in place, and the helices for the columns were wound and attached to some of the vertical rods at the shop to preserve the pitch. The vertical rods in each column project 6 in. above the surface of the floor slab above, where they enter 12-in. gas-pipe sleeves into which the ends of the vertical rods in the next column are placed. To insure proper spacing the rods placed on the work were slipped through a wooden disc template with holes bored near its circumference at points immediately above the gas-pipe sleeves on the floor below. The reinforcement for each beam and girder was built as a truss, the stirrups being hot shrunk on the longitudinal rods in their proper positions. In some of the heavier girders two such trusses were made for each girder and placed side by side in the form. Each girder and column unit was shipped to the work bearing a tag numbered to correspond with a number on the plan showing the proper position of the reinforcement. This method of preparing and placing steel reinforcement, which is known as the Unit System, it is said, not only assures the accurate placing of the steel but also effects an economy of labor.

The concrete is a 1:2:4 mixture of Giant Portland cement sand and ¾-in. trap rock. It was prepared in a Ransome mixer and was elevated with a Ransome self-dumping hoist, wheel-barrows being used to distribute it on each floor. The placing of concrete was begun about the middle of August, 1906, and the building was completed December 20.

The structural designs were prepared and the reinforced concrete work executed by Messrs. Tucker & Vinton, New York City; Mr. R. L. Bertin, chief engineer; Mr. P. H. Trout, superintendent of construction. The architectural plans were made by Mr. W. C. Lewis, of New York. Mr. Thomas D. Connors was the contractor for the brick work.

An Interesting Business Organization.

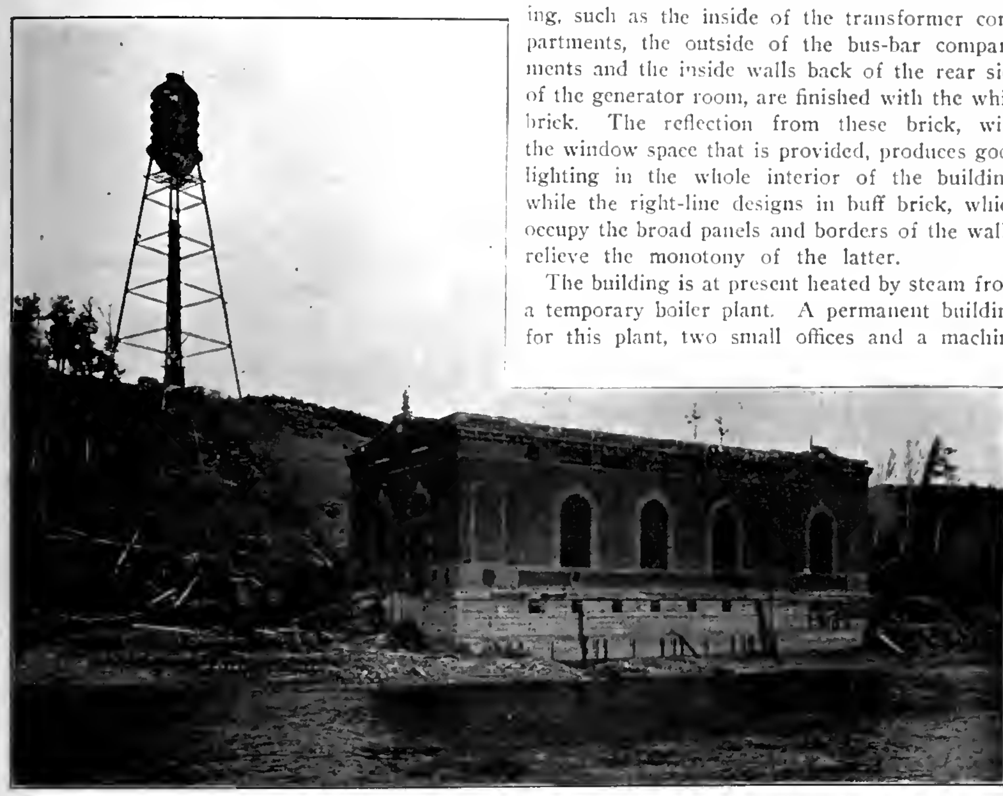
The business organization of the Stone & Webster Engineering Corporation of Boston is an interesting example of the perfection it is possible to attain in a large staff when care is taken to profit by past experience. When the firm of Stone & Webster began work on an extensive scale, construction was handled from its Boston office almost entirely. The more important details were designed there and the plans then turned over to a competent man who was sent to the site and allowed to finish up the work as he saw fit, funds being sent to him as he needed them. The work was done well under this method, but the headquarters office was generally in the dark concerning its progress and what it was costing. It was very soon discovered that there was a marked difference between a good constructor and a good engineer and that neither of them had any particular faculty of keeping the main office promptly posted concerning what they were doing. Even when reports were sent to headquarters, they were handled by different individuals and it was discovered that the data accumulated in this way were of little value for future work. About four years ago the Columbia Improvement Co. was organized to carry on the construction work the Stone & Webster Co. had in hand, but this plan, although a step in advance, proved to be not wholly satisfactory. Accordingly it was determined to combine the improvement company, the engineering department and the purchasing department, all of which are necessary factors in construction work, into a single organization, the Stone & Webster Engineering Corporation. The president of this company has three departments reporting to him, one under the vice-president and treasurer, the other under the engineering manager, and the third under the construction manager. The vice-president and treasurer looks out for the auditing, purchasing and office management at headquarters and the thirteen district offices. The engineering manager has charge of the engineering and architectural work and the drafting office. The construction manager has charge of thirteen district offices, and one of them, that in Texas, has three subsidiary offices. This organization keeps specially trained men in all the branches of engineering and construction work available for any of the Stone & Webster companies, and for general work.

The McNulty Building.

The Geological Conditions in the National Forests are to be investigated by the U. S. Geological Survey, the geologists being instructed to assist claimants to mineral lands in these reserves who are acting in good faith. The Government encourages mining in the forest reserves but many fraudulent entries have been found covering non-mineral lands and deposits which can never be profitably mined. The investigation will not only be of value to the Forest Service and to the miners, but will prevent such fraudulent practices.

The Hydro-Electric Development of the Great Northern Power Co.—Part II.

Station Building.—The building to house the ultimate installation of 80,000 h.-p. in generating equipment will be 77x313 ft. in plan, 90 ft. high, and of thoroughly fireproof construction throughout. A section of this building 181 ft. long has been completed, and is arranged to provide for the addition of the remainder. The design of the building is particularly well-chosen and was developed along pleasing artistic lines capable of practical application. The substructure of the building has a total height of 38 ft. and is of monolithic concrete built on a brown sandstone ledge which underlies the site. The superstructure has a steel frame enclosed in brick masonry trimmed with concrete blocks. The roof is carried by steel trusses which are a part of the building frame. The roof consists of book tile covered with four-ply roofing felt laid in asphalt and finished with tar and gravel.



Power Station during Construction, Showing Standpipe in the Rear.

The treatment of the exterior of the building is comparatively simple but produces a very satisfactory appearance. The outside walls of the substructure were molded to relieve the dead, flat surface of the concrete and the latter was carefully spaded in the forms to produce a homogeneous finish. The outside of the superstructure walls are finished with a mild red pressed brick. The concrete block trimmings, including the door and window lintels, the water tables, the stones of the corner columns and so forth, were cast in molds and were placed after they had hardened. The results secured by this combination of the brick and concrete blocks are all that could be desired.

The arrangement and finish of the interior of the building also evidence what can be done in proportioning and treating a structure of this type in order that the rough appearance so general in such structures may be relieved without diverging from practical limits. A basement, 18 ft. in height, extends under the entire building and forms the upper part of the monolithic substructure. The penstocks, water-wheels, auxiliary pumps and most other crude appearing equipment are in this basement. The latter is well lighted by windows on all four sides of the building, however, and its concrete walls were finished smooth as they were built. Above the basement, the building is divided into two equal parts by a longitudinal wall. A generator room, 38 ft. wide, occupies the river side; back of the wall and along the generator room are compartments for transformers, in the rear of which are compartments for the high-tension bus-bars, and the high-tension switching connections, and on a reinforced concrete floor over these various compartments are the main switches. The main floor of the building has a heavy reinforced concrete floor carried by the side walls of the substructure and by reinforced concrete columns. The inside walls of the generator room have a 7.5-ft. wainscoting of white enamel brick, above which they are finished with white and buff brick laid to right-line designs in the panels between the piers enclosing the columns of the steel frame and around the edges of the walls. Common building brick was obtained in both colors, so the designs were followed without added expense. All other interior surfaces of the building, such as the inside of the transformer compartments, the outside of the bus-bar compartments and the inside walls back of the rear side of the generator room, are finished with the white brick. The reflection from these brick, with the window space that is provided, produces good lighting in the whole interior of the building, while the right-line designs in buff brick, which occupy the broad panels and borders of the walls, relieve the monotony of the latter.

The building is at present heated by steam from a temporary boiler plant. A permanent building for this plant, two small offices and a machine shop, which would be distinct from the station building, has been contemplated, but it is now expected that space will be available for these purposes in the future extension of the main building.

The portion of the main building that is completed is designed to accommodate four 10,000 h.p. water-wheel-generator units, and exciters for eight units of that capacity. Three of these main units are being installed, and the fourth will be added as soon as it is required. These units are spaced 32 ft. apart on centers and are in a single row, with space for the exciters between the end of this row and the four additional units which are to be installed later in the future section of the building.

The initial hydraulic appartus consists of three turbine water-wheels, each having a maximum capacity of 13,000 h.p. under the available head of 378 ft. These wheels were built by the Allis-Chalmers Co., of Milwaukee, after general designs of the Escher-Wyss Co., of Switzerland. They are a modified form of the vertical-shaft Francis pressure type wheel, and are designed to operate at 375 r.p.m. Each of the wheels is connected by a penstock laid on the floor of the basement, with one of the 7-ft. pipe lines. The water is discharged from each wheel into a steel draft tube that passes through the basement floor and the front wall of the substructure to the river.

The penstocks are reduced in diameter gradually from 84 in. at their junction with the pipe lines to 66 in. just back of the wheels. At this 66-in. section a hydraulically-operated gate valve is placed in each penstock. These valves are set on edge on the concrete floor of the basement. They are believed to be the largest ever built for such high pressure, weighing 31 tons each and occupying a floor space 28 ft. in length. The water can be cut off from the wheels by these valves when repairs are required on the latter and also in case a leakage occurs through variable orifice gates in the wheels when the units are not in service.

Two 18-in. by-pass relief valves are placed on each penstock between the 66-in. gate valve and the water wheel which the penstock serves. These relief valves are built in a general way according to Escher-Wyss design. They are arranged so they can be operated automatically by a governor on the water wheel, or they can be set to open when the pressure in the penstock rises above a predetermined amount. It is intended at first to connect one valve on each unit so it will be operated by the governing mechanism of the water wheel and to set the other valve of each pair so it will open before the standpipe is overflowed. Each valve is fitted with a dash pot having a time-element release that closes the valve gradually and automatically after the pressure is relieved, in order to reduce the waste of water. As these relief valves are operated in multiple through the cross receiver at the standpipe, if one of them fails to work the remaining five will still be in service to meet the necessity for a relief of pressure. When the four additional main units are placed this multiple operation of the relief valves will be further improved.

The penstock of each water wheel terminates in a large tapering case, the cross-section of which is generally circular, the case being built on a spiral so as to surround the runner of the wheel. This case, generally termed the scroll case, is a steel casting made in two parts, having a combined weight of over 83,000 lb. Water is admitted to the runner from every point on the inner side of the scroll case, passing through an annular casting containing deflector blades and through movable guide vanes, or gates in a second case inside this annular casting. The scroll case, the annular casting and the guide case are all concentric with the shaft of the wheel. The movable gates, which are similar in general arrangement to register gates, resemble in shape to the head of an axe, thick at the middle, and each turn on a vertical pivot placed in the gate the same as the handle is placed in the axe. The gates are set in a circle concentric with the shaft of the runner, their arrangement being such that they overlap and can be turned to close the opening between them.

The amount of water supplied to the runner is controlled by the position of these gates, which position is determined in the following manner by a fly-ball governor driven by the water wheel: The pivots on which the gates are set extend to the top of the guide, or gate case, where they are each connected by a horizontal link with a bolt in a shifting ring, which fits around that case. This ring is arranged to revolve on an axis concentric with the shaft of the runner, but is required to move only a very slight amount in order to close or open the register gates. Two heavy links attached at diametrically opposite points on the shifting ring are each connected through a positive motion to the piston rod of one of two pairs of operating cylinders which are a part of the governing mechanism of the unit.

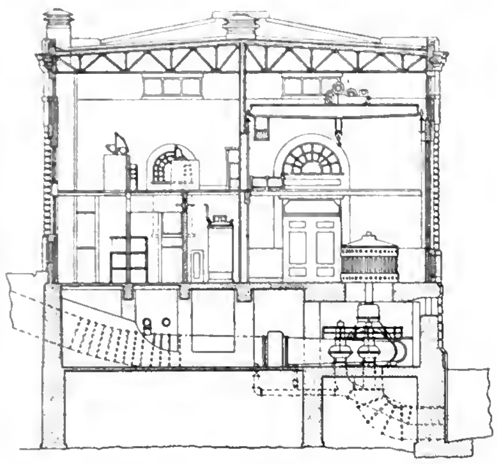
These two pairs of operating cylinders are placed horizontally, one pair on each side of a yoke over the wheel. The operation of each pair of cylinders is the same, the two cylinders of each pair being in tandem. Each cylinder contains a piston and the two pistons of the pair are connected to one piston rod. One cylinder of each pair is connected with the penstock, and the other with a high-pressure oiling system. The connection with the latter is through a pipe fitted with a variable orifice valve which is controlled by a fly-ball governor on the floor of the generator room, this governor being geared to the shaft of the runner of the water wheel. The pressure maintained on the oiling system being much higher than that in the penstocks, when the valve in the connection to that system is opened to admit oil to one cylinder of each pair, the pistons in the oil cylinders are pushed ahead against the lower pressure of the water on the pistons in the other two cylinders. The two pistons of each pair of cylinders are thus moved, the motion being transferred to the shifting ring by a link attached to the rod connecting the pistons, and through the links on that ring connecting with the pivot of the register gates the position of the latter is altered. A reverse motion is obtained by draining oil from the two oil cylinders, which reverse is also accomplished automatically by the governor. Each piston rod also carries a cross-head so it may be connected to one of the two relief valves of the unit by a long lever arm.

The runner of each water wheel is 62 in. in diameter and is mounted on the lower end of a vertical 15 in. shaft. The water passes horizontally into the wheel and then down through the draft tube. Such water as may splash over the top of the wheel will be drawn out of the case in which the latter is enclosed, by two 6-in. pipes leading down through the basement floor to a connection with the draft tube.

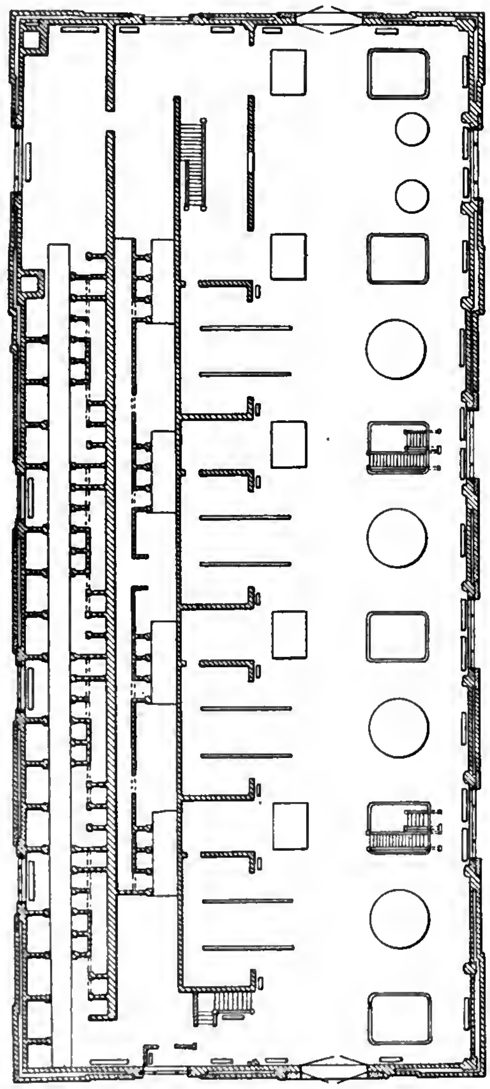
The generator of each unit is a 7,500-kw. 3-phase, 25-cycle, 6,600-volt vertical revolving-field machine built by the General Electric Co. The revolving field of each generator is mounted on an extension of the vertical shaft of the water wheel. The total weight of the revolving element of the unit is carried between the water wheel and the generator by a thrust bearing on the shaft. Two guide bearings are also provided to preserve the alignment of the revolving parts.

The thrust bearings each consist of a heavy ring attached to the shaft of the unit and resting on a second ring supported by a yoke on the wheel casing. The contact surfaces between these two rings are grooved and the weight of the revolving element of the unit is supported on oil forced between the two rings, which are enclosed in a tight case.

A complete system of pipes and pumps supply oil to the step bearings, each unit having an individual oil pump. These pumps are of the mesh-gear type and are specially designed for this service. They are two-stage machines, each stage being arranged to raise the pressure of the oil 200 lb. per square inch, so that the oil can be delivered at 400 lb. per square inch, if desired. Each stage consists of two closely-meshed gears operating to a snug fit in a tight gear case. The oil is squeezed through between the teeth of the gears as they mesh together with sufficient force to apply the pressure. The corresponding gears of each stage are on the same shaft, and the two shafts are geared to a third shaft. A Morris roller-bearing chain which passes over a sprocket on this main shaft and over a sprocket on a jack shaft geared to the vertical shaft of the main unit drives the pump. The latter takes suction from a central supply-tank under the basement floor and delivers into a small, closed, vertical receiver placed over it. One pipe leads from this receiver to the step bearing; a second pipe supplies oil to the cylinders of the operating mechanism which controls the position of the register gates of the water wheel. The drip from the bearing and the discharge from the cylinder are conveyed to a tank fitted with cooling coils through which water from the penstock is constantly circulated, the overflow from this tank being conveyed to the central supply tank by gravity.



Sectional Elevation of Power House.



Plan of Power House.

The oil supply system for each unit is also connected to a general system that is furnished with pressure by two pumps of the same size and type as those for the different units. These pumps are used while the units are being started and simply float on the oiling system as a relay. Each of them is operated by a bevel-gear drive from an impulse water wheel supplied with water through a connection with the penstocks. These reserve pumps draw from the central tank under the basement floor.

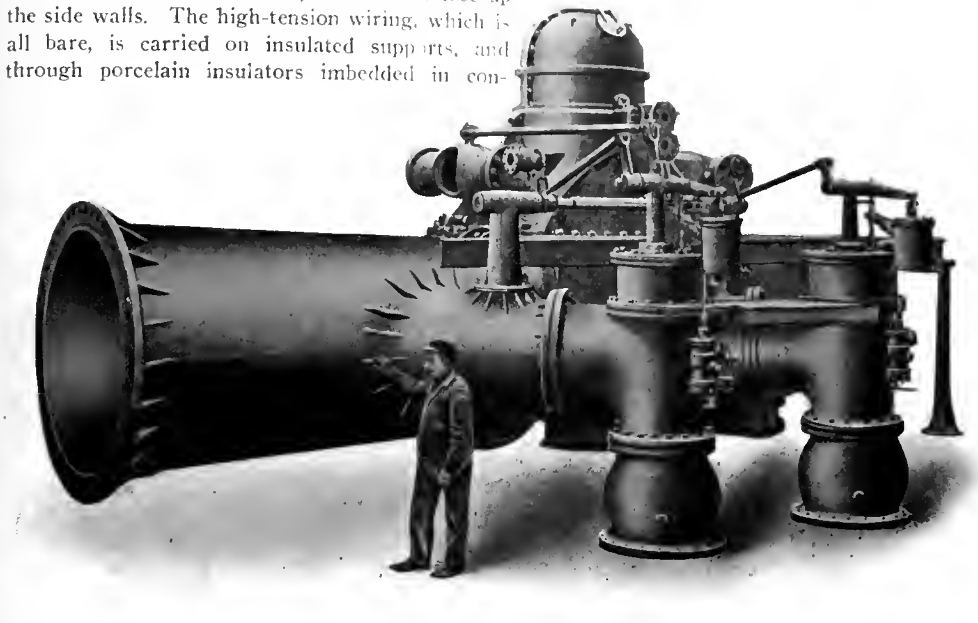
Exciters. Excitation current for the main generators is furnished by two 250-kw. 8-pole 125-volt direct-current generators each direct-connected to a vertical 500-h.p. impulse water wheel. Each of the generators has sufficient capacity to supply excitation current to all of the eight main units which the station will eventually contain. The water wheels are supplied with water from the penstocks, through a ring system of 16-in. pipes. Each leg of the ring is connected with each penstock and is fitted with valves arranged so either wheel can be supplied from any penstock. The amount of water furnished to either wheel is automatically regulated by a valve operated by a governor, but which can also be controlled by hand. The water is discharged from these wheels into the river through a pipe in the front wall of the building.

Transformers. Current from each main generator is delivered through auxiliary bus bars to a single 7,500-kw. three-phase transformer. The transformers are each placed in a separate fire-proof compartment immediately in the rear of the generator room and at the level of the floor of the latter. They are the largest transformers of this type ever built, and on account of their size permitted several special features of design. Each transformer is 14 ft. 10 in. high, 14 ft. long and 5 ft. 10 in. wide, its weight being 171,000 lb. The core and windings, which weigh about 65 tons, are hung from the cover by a framework and can be lifted bodily out of the containing steel tank. The transformer windings are arranged to step the generator voltage of 6,600 volts up to 30,000 or 60,000 volts for transmission, as may be desired.

Strictly speaking, the transformers are oil-insulated and water-cooled, although no water enters the containing case of the transformer, the oil being cooled outside the case in Worthington surface condensers of a special design. A motor-pump set, consisting of a motor direct-connected to a centrifugal pump on one side for handling oil, and to a second centrifugal pump on the other side for handling water, is installed in duplicate in the basement of the building. Two of the condensers are also installed, and are likewise in duplicate. The oil pump draws warm oil from any transformer into one of the surface condensers through a connection to a pipe header suspended from the ceiling of the basement, and then this same pump delivers the cooled oil to a compartment in the base of the transformer core, from which it rises through the latter and the windings. The overflow pipe from the transformer is equipped with a safety valve which closes if the level of the oil in the tank falls below the point essential for proper insulation. A 5,000-gal. tank placed in a small concrete building on the hillside above the station supplies fresh oil to the system. As this tank is always connected to the oil system a pressure greater than that reached by the water used in cooling is maintained; this arrangement precludes the liability of cooling water entering the oil system. The oil can be drained from any transformer to a 5,000-gal. cooling tank in the basement by gravity through either of two distinct outlet pipes. The latter are both fitted at the transformers with quick acting valves for use in an emergency.

Wiring Scheme. All connections between the bus bars and the various units are made through motor-operated oil switches on the main switching floor over the transformer compartments and the space occupied by the high-tension bus bars. These switches are all arranged for remote control from a benchboard on a gallery which projects out from the switching floor over the middle of the generator room, thus placing the operator in plain view of all the main units. The voltage at this board is the same as that of the exciters. The oil switches are each in a separate compart-

ment, which is built of brick laid in cement mortar and has concrete bottoms and tops. The motor which operates each switch is mounted on the top of the compartment for the latter. The front of each switch compartment is not built up, but is closed by loose asbestos-board doors hung over the openings. The bus bars are all in separate brick and concrete compartments, an opening being left at each support for the buses, in the sides of such of these compartments as are closed. All low-tension wiring is insulated and is laid in conduits in the floors, and carried free up the side walls. The high-tension wiring, which is all bare, is carried on insulated supports, and through porcelain insulators imbedded in con-



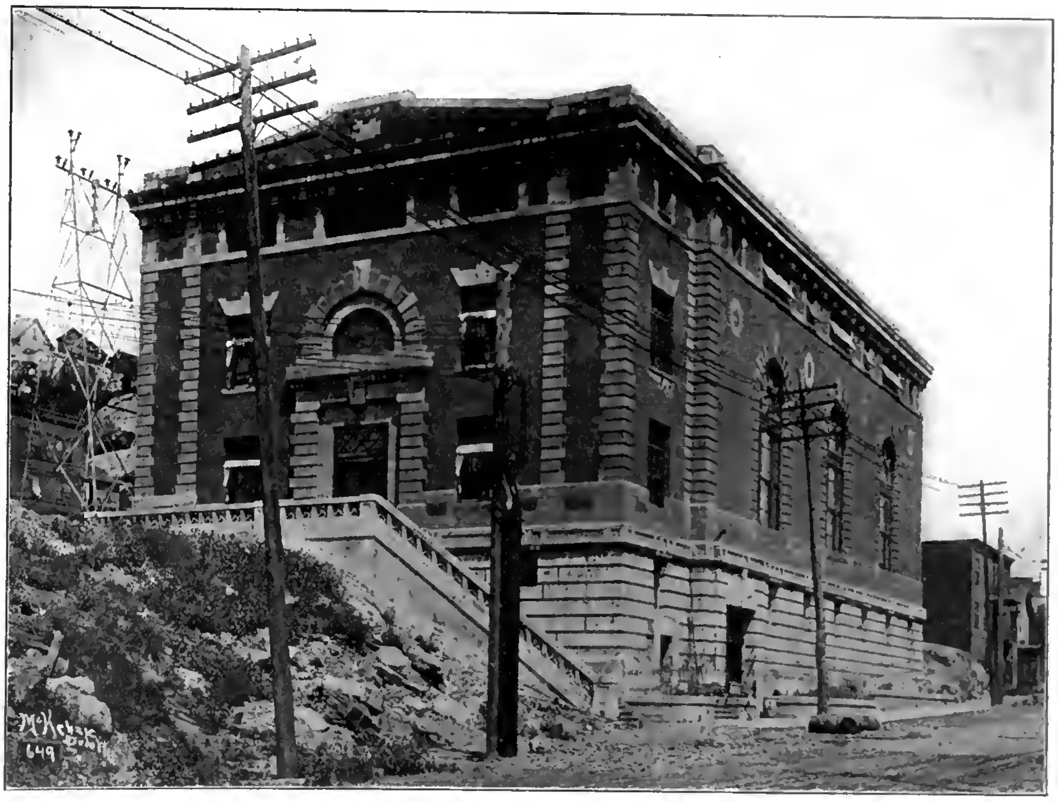
One of the Main Water Wheels Set up in the Shop.

crete blocks, where a connection passes through a wall. A disconnecting switch is placed on each side of every oil switch, in order that repairs may be made with perfect safety.

The three main leads from each generator pass through conduits buried in the floor of the generator room to the wall in the rear of the transformer compartments, and then up the rear side of that wall to the switch floor. Three sets of motor-operated oil switches are provided in a separate group on this floor for each generator. The current from the latter is passed through one set of these switches to a set of auxiliary bus bars in compartments built up in connection with the group of compartments containing the oil switches for that generator. From these auxiliary buses the current may be passed through one set of switches directly to the transformer immediately in the rear of the generator, or through a third set of switches to a set of main 6,600-volt bus bars, and from these buses connections may be made to any transformer through motor-operated oil switches. These main 6,600-volt bus bars and the switches which operate them are in a continuous row of compartments on the switch floor just back of the separate groups of compartments for the switches and auxiliary buses for each generator.

The leads from the high-tension side of each transformer are carried through separate compartments immediately under the concrete floor of the switch room to motor-operated oil switches on that floor; these switches are inserted in connections to auxiliary high-tension bus bars placed in separate compartments at the main floor level of the building. These auxiliary buses can be connected through a separate set of motor-operated oil switches to main buses, which are in separate compartments immediately in front of those for the auxiliary buses at the first floor level. Each set of these main buses can be connected to either of two transmission lines that go out of the plant. Each wire of these lines is in a separate vertical compartment built on the rear wall of the building and is provided with lightning arresters and a static discharger. In general the whole wiring system is thus arranged so current from any generator may be passed through any transformer and out through any transmission line, which arrangement is also contemplated to be extended in the future extension of the station.

The power for the auxiliary motors and for lighting in the building is obtained by stepping down a portion of the 6,600-volt current to 440 volts through three transformers in the basement. The switches in the connections to these transformers are also operated by motors controlled from the benchboard.



Duluth Sub-Station Showing Architectural Treatment.

The switchboard for controlling the ultimate installation of 80,000 h.p. is unusually compact, being not quite 19 ft. in length. The panel for the station lighting and power is placed at the middle of the board, and at each side of this panel are four panels for the eight main units that will be included in the completed station, with a panel at each end for the two exciter units. The panels are of blue Vermont marble, and are set in an ornamental iron frame designed to be in keeping with the remainder of the interior finish of the building. The small switches controlling the motor operated oil switches are on an inclined benchboard at the front, this board being surmounted by vertical panels for the indicating and recording instruments.

Crane. A 60-ton crane, equipped with alternating current motors, spans the generator room and travels the full length of the latter on runways carried by the building frame. The equipment on the floor of that room can thus be reached and hatchways in the floor of the room afford ample opportunity to place equipment in, or to remove it from the basement with the crane. The transformers are on trucks on a track so they can be rolled out under the crane, the front of the compartment for each transformer room being closed by removable doors. A railroad track is also extended into the building on the floor of the generator room.

Transmission Lines. Two three-phase transmission lines, carried on one set of four-legged steel towers, have been built to a sub-station in Duluth, 14 miles from the power station. The towers on which these lines are carried were placed at one side of a 100-ft. right of way, in order to provide space for a second set of towers at the opposite side. The towers are spaced 300 to 1,000 ft. apart, and were built in three heights, 40, 52 and 60 ft., depending on the topography of the country; specially heavy towers were also built at angles in the line. The four legs of each tower converge together at the top in pairs and are thoroughly cross and sway-braced. The two transmission lines are carried at each end of a cross arm at the top of the tower, the three wires of each line being placed at the corners of a 72-in. equilateral triangle.

At present a potential of 30,000 volts will be maintained on the transmission lines, which are No. 00 six-strand copper cables with hemp cores. These lines are designed for 60,000 volts, which will be used when longer transmission is required. A trussed steel pole is extended above the transmission lines on each tower and carries a steel cable of the same size as the copper cables of the transmission lines, as a conductor for lightning protection. This steel cable is grounded at each tower to increase the protection afforded.

A telephone line from the sub-station to the power station is also carried by the towers of the transmission line. The instruments on this telephone line are in booths set on insulators, these booths also being entered from an insulated platform, as protection from effects from the high-tension lines.

Market for Power. The market in short transmission distances from the sub-station in Duluth will consume all of the power that can be furnished by the generating equipment that has been installed. Arrangements have already been made to supply power to the companies which operate the local electric lighting and power stations in Duluth and Superior and for the street railway lines in both of these cities. Various large industrial plants and some of the extensive coal-handling docks along the water front of Duluth Harbor have also arranged to operate on power from the Duluth sub-station. A transmission line has been extended to the waterworks pumping station, from which the distributing system in Duluth is supplied, to operate a motor-driven pump in that station, the latter being a little over 11 miles from the sub-station. The demand for power by these assured consumers will certainly increase very rapidly, since the two cities are growing at a remarkable rate. Additional demands for power will also doubtless be made by other industries already established, and by those which have been contemplated since the inception of the project to develop the St. Louis River. The extensive operations in the Mesabe and Vermillion Iron Ranges, which are within 70 to 90 miles of Duluth, offer a market for power, however, aside from the demands which will doubtless develop in Duluth and Superior, that together with the existing market in those two cities, will, it is believed, eventually, consume more than can be developed on the St. Louis River even when the entire project of the Great Northern Power Co. has been put into execution. At any rate, that part of the development which has been started can scarcely be carried to completion fast enough to meet the power demands certainly in sight.

Sub-station. At present all distributing circuits will be taken from the sub-station in Duluth to which the transmission lines from the power station lead. This sub-station, which is 73x140 ft. in plan, is exactly similar in design and arrangement to the power station. The current from the two incoming transmission lines passes through a wiring system, which is the same as the one in the power station, allowing current from any incoming line to be passed through any transformer and supplied to any outgoing line. Three transformers of the same size and design as those in the power station have been installed. These transformers are arranged to step the incoming current from 30,000 or 60,000 volts down to 13,200 volts. All large consumers of power in Duluth and Superior will be supplied with 25-cycle three-phase current at this potential. The floor of the room in the sub-station corresponding to the generator room in the power station contains three 1,500-kw. motor-driven generator sets which furnish 600-volt direct current for street railway service in Duluth.

Six underground distributing circuits, aggregating about 12 miles of cable, and 16 miles of overhead circuits have been constructed. All important lines have double circuits each capable of carrying the total load supplied by the line. One of these underground circuits extends up the hillside back of the city and thence overhead for 11 miles to the waterworks pumping station. Two others extend about a mile east from the sub-station along the water-front to the power station of the local lighting company. A second two are carried about 1½ miles to a narrow channel across the bay between Duluth and Superior, and thence for 1,200 ft. under the bay in two No. 0000 rubber-insulated and armored submarine cables laid in a trench dredged 30 ft. below the low-water level. From the end of these submarine cables the underground circuits are continued about 1¼ miles to a static discharger, and are then continued overhead for about a mile to the power station of the local lighting and power company. Two motor-generator sets, one of 750-kw. and the other of 1,500-kw. capacity, which will supply direct current for operating the street railway system in Superior, are located in that power station. The latter will also be supplied with power from these circuits. A secondary sub-station will be erected later in Superior at the end of the underground circuits where the static discharger has already been installed.

The sixth underground circuit extends west from the sub-station along the water front for about two miles to a static discharger and then overhead two miles farther to two large industrial plants which are to be supplied.

Switchboard in Sub-Station.

The underground work for the two lines along the water front in each direction from the sub-station and for the line to Superior include eight tile ducts each, six of which are available for future use; manholes are placed about 400 ft. apart on these lines with stubs for connection to local consumers. Two three-conductor paper-insulated lead-covered cable, all No. 000, and each having a capacity of approximately 5,000 h.p. at 13,200 volts are laid in each of the circuits. These cables were made and installed by the Roebling Sons Co., of Trenton, N. J. The overhead construction consists of a pole line carrying two circuits and can be framed for four circuits. The poles are placed about 125 ft. apart and are 50 to 60 ft. in height carrying the lines above all those which are crossed; such local wire lines as are crossed are protected by guard wires.

Methods Used in Construction. The power company built a standard-gauge track 3½ miles long, from the end of a branch of the Northern Pacific R. R. to the power station, for use in delivering the materials required in construction at the power station and in that vicinity. The equipment for the station was also delivered over this railroad, which will be permanently maintained. The plant and materials required in building the service reservoir and the upper works of the development were brought in on the line of the Northern Pacific R. R., which crosses the channel. A spur track was extended from this railroad directly to the site of the main dam and greatly facilitated the delivery of materials for that dam and for several of the other adjacent smaller dams.

Although the project involved a large amount of construction work in the aggregate, the work was so evenly distributed that outside of the main dam and the power house no very great opportunity was presented to employ extensive construction plant. The main dam was built in a manner, however, that greatly facilitated its construction. The spur track from the railroad was carried up on a trestle that extended over the site of the retaining wall at one end of the dam and approximately at right angles to the spillway of the latter. A concrete mixing plant was erected at one side of this trestle, the sand and gravel used in the concrete being dumped from cars on the trestle into separate stock piles under the latter. A trench 6x6 ft. in cross section and about 200 ft. long, had been built under the site of the stock piles previous to the delivery of any materials, and was timbered over so as to form a tunnel under the piles. A belt conveyor placed in this tunnel was fed through chutes in the tunnel roof and delivered at the end to the boot of a bucket elevator. The supply chutes were placed at convenient intervals and were controlled by cut off gates. The bucket elevator was arranged to deliver to either of two storage bins erected over the 1 yd. Chicago cubical concrete mixer which was installed, one bin being provided for gravel and one for sand. Cement was stored in a shed close to the mixer plant and was raised to the charging platform of the latter by a bag elevator. A 1,000 ft. span Flory cableway, on 70-ft. towers was erected on the long axis of the spillway and spanned all of the straight part of the dam. The concrete mixer discharged into 1-yd. skips on

flat cars on a narrow-gauge track that extended from the mixer to the path of the cableway, these skips being picked up and carried to place by the latter.

The main dam, and in fact all concrete dams were built in alternate 30 ft. sections with a tongue-and-groove expansion joint extending entirely through the dam at the junction of each two sections. The retaining wall containing the three 7x9-ft. sluice gates and about half of the spillway section adjoining it were built first, a cofferdam being used in the river. The latter was later diverted through the sluice gates while the remainder of the dam was being built in a second cofferdam.

Concrete mixers were also used in building practically all of the other concrete structures included in the development, and, where feasible, plants for handling the materials were installed. Much of the concrete work on the dam and power house was laid in the winter when the temperatures frequently reached several degrees below zero Fahr., but all of it placed under such conditions is perfectly satisfactory, due chiefly to two reasons. First, the concrete materials and the water, were all heated by steam coils before being mixed, and after the concrete had been placed it was covered with canvas, under which fires were constantly maintained in salamanders until the concrete had received considerable set. Secondly, the weather remained uniformly cold until after the concrete was of considerable age, so no alternate freezing and thawing occurred.

In all, over 50,000 cu. yd. of concrete was used in the various structures connected with the development. The proportions of the concrete were varied continually to suit the materials, an endeavor being made to always secure about 10 per cent. surplus of mortar. Universal Portland cement, about 60,000 bbls. of which was required, beach sand and lake gravel were used exclusively for concrete, except at the lower head gates, where satisfactory gravel was obtained from the excavation. A laboratory was maintained on the work to test the cement daily and to determine the character of the sand and gravel, so the concrete mixture could be varied properly. In all of the cement used none was rejected. The sand was of excellent character, varying uniformly from quite fine to very coarse, and the gravel had the same quality, so the two formed an excellent combination, the voids in the latter frequently being only 20 per cent., or less.

The canal and forebay were built with four steam shovels and narrow-gauge dump cars handled by light locomotives, the total excavation in the canal being over 400,000 cu. yd., of which 100,000 cu. yd. were rock. Two stiff-leg derricks were also used in a part of the work where the material from the excavation was wasted.

View of the Transmission Line.

View of Main Dam under Construction.

The Concrete Mixing Plant at the Main Dam.

The project to develop the St. Louis River, according to the plans which have been followed, was conceived by Mr. F. A. Cokefair, chief engineer of the Great Northern Power Co., and it is largely due to his efforts that the project was carried out. Mr. C. C. Cokefair, president of the Great Northern Development Co., organized the Great Northern Power Co. and financed the project. Mr. C. A. Duncan is now president, and Mr. E. P. Coleman is general manager of the company. Capt. Alex. McDougall is a director of the company and has been actively interested in it since its inception. In addition to local capital that is interested in the company, Messrs. Chas. D. Barney & Co., of New York, and Tucker, Anthony & Co., of Boston, are managers, and the Knickerbocker Trust Co., of New York, is the trustee of the company. Mr. F. O. Blackwell, of Messrs. Viele, Cooper & Blackwell, consulting engineers, of New York, is consulting engineer for the company. During the design and construction Mr. E. C. Bacot was in charge of the electrical engineering department of the company and Mr. W. D. Rittenhouse, mechanical engineering department, under the supervision of Mr. F. A. Cokefair. The power station and sub-station were designed by Mr. A. H. Albertson, architect, of New York.

The contract for the construction of all such parts of the development that have been built was awarded to the National Railway Construction Co., of which Mr. Thos. Pettigrew is chief engineer. This company sub-let some parts of the construction work, but built the most important structures. The principal sub-contractors, in addition to those which have been mentioned, were Messrs. Truax & Thomas, who built two of the reservoir dams and the 3½-mile railroad, and Mr. J. W. Hilliard, who erected the sub-station. The electrical equipment for the entire project was furnished and installed by the General Electric Co. The hydraulic apparatus was built and erected by the Allis-Chalmers Co.

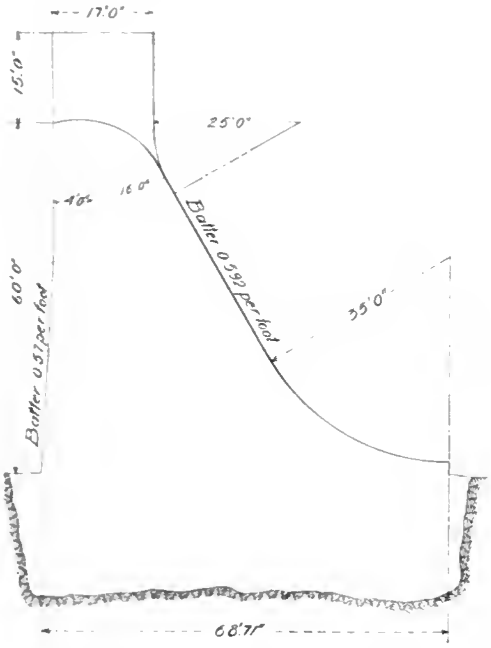
Lightning Protection for Chimneys.

Standards for lightning protection for power plant chimneys in the Navy Yards have been adopted by the U. S. Navy Department, the proposed means being varied for different heights of chimneys to cover those found in the different yards. It is specified that the conductors shall each be made up of seven No. 10 copper wires, two in number for chimneys up to 50 ft. in height, three for chimneys between 50 and 100 ft., and four in number for those higher than 100 ft., in all cases being symmetrically disposed around the stack and forming a cage enclosure. They are to be fastened firmly without insulators to the outside chimney surfaces by bronze anchors, the latter being spaced 10 ft. apart and soldered to the conductors at 50-ft. intervals. At the bottom of the stack the conductors connect with 3 ft. x 3 ft. x ⅛-in. copper earth plates buried in the ground below the water line, and at the top to a 1½ x 1½-in. copper ring, to which the discharge tip rods are attached. The latter are of ¾-in. solid copper, 10 ft. in length, spaced 4 ft. apart around the circumference of the chimney cap, each terminating in a two-pointed aigrette. The portions of the conductors near the chimney base are to be protected by a 1½-in. galvanized-iron pipe sheathing, rising 10 ft. above the ground level and extending 3 ft. below it.

The New Water and Sewerage Systems of Manila.

Early in 1906 the municipal board of Manila, P. I., let contracts for a sanitary sewerage system, and a large addition to the water supply of the city. The work is now well under way and it is expected that the water supply system will be completed about the middle of next year, and the sewerage system about a year later. The new water supply is to be taken from the Mariquina River, about 10 miles northeast of Manila, and will be brought to the city partly through a riveted steel pipe line and partly through a free flowing conduit. The work necessitates the construction of a dam at a gorge in the river, creating a reservoir with a capacity of about 2,000,000,000 gal., and the construction of a distributing reservoir about a mile from the present one. The sanitary sewerage system is to be extended to all parts of the city, and on account of the low elevation will consist of a combination of gravity and pumping systems.

The dam which will create the impounding reservoir has a length of about 400 ft. on the crest, the central portion, 160 ft. in width, being designed as an overflow or waste weir with its crest 15 ft. lower than the remainder of the dam. The maximum height above the bed of the stream is approximately 75 ft. The elevation of the reservoir is about 212 ft. above sea level.



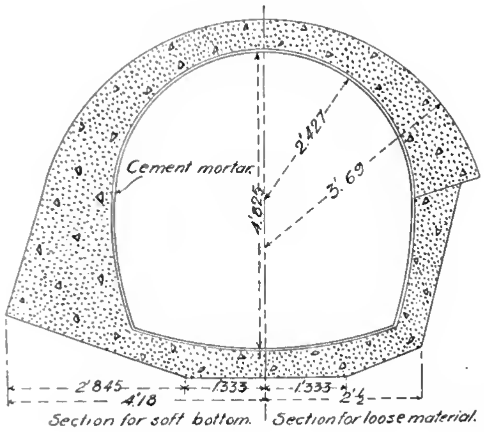
Spillway and High Sections of Dam.

The foundation of the dam is a bed of solid rock which was thoroughly cleaned of all dirt and debris and washed before the work was started. The bonding of the masonry to the foundation was further secured by stepping and grooving the rocks after all fissured and unsound portions had been removed. The excavation for the foundations amounted to about 16,000 cu. yd., 11,000 of which consisted of solid rock.

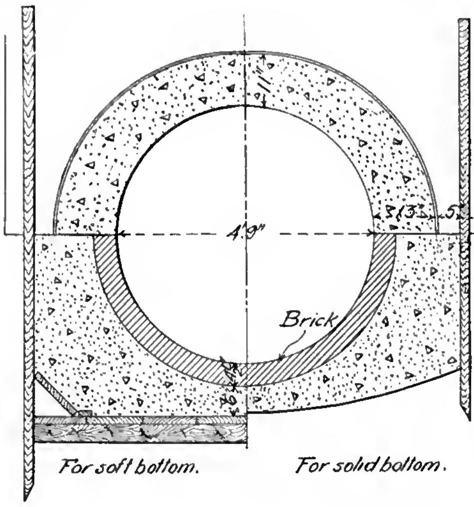
The dam is built of rubble concrete masonry containing about 50 per cent. of large stones laid in irregular fashion so as to avoid continuous joints through the structure. The stone is a marble—a high grade of limestone. The concrete is a 1:2½:5 mixture, the aggregate being gravel and broken stone, in sizes varying up to 2 in. in maximum dimension. The sand, gravel and stone were obtained in the vicinity of the dam. The upstream top and downstream faces are built of coursed-rubble made with stone, dressed so as to make ¾-in. joints, for a depth of at least 4 in. After laying the joints were raked out to a depth of 2 in. and pointed with a 1:1 cement mortar. The total yardage of the dam including large stones and concrete is about 28,000 cu. yd.

The gate house controlling the flow from the reservoir to the pipe line is built as part of the dam at one end of the spillway section. It measures 27x40 ft. in plan, the longer dimension being parallel to the axis of the dam. Two pipe lines run through it, one a 42-in. line carrying the supply to the city and the other a 36-in. pipe serving as a waste line and discharging into the river a short distance below the dam.

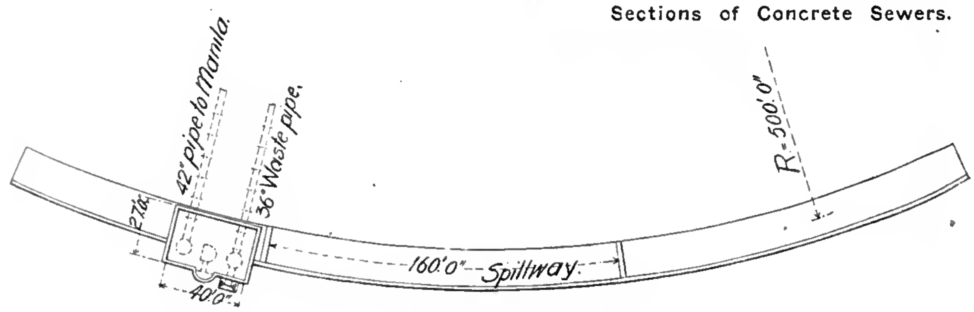
The pipe line consists of a 42-in. riveted steel main 10½ miles long, discharging at the end nearer the city into a conduit which follows the hydraulic gradient. For about two miles it follows the valley of the Mariquina River and then starts across country in a direct line for Manila, passing under the Mariquina River through a 36-in. cast-iron pipe. Through all parts of its length it is between 50 and 100 ft. below the hydraulic gradient, a depth of about 100 ft. being maintained for all but a short distance of the line. The pipe is made of plates about 2/10 of an inch thick of 2 courses, the smaller fitting into the larger, each course corresponding to the width of plates from which the pipes are made, being about 60 in. long. The longitudinal seams are double riveted and the circular seams single riveted, except at curves where circular seams are double riveted at the beveled joints, the rivets used being 7/16 in. in diameter. The pipes are fabricated at the shop of the Atlantic, Gulf & Pacific Co., in Manila, and transported to the work in sections 20 and 30 ft. long, depending upon the transportation facilities and the condition of the roads. The steel plates for the pipe were furnished by Henry H. Peabody & Co., having been purchased by the Municipal Board of Manila under contract awarded at the time of letting the remainder of the work. The pipe is caulked at all seams inside and out before being coated, and and tested at the shops to a hydraulic pressure of 100 lb. per square inch. After being laid in the trench, the pipe is again tested, the field riveting having been completed, to a pressure of 75 lb. per square inch. Blow-off pipes are provided at all sags in the line, and air valves at all summits, these in all cases being enclosed in suitable wells. The blow-off pipes are 6 in. in diameter and are discharged into convenient water courses. Brick manholes, 14x16 in., are spaced approximately 500 ft. apart throughout the entire line. The excavation for the pipes lines amounted to about 58,000 cu. yd. of earth and 18,000 cu, yd. of loose, solid and adobe rock. The minimum covering of the completed pipe is 2 ft.



Sections of Aqueduct.



Sections of Concrete Sewers.



Plan of Dam on Mariquina River.

The crossing under the Mariquina River near San Mateo is made through a 36-in. cast-iron pipe about 500 ft. long at each end of which reducers join on to the 42-in. riveted steel pipe in gate houses through which the valves controlling the 8-in. blow-off pipes are controlled. These gate houses are circular, 8 ft. in diameter, and surmount the 6-ft. concrete wells in which the valve mechanism is set.

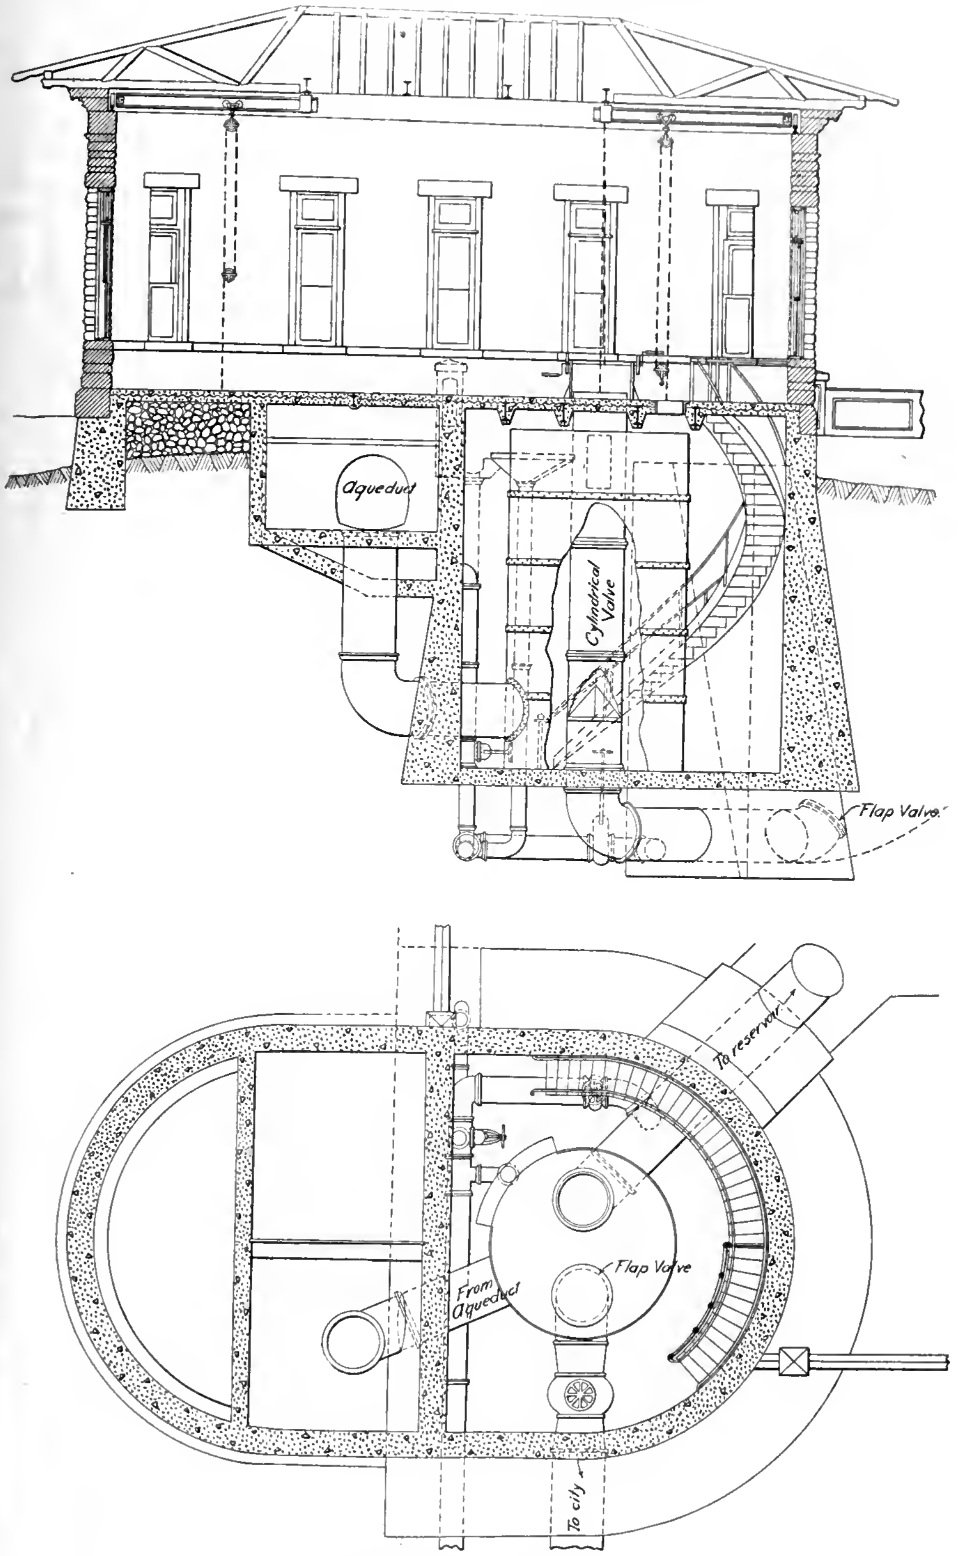
From the end of the pipe lines to the distributing reservoir, water flows through a concrete aqueduct constructed in tunnels the entire distance of 4 miles. Part of the work is done by the cut and cover method, but the greater part by tunneling carried on from 12 shafts. The total amount of earth and rock to be moved is about 34,000 cu. yd., most of which is adobe rock. The conduit has a horse-shoe section about 4½ ft. wide and a maximum height of 4 ft. 10 in. In solid rock sections the conduit is lined with a coat of 1:1 cement mortar, while in those parts where a full concrete section is required the same mortar finish is applied to the concrete. Where the line runs through loose material or a soft bottom is encountered, the concrete is spread out to afford an adequate foundation, and in places where the conduit runs through a section of rock overlaid with loose material the cut and cover method is used, excavating the lower part of the conduit in solid rock and building a concrete roof having the same interior arch as the other sections. The minimum thickness of concrete at the crown of the arch, is 6 in.

The siphon is composed of two 42-in. cast-iron pipes connected to the conduit by means of concrete siphon chambers, 8 ft. wide and 8 ft. high, to which access is had by means of 24-in. manholes.

The distributing reservoir is located about a mile east of the present Deposito, as the present reservoir is called, and 1½ miles outside the city limits of Manila, at an elevation of about 112 ft. above the level of the sea. It is rectangular in plan, measuring 504x769 ft., 20 ft. deep, and

has a capacity of 50,000,000 gal. It is built on ground sloping to the south with a maximum difference in elevation of 15 ft. The bottom of the reservoir is about 25 ft. below the natural surface where the ground is highest, and about 8 ft. where it is lowest, and consequently the greater part of it lies in excavation and only part of the banks are carried up above the natural surface. The banks slope 1:1 and in the rock section are covered with a thin coating of cement mortar while the other parts of the banks are lined with a 4-in. layer of 1:2½:4 concrete. Expansion joints are left in the lining every 20 ft. Where the top of the reservoir is above the natural surface of the ground an embankment is built up in the customary manner, laying thin layers of good earth and watering and rolling them thoroughly. A 10-ft. driveway on a 10 per cent. slope leads down inside the embankment so as to allow access to the bottom of the reservoir for wagons should it be necessary to make repairs. The excavation here involved amounted to 29,000 cu. yd. of earth and approximately 235,000 cu. yd. of rock.

The water supplied to the conduit is measured before entering the reservoir over a weir built into a concrete chamber which is surmounted by a suitable building. The weir box is 12 ft. wide and 29 ft. long from the end of the conduit to the weir. The weir itself consists of a steel plate bolted to plates set into the concrete of the chamber, the notch being 6 ft. wide and 2 ft. deep. The crest is approximately 3 ft. 3 in. above the bottom of the chamber. A 20-in. drain pipe controlled by a gate valve allows the silt that may accumulate in the chamber to be flushed out.



Gatehouse at New Reservoir.

The flow into and out of the reservoir is controlled from a single gate-house located at the corner of the dam toward Manila. The aqueduct, the gates of the reservoir and the supply pipe leading to Manila all meet in a riveted steel distributing tank and are fitted with suitable valves so as to divert the flow as desired. The aqueduct enters immediately below the floor of the building, which is on a level with the top of the embankment, and terminates in a concrete chamber across one end of which is a screen shutting off a second chamber, from which a 42-in cast-iron pipe leads down to discharge into the tank near the bottom of the latter. The discharge into the reservoir from the distributing tank is controlled by a cylindrical valve, and by a flap valve on the end of the pipe in the reservoir. The flow into the main leading to the city is governed by a flap valve which can be raised by mechanism on the floor of the gate house, and by a 36-in. gate valve located outside the steel tank in the concrete chamber. A 12-in. overflow pipe is attached to the tank and an 18-in. drain pipe is connected with the line connecting the tank and the reservoir.

The gate house is built with semi-circular ends 47 ft. 8 in. on the longest and 26 ft. 8 in. on the shortest dimension. It is built of ashlar masonry laid in Portland cement mortar, and the interior is finished with Mariquina marble. The water will be conveyed to the city from the new reservoir in a 42-in. cast-iron pressure pipe, the supply in the city being wholly by gravity due to the elevation of the reservoir.

Sewerage System.—Up to the present time Manila has been without a sewer system and the one now being built is a sanitary system, a distinct arrangement of open drains being projected to care for the storm water. The ground on which the city is built is very flat and varies in height above mean high tide from 2 or 3 to about 10 ft., and for this reason a purely gravity drainage system was out of the question. The natural solution of the problem of the disposal of the sewage was to discharge it into the bay at such a point where it would not be obnoxious and this plan has been adopted. The city has been divided into 6 districts, 3 on each side of the Pasig River, in each of which an independent gravity drainage system will be installed. The sewage of each district will drain to a pumping station from which it will be forced to the main pumping plant located on the shore of the bay at the beginning of the force main through which it will be discharged. All of the sewage from the three pumping stations on the south of the river will be carried under the river to the main pumping station through a twin inverted siphon consisting of two 24-in. flexible joint, cast-iron pipes.

There will be in all about 52 miles of sewers, 7½ miles of which will be composed of brick and concrete, ranging in size from a 2 x 3-ft. egg-shaped to a 4¾-ft. circular section, laid at depths ranging from 12 to 18 ft. below the surface of the ground; and about 42 miles of glazed terra-cotta pipe from 8 to 24 in. in diameter, laid from 5 to 16 ft. below the surface. In addition to these lines, there will be one 42-in. cast-iron outfall pipe, 6,500 ft. long, laid below the bed of the harbor, the crossing of the Pasig River above mentioned, and cast-iron pipe crossings of 9 esteros or canals.

The sewers are laid throughout in loose material, consisting of mud, sand and light clay, the sides of the trenches requiring very careful sheeting to retain the soft material. Pumping has to be done continually while the work is in progress. Much of the sheeting is left in place in order to prevent the caving of the streets beside the trench after the latter is refilled. The large sewers are built of concrete, with a single layer of brick laid in the concrete to form the invert. In the egg-shaped sewers a moulded concrete block replaces the brick in the sharp curve at the bottom of the invert. In insecure foundations the sewers are supported on timber platforms. The lower half of the terra-cotta sewers is surrounded with an annular ring of concrete from 4 to 6 in. thick, depending upon the size of the pipe, and where the foundation is not firm, the concrete instead of being placed as a ring is spread out so as to afford a footing and placed

upon a timber foundation the same as for the large sewers. The Portland cement used both on this work, and on the water-works system is of English make, K. B. & S., and White Bros.

The estero crossings are made by double lines of cast-iron pipe ranging in diameter from 16 to 36 in., the pipes in all cases going well below the bed of the canal. On each bank there is constructed a chamber, to which access is had through a manhole, in one of which are located gates for shutting off the flow in the pipe. In some cases where only one pipe was necessary a safety outlet has been provided through an extra chamber whereby the sewers can be diverted into the estero in case it is necessary to make repairs to the pipe. By closing a gate dividing the two chambers, the sewage is forced through the temporary discharge pipe which opens from this chamber. The second chamber is therefore left free and can be drained to afford a working place in putting cleaning devices through the pipes or making repairs. The pipes, whether single or double, are completely enclosed in concrete and where the soil requires it are placed on timber platforms. These estero crossings vary in length between man-holes on the banks from 84 to 223 ft. The crossing of the Pasig River is built of two 24-in. flexible-joint cast-iron pipes laid with their tops about 23 ft. below mean low tide level. The crossing is about 650 ft. long between the man-holes on the banks. These crossings of the esteros and the river were put in by dredging trenches, and lowering the pipe from barges.

The outfall pipe leading under the bay consists of a 42-in. cast-iron pipe with bell and spigot ends, 6,500 ft. long, supported on piles 9 ft. apart throughout the entire length. The piles are capped with a 10 x 10-in. timber, 6 ft. 6 in. long, and every 18 ft. additional piles were driven on both sides of the pipe to hold it against lateral movement.

The bay is quite shallow where the pipe runs, the water being from a few feet to about 8 ft. deep at mean low water. The pipe was laid in a trench excavated by a hydraulic dredge and after it was in place and calked the trench was refilled. The pipe was put together in sections 48 ft. long, consisting of four 12-ft. lengths, and loaded on barges and towed out to their position. The barges were brought up alongside a scow on which four tackles were rigged for lowering the pipe to place. The pipe was calked with oakum and soft lead by divers. The end of the pipe is located in 8-ft. of water in a concrete block 14 ft. square and 12 ft. high, resting on a timber platform built on piles.

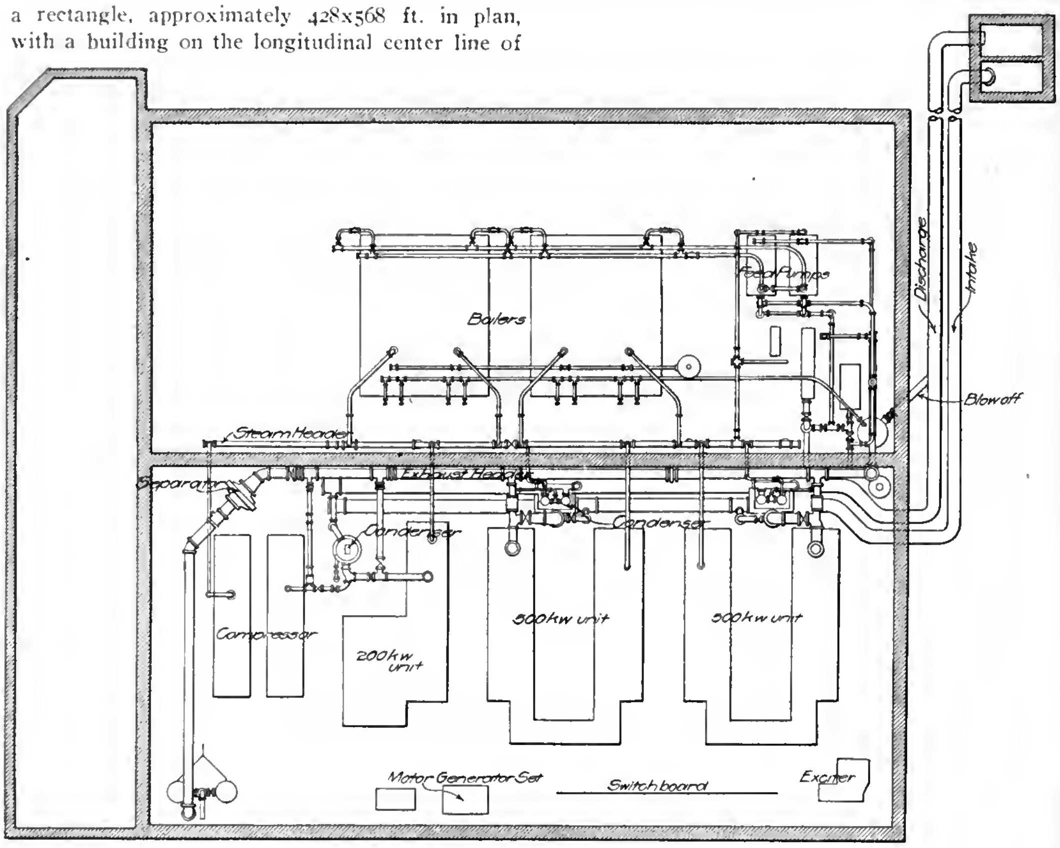
The amount of the contract for the water-works system is $1,026,000 and for the sewerage system $1,631,000. The work is under the Department of Sewer and Water-Works Construction, the water system being designed and in charge of Mr. J. F. Case, chief engineer of the department. The sewer system was designed by Mr. O. L. Ingalls, principal assistant engineer of the department. At the present time the sewerage system is 50 per cent. completed, the tunnels 75 per cent., and the riveted steel pipe line 33 per cent.

The steel pipe and tunnel of the water-works system, and the entire sewerage system are being built by the Atlantic, Gulf & Pacific Co., and the dam and reservoir by the Matson, Lord & Besler Co.

A LARGE DEPOSIT OF IRON ORE has been discovered on the Island of Cuba, in the Province of Oriente. It is located on a plateau ten miles long by about four miles wide. A large number of borings have been made and the property involved, about 27,000 acres, has been secured by a company that is about to develop it.

The Power Plant of the Elgin National Watch Works.

The manufacturing works of the Elgin National Watch Co. at Elgin, Ill., are in a group of large factory buildings on the left bank of the Fox River. The original buildings of these works were not arranged according to any defined plan, but had been added from time to time as more space was required. Several years ago after the business of the company had grown to large proportions, a broad general plan for the complete arrangement of the works was adopted. This plan contemplated that most of the old buildings should be abandoned and replaced by new ones, which could be arranged to better facilitate the operation of the works. The new buildings were to be placed around the sides of a rectangle, approximately 428x568 ft. in plan, with a building on the longitudinal center line of the rectangle. A part of this plan has been carried out by erecting new buildings along the front side and one end of the rectangle, and by abandoning some of the original buildings.



General Plan of Power Station.

The new buildings that have been completed are four stories and a basement in height, their design conforming to the uniform proportions of the general plan. They are of fire-resisting construction throughout and are built to produce the best of light and ventilation for the large number of employes housed by them. The greater part of the manufacturing carried on in these buildings is exceedingly intricate, but a considerable amount of work is done by machines which, together with the lighting, heating, ventilating, and service systems for the various buildings, necessitate a large power plant capable of responding to a load which varies widely from hour to hour and from season to season.

The original power plant of the works was in two brick buildings near the center of the rectangle of new buildings. The demands for power had gradually outgrown the capacity of this plant until the equipment of the latter was no longer equal to the requirements, although such additions as were feasible had been made to it from time to time. A plan for an entirely new plant arranged to provide for the growth of the works was therefore adopted and carried out.

The new power plant is in a separate brick building at one corner of the proposed rectangle of new factory buildings. The end of this building is in line with the buildings along the end on the river side, and the front of it is about 100 ft. from the site of the buildings which will occupy the rear side of the rectangle. The exterior of the power plant building conforms with the design of the new factory buildings. It is 108.5x115 ft. in plan and rises to a height of 61 ft. above the footings. The building has a concrete substructure built on solid rock. The side walls are of buff brick, trimmed with Bedford sandstone and ornamental terra cotta. The roof is carried by steel trusses resting on the side walls. The interior of the building is divided by a longitudinal brick wall into an engine room, 53 ft. 11 in. wide, and a boiler room 49 ft. 6 in. in width, a basement 11 ft. in height extending under the entire building. The basement has a concrete floor and the floors of the boiler and engine rooms are of reinforced concrete.

Coal for the plant is delivered by the Chicago & Northwestern Ry. and the Aurora, Elgin & Chicago third-rail electric line, the latter connecting with the Illinois Central and the Chicago, Milwaukee & St. Paul Railroads. An elevated switch track is extended from these lines over a track hopper at one end of the building. The coal is handled from this hopper to overhead storage bunkers in the boiler room by a traveling Link Belt gravity-overlapping-bucket conveyor, with a capacity for handling 40 tons an hour. The coal feeds by gravity from the track hopper into a crusher, belt-driven by a 15-h.p. induction motor in the basement of the boiler room. The conveyor is driven by a 7½-h.p. induction motor in a tower over the track hopper at the end of the building. It extends vertically up the end of the building from the crusher to the top of the boiler room, then horizontally the length of the latter, down at the opposite end of the room to the basement and thence in a horizontal run along the floor of the basement to the crusher again.

The boiler room contains four Cahall horizontal sectional water-tube boilers, which are placed in pairs in a row, with space at one end of the row for an additional pair. Each boiler is equipped with a Mansfield traveling chain-grate stoker, 6 ft. 5 in. wide. The coal conveyor de-

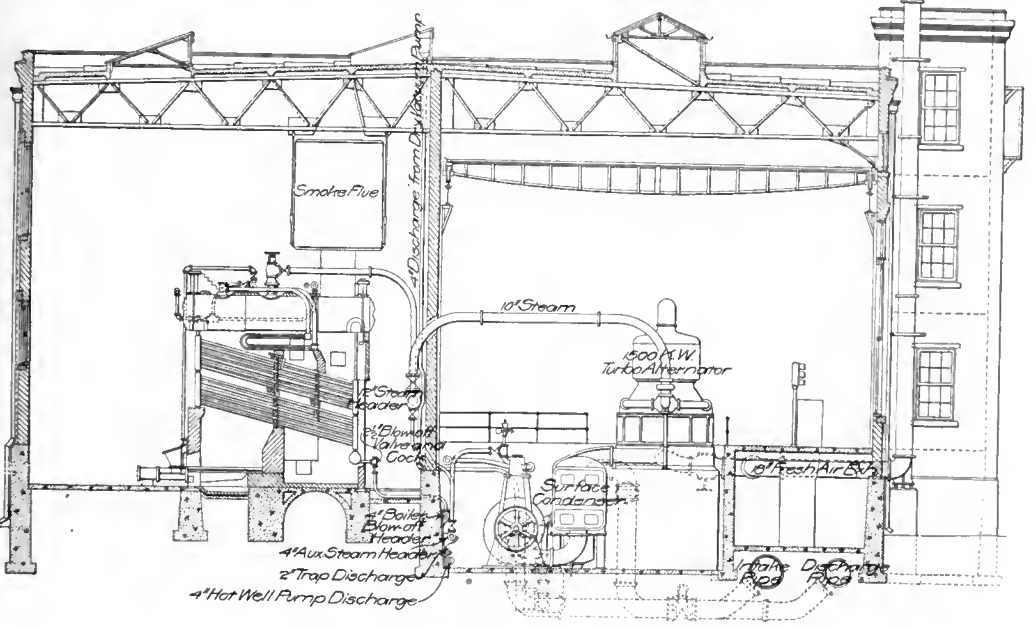
livers to four overhead storage bunkers, with a capacity of 1,000 tons, one for each of the present two pairs of boilers, one for each pair that will be installed in the future and one for storage. The bunkers each have two downspouts, one for each of the two boilers of the pair which they serve. The downspouts are controlled by undercut gates, and feed directly into the charging hoppers of the stokers. The coal which falls through the front ends of the stokers is caught in a hopper built in the concrete floor in front of each stoker. These hoppers are covered with an open grating and extend down to the horizontal run of the conveyor in the basment, so the coal which reaches them may be elevated to the bunkers again. The ashes fall from the rear end of the stokers into a pit built in the setting below the floor level of the boiler room. These pits are also connected by a chute with the space back of the boiler arch, so the fine ashes and soot caried over into that space can be removed through them. The run of the conveyor in the basement is placed close to the fronts of the boiler settings enabling the ashes to be drawn into it from the pits. The conveyor delivers the ashes to a storage bin over the track at the end of the building, from which they can be fed by gravity into cars on the track.

Washed Illinois screenings, containing from 10,000 to 11,000 B. t. u. per pound, are burned exclusively under the boilers. Careful firing is therefore essential to obtain satisfactory results. In order to assist in checking the operation of the stoker an Ados CO_2 recorder has been installed to analyze the flue gases. This instrument is placed in a tight wooden booth against the wall directly in front of the boilers where the firemen can see it at all times. A door is built in each side of the booth to permit the removal of the recorder. A double door in the front of the booth is provided at the top with a glass so the operation of the recorder may be observed without opening the larger front door. Gas is furnished to the recorder from the flue leading from the boiler to the stack by a device which insures a fresh supply for each analysis.

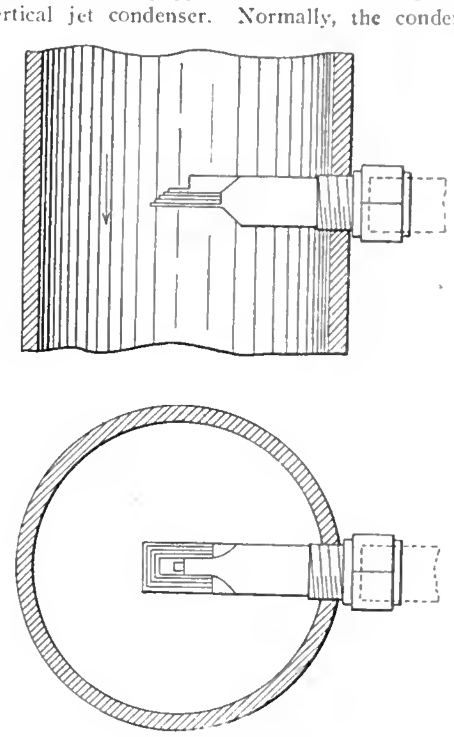
The recorder can be set so it will make and record automatically the results of analyses at various intervals, but in this case an analysis is made every 5 minutes. The results obtained are recorded on a strip of paper carried by drums moved by clock-work similar to a recording steam or water-pressure gauge. From the results thus obtained the percentage efficiency of the furnaces can be readily calculated.

When the recorder was placed in operation in June, last, the efficiency of the furnaces was found to be about 70 per cent., that is to say, 30 per cent. of the heat value of the coal was being lost up the stack. After the recorder had been in use about four weeks the loss was reduced to 15 per cent., due to greater care used by the firemen and to changes which had been made in the grates. The incentive given the firemen by the constant check on their work afforded by the recorder and the opportunity to observe the results of different methods of firing are considered to be the chief reasons why better firing is obtained.

Exterior of Power Station.



Cross-Sectional Elevation of Power Station.



Cylinder Lubricating Device.

The boilers embody no special features of design. They are rated at a combined efficiency of 64 per cent., when producing 300 h.p. each at 180 lb. pressure and on the washed screenings used; and a combined efficiency of 58 per cent., when producing 450 h.p. each, under the same conditions. Feed water is supplied to them from a Cochrane feed-water heater, on an elevated platform at one end of the boiler room, by either of two Prescott duplex feed-water pumps. These pumps are also arranged so they can draw cold water from a suction main connected directly with the river. A service pump in the basement of the boiler room supplies river water to the heater. Duplicate delivery lines from the feed pumps are carried over the front end of the boiler settings and are cross-connected at each of the four boilers, so any of the latter may be supplied from either line.

The two drums of each boiler are connected to a 9-in. steam header along the rear wall of the boiler room. This header is connected at each end to a 6-in. auxiliary header in the basement of the boiler room, forming a ring system. The main steam-consuming units in the basement of the boiler room are supplied from the 6-in. auxiliary header.

The engine room contains three main generating units, an air compressor, a steam-driven and a motor-driven exciter set, a motor-generator set and a 15-ton Whiting hand-operated crane. One of the main units consists of a 22x36x42-in. McIntosh-Seymour cross-compound engine, direct-connected to a 500-kw. Crocker-Wheeler 60-cycle 225-volt 3-phase alternating-current revolving field generator, operating at 100 r. p. m.; the other main unit is the same as the first, except that its low-pressure steam cylinder is 40 in. instead of 36 in. in diameter. This difference in the two engines was made in order that the second unit could operate non-condensing more economically.

The buildings of the works are heated by the Paul and the Webster exhaust steam systems, which are supplied chiefly from the non-condensing main generating unit. The latter, however, can be operated condensing, if desired, as each main unit is equipped with an Edwards twin vertical jet condenser. Normally, the condensing main engine carries the day load during the months when the heating system is not in service, or when it can be supplied with exhaust steam from the smaller steam-consuming units in the plant; and the non-condensing main unit carries the load at other times. The night load is carried by the 200-kw. generating unit, for, although a considerable portion of the machines in the works which require power are run continuously, most of the buildings of the works are closed at night, thus relieving the load due to lighting, heating, ventilating and service. This third unit consists of a 13x22x30-in. McIntosh Seymour Corliss tandem-compound engine direct-connected to a 200-kw. Crocker-Wheeler generator of the same type as the generators of the two large units, but operating at 150 r. p. m. This unit is equipped with an Allis-Chalmers vertical jet condenser, and is designed to operate condensing. The motor-driven exciter consists of a 50-h.p. induction motor driving a 30kw. 125-volt direct-current General Electric generator. The steam-driven set has a 50h.p. McIntosh-Seymour high-speed engine direct-connected to a Crocker-Wheeler generator of

the same capacity as the other, both units running at 300 r. p. m.

All three engines are designed to run on steam at 180 lb. pressure, and are equipped with non-releasing valve gears. The large engines can each develop 750 h.p. at one-fifth cut-off; 1,100 h.p. at one-half cut-off; and 1,378 h.p. at seven-tenths cut-off. They were also built under the following speed regulation guarantee: with steam at 100 to 180 lb. pressure and a variation from no load to the full rated load of 750 h.p., or vice-versa, the revolutions per minute shall not vary more than 2 per cent.; with the same variation in steam pressure and changes from no load to a load of 1,100 h.p., or vice-versa, the speed variation will not exceed 6 per cent. of the normal.

The three condensers for these engines are supplied with cooling water through a 24-in. main leading from an intake in the river. A screen chamber covered by a small brick building is placed on this injection main near the intake. The discharge from the condensers is carried back to the river by a 24-in. main that passes through a chamber in the sub-structure of the screen chamber building and terminates at the intake. A manhole provides means of entering this chamber on the discharge main. The blow-off from the boiler is also carried to the chamber on the discharge pipe.

The air compressor in the engine room is of the two-stage cross-compound type, with a capacity of 500 cu. ft. of free air a minute, when operating at a 100 lb. pressure. This machine delivers to two receivers in the basement of the engine room. The air is piped to all parts of the works, in which it is used for a multitude of purposes in connection with the manufacturing processes.

The motor-generator set consists of a 100-h.p. alternating-current induction Crocker-Wheeler motor direct-connected to a 75-kw. 220-volt direct-current generator. The latter supplies power for operating direct-current motors for elevators in the various buildings, and for a few direct-current motors in different parts of the works.

The operation of the electrical units is controlled from a switchboard at one side of the front of the engine room. This board has sixteen panels of blue Vermont marble and is equipped with General Electric apparatus and instruments. A panel is provided for each of the main generator units, one for the two exciters, one for the motor and one for the generator of the motor-generator set and a totalizing panel. The remaining eight panels are each for one of the eight circuits into which the distribution system is divided.

The exhaust-steam heating system is supplied from an 18-in. header extending the full length of the basement of the engine room. The exhaust of all of the steam-consuming units in the plant are connected into this header. A riser extends from one end of the latter to an exhaust head above the roof. The feed-water heater in the boiler room is connected to a by-pass on this riser, in order that it may or may not be supplied with steam from the exhaust system. The exhaust riser is equipped above the by-pass to the heater with a back-pressure valve, a 6-in. air vent leading from just above this valve to a blow-off tank in the basement.

A 26-in Crane horizontal oil separator is placed on the 18-in. exhaust main just beyond the last connection with a steam-consuming unit. The oil and water removed from the steam by this separator are passed through a second specially designed separator in which most of the water is removed and run to the sewer, while the oil is collected, filtered and reused

The heating system for the buildings is operated on about 4 lb. pressure, in order to supply a distant building. When sufficient exhaust steam is not available from the units which are in service connections are made so live steam can be supplied. The condensation returned from the system is pumped to the feed-water heater by either of two Worthington volete pumps, with a capacity of 125 fal. a minute, which are in a sump in one corner of the engine room basement. Each of these pumps is direct-connected by a vertical shaft to 3-h.-p. vertical induction motor.

The boiler room contains a 20-ton exhaust-steam-absorption Carbondale ammonia refrigerating machine for cooling the drinking water supplied to the works. This machine has a capacity for cooling 600 gal. of water an hour from 80° Fahr. to 40° Fahr. A duplex Dean steam pump, with a capacity of 3,000 gal. an hour, circulates the cooled water through a piping system extending to the various buildings of the works.

Two fire pumps, one a cross-compound Underwriters machine, with a capacity of 1,000 gal. a minute, and the other a simplex Blake, with a capacity of 1,600 gal. a minute, are placed in the basement of the boiler room. These pumps draw water from the river and are connected to a private fire-protection system of the works. The buildings of the works are equipped throughout with automatic sprinkler system supplied from the fire-protection lines, which are normally under pressure from the city mains. The connection between the latter and the fire protection system is provided with a check valve which closes when the fire pressure from the station is turned on the system.

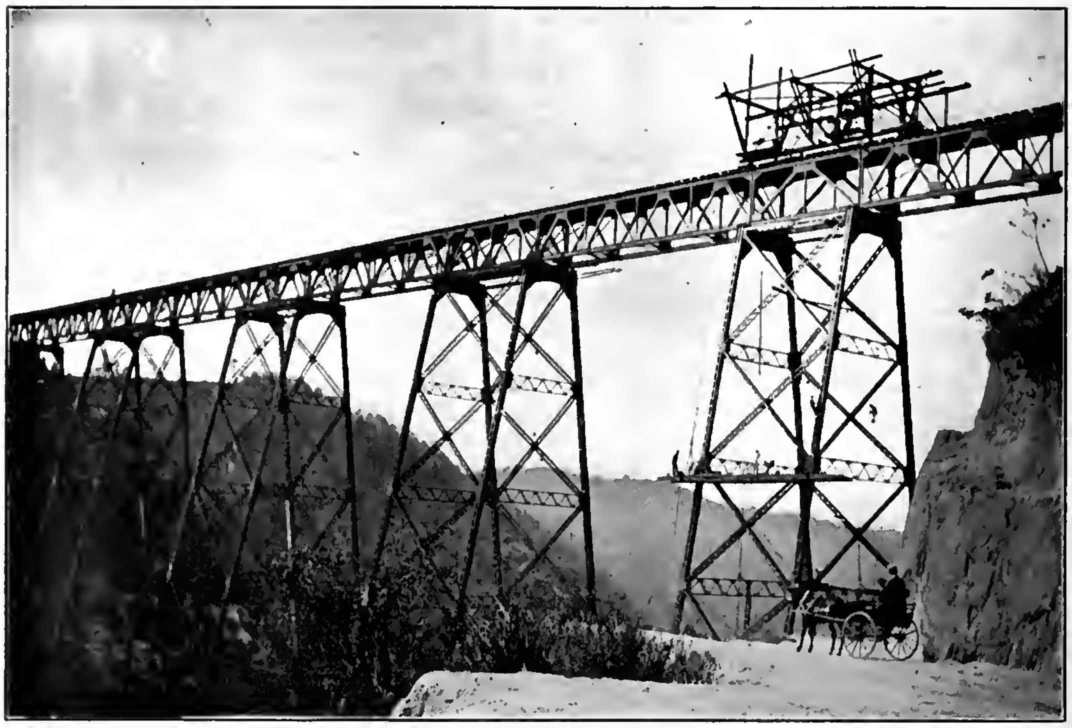
Water for flushing toilet fixtures in the different buildings is supplied from tanks carried by the roof trusses of the building. A 4-in. Worthington centrifugal pump, direct-connected to a 15-h.p. induction motor, is placed in the basement of the engine room and pumps river water to these tanks. This unit operates at 1,200 r.p.m. and was formerly installed in the old plant where it operated satisfactorily for three years at this relatively high speed.

Lubricating oil is supplied to the various units in the plant by a gravity-feed distributing system. A supply tank for cylinder oil and one for engine oil are suspended in the roof trusses. Two small duplex pumps raise the oil to these supply tanks from two storage tanks in the basement. The cylinders of all steam-consuming units are supplied with oil through a special form of oil atomizer which was designed and patented by Mr. W. L. Parker, chief engineer for the company. This atomizer is simply a short piece of threaded pipe of the same size as the tap for the regular oil inlet in the steam supply line to the unit. The opening of the pipe is contracted toward the end, inside the steam line, and terminates on a flat surface which forms the top of a rectangular projection with three sides widened out below this surface by steps, as shown in an accompanying illustration. The opening from the pipe on this surface is placed so the latter is against the direction of steam flow, with the result that the steam drives the oil in a fine spray from the bottom steps of the three sides of the small rectangle.

These atomizers were first used in the original plant of the works, in which they produced excellent results and are being used in the new plant with equal satisfaction. They have also been used to relieve troublesome cylinder lubrication conditions in a number of power plants in Elgin and vicinity.

The oil drips from the various units in the station are returned to two Turner oil filters in the basement of the engine room. These filters are over two storage tanks, one for cylinder and the other for engine oil, from which the oils are raised to the supply tanks under the roof.

Mr. Geo. E. Hunter is general superintendent and Mr. W. L. Parker is chief engineer for the Elgin National Watch Co. Mr. J. W. Lyons, of Chicago, was retained as consulting engineer for the company during the design and construction of the plant.



Traveler Dismantled for Use in Painting and Riveting, Las Vacas Viaduct.

An Interesting Competitive Test of marine engines will be made when the three scout cruisers, now under construction for the United States Navy Department at Quincy, Mass., are in the water. These ships are of identical dimensions, the only difference being that one of them will be equipped with the Parsons turbine, another with the Curtis turbine, and the third with ordinary reciprocating engines. It is purposed to have a triple trial of these vessels, taking them to sea at the same time, subjecting them to the same exactions, and observing the relative merits of the different types of motive power. It is expected that the trial will take place late in the Summer of 1908, by which time the ships should be completed. This will be the first opportunity American naval experts have had to examine closely the practical operation of turbines as applied to naval uses.

The Erection of the Las Vacas Viaduct.

The narrow gauge single track Las Vacas Viaduct of the Guatemala Ry. is 743 ft. long and 229 ft. high and has seven 30 and 40-ft. towers, supporting one 55-ft. span and seven 75-ft. spans. The towers are each made with two vertical bents having a maximum of seven stories and have X-braces in all faces and horizontal struts in the transverse planes only. The tops of the bents have transverse box girders about 4 ft. deep and 18 ft. long which weigh about 3,500 lb. each and have the column flanges field riveted between their webs. Each span is made with a pair of lattice girders 12 ft. deep and 10 ft. apart on centers with the usual top and bottom laterals and transverse sway bracing. The lower flanges of the trusses are seated on the box girders. The 30-ft. and the 75-ft. spans weigh about 26,000 and 50,000 lb. respectively and the maximum tower weight is about 25,000 lb., the total weight of the viaduct being nearly 1,000 ginning of operations. It was determined to erect the viaduct by the cantilever method with an overhead derrick traveler and plans for it were prepared and the operations outlined as illustrated in The Engineering Record of February 2, 1907.

The 35,000 lb. steel traveler was designed for service in the erection of other viaducts now under construction for the same R. R., and consisted essentially of a pair of riveted trusses about 53 ft. long, 10 ft. deep and 10 ft. apart on centers connected by transverse and lateral bracing in the planes of the top chord only and mounted on four wheels. The forward vertical end posts were continued 23 ft. above the top chords and braced together transversely to form masts for a pair of 60 ft. tapered steel booms 30 in. square at the center. Each boom was rigged with a 4-part topping lift and a 5-part hoisting tackle of 6,500 lb. capacity. A wooden boom 20 ft. long was also provided between the steel booms. Swinging tackles were attached to the they were used as anchorages for the succeeding span. For this service the trusses were to be temporarily reinforced by wooden vertical posts to carry the vertical shear over the tower bents.

The traveler was to advance to the front of the tower and erect a wooden falsework tower about 50 ft. high to receive the 2nd panel point of the first 75-ft span. After the span was erected up to the tower it was to be connected for reaction stresses to the forward end of span 2 and the traveler moved forward on it to complete its erection and erect the 2nd tower. When this span was completed its forward end was to be jacked up from the 2nd tower releasing the connections between the rear end of the span and span 2 and the traveler advanced to complete the remainder of fthe viaduct in the same manner. The travelers were designed by Mr. H. D. Bush, and the method of erection and the other details of plant were developed by Mr. A. W. Buel.

Erecting Section of a Tower Bent.

Erecting First Tower from Falsework.

tons. The towers have a maximum width of about 87 ft. at the base where one column of each bent has an expansion bearing. Excepting some suspension rods supporting the longest members and diagonals in the horizontal planes through the bases of the towers all members of the viaduct are riveted and all were shipped separately and assembled in erection. The details of the design were described in The Engineering Record of Jan. 26, 1907.

The location of the viaduct is remote and rather inaccessible, supplies and skilled labor are difficult to secure, no machine tools or steelworks are available within a great distance, many weeks are required to receive erection plant or materials from the bridge shop and communication with headquarters in New York is difficult and costly so that it was imperative that the erection plan should be fully developed before construction was begun and that all plans and materials should be at the site for the be- extremities of a long horizontal transverse beam fastened to the deck in the rear of the mast and the traveler was anchorred to the finished viaduct when in service. Materials were delivered at grade at the first end of the viaduct and are run through the traveler underneath the top lateral bracing. The hoisting engine and boiler were carried on an extension at the rear ends of the top chords of the traveler trusses and served to counter-balance ordinary loads on the derrick booms.

It was proposed to assemble the traveler at grade on the ground just beyond the first abutment of the viaduct and in that position to erect with it the first bent of the first tower and the first span. The traveler was then to advance partly on the first span and complete the erection of the tower and the tower span, the latter being temporarily connected by top chord links and bottom chord blocks to the first span so as to transmit temporary erection stresses when

When the work was executed some of the conditions encountered varied slightly from what had been anticipated and the erection although conducted closely on the lines above described was modified somewhat to suit the cirumstances and to secure the greatest total expedition and economy. The principal modifications consisted in the omission of the wooden boom, the operation of the swinging lines by hand tackles, the erection of the trusses in sections, bracing them transversely by bolted wooden outriggers, the movement of the entire traveler back and forth to carry pieces forward instead of raising and lowering the booms, and the modification of the traveler to serve for a moveable riveting and painting scaffold after the erection of the steel work was completed. All of these changes were made with a careful recognition of the existing conditions and were fully justified by the successful issue of the work. The cautious handling of assembled sections of the

trusses as single units and the method of carrying them forward and connecting them proved simple and convenient and suggests similar methods of operation in designing future cantilever erection of small riveted trusses, a class of work which has been very seldom attempted by the cantilever methods. The erection methods are well described in the following letter from Mr. W. D. Penny, contractor.

"I consider the traveler the finest machine for viaduct work I have ever used. The booms worked admirably in the heaviest wind, and it blew very hard twenty-five per cent. of the time. The tackles to swing the booms were 10-in. blocks rove with 1 1-4-in. manilla lines; there were times I wished they were larger. Each line was run individually to a hand winch, these winches being bolted to the sides of the traveler just above the sills and easily reached from the track. The reasons that these lines were not led to the winches of the donkey were to avoid the confusion of too many lines being operated at once and to avoid the tying of lines at winch heads as much as possible, but the chief reason was that the winches were worked by native labor and a considerable saving in money was effected. One man at each winch could easily and safely in the heaviest wind swing the booms with a heavy post suspended from each. I never put in the center boom. I could see no benefit to be obtained from the use of it.

I never cantilevered the entire length of any cantilever spans, for the following reasons. First, it would have made the box girder a diffifficult and slow connection in a very inaccessible place. Second, I was afraid I could not get sufficient guys on the end of the span and did not like to run the traveler out so in the heavy winds. So I adopted the following plan in erecting the cantilevers.

"I backed the traveler up till I had sufficient room to connect together one side section of first portion of the cantilever. This I put together, laying it down under the booms, firmly bolting and drifting it together and connecting all lateral plates, etc. It was then picked up by both tackles, one attached to the bottom chord and one to the top chord and properly balanced. The traveler was then run ahead to a proper connecting distance and firmly clamped down. The section was never raised over a foot from the track while being run out, so when the tackle on the bottom chord was slacked off the section hung almost in the connecting position, it only being necessary to slack it down about a foot. The cantilever links were then connected and the section slacked off. The operation of picking up, carrying out and connecting the section never occupied over a half an hour. To move the traveler with the section suspended to it, all I ever used was a 1¼-in. runner on each side.

"In erecting the towers I raised one section on the side nearest to the traveler, then moved out as far as possible on the center section of the span and out hauled the difference with a runner from the donkey. This operation was continued until the third section from the top was reached; then one side of the tower was run up to the top, the box girder put on and the bottom chords of the span connected. The rest was easy.

"In running up one side of the tower, the tower braces were connected to the third section down. This left only two sections without bracing, and even with the box girder on, before the bottom chords were connected, there was very little sway motion. To back up, raise the box girder with both boom tackles, run out and connect it, generally occupied twenty minutes. It was the easiest connection we had. I never telegraphed ahead anything but light members. I found it quicker and safer to back the traveler up and run ahead with the load, it could be moved so easily.

"To wind-brace the cantilever, I bolted a 12x12-inx30-ft. piece across the end of the first section of the span, then bolted 3x12-inx30-in. pieces from the end of the timber both ways to the span. There never was any motion to speak of. The booms were very seldom raised or lowered, and never with a load. We avoided the raising of the booms by moving the traveler, In erecting the first 75-ft. span, I avoided counterbalancing and cantilevering by running the near side of the tower to the top at once, bracing it at some of the sections to the timber tower.

"The only casualty of any kind during erection was the death of one native, who in passing fuel from the deck of the viaduct to the donkey engine on the traveler, carelessly fell between the ties. This happened on the highest part of the structure. He had a clear fall to the ground, and was, of course, instantly killed.

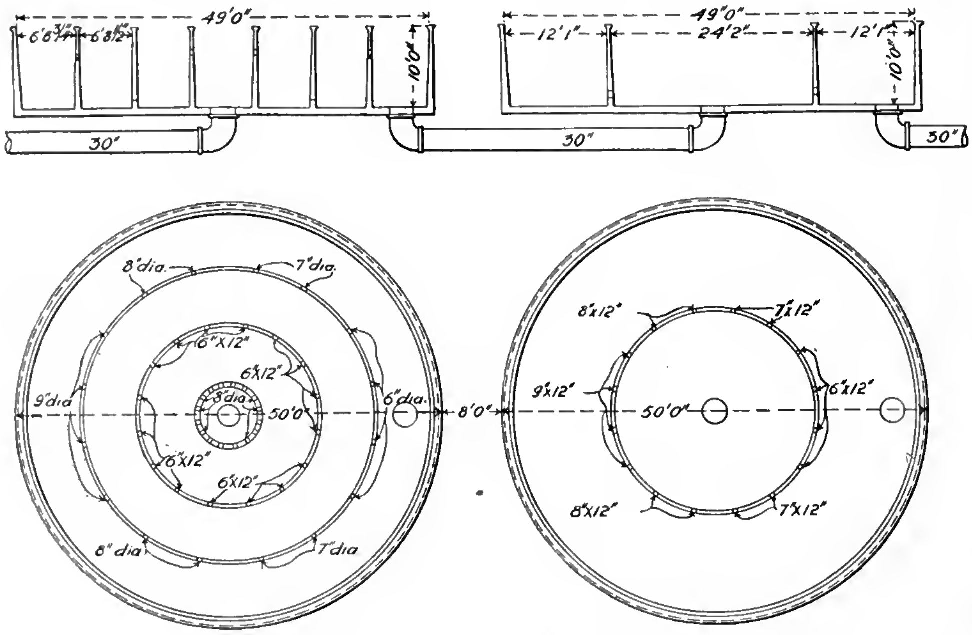
"Although the erection is finished, I have the traveler still in commission, using it to rivet and paint from. I have taken off the booms and high end bent, removed the hoisting engine and the deck, putting false caps 5 ft. above the original deck to give head room for locomotives. I have scaffolds 4 ft. wide and 45 ft. long suspended by 10-in. blocks and 1¼-in. lines hung on each side of tower. Each scaffold carries two gangs with their tools, including forges. The scaffolds are started at the top and lowered as the riveting and painting proceed. When tower is completed to the ground, they are hoisted to the top and the operation repeated."

The viaduct was designed by Mr. V. G. Bogue, New York, Mr. W. H. Kennedy and Mr. A. W. Buel, associated engineers on railways and bridges respectively; Mr. S. F. Shaw is chief engineer and Mr. J. H. Pope bridge engineer of the railway company. The steelwork was fabricated by the Baltimore Bridge Co. Mr. H. D. Bush, vice president and manager, and was erected by Mr. W. T. Penny.

A 150-TON WHARF CRANE has just been completed at the works of Messrs. Armstrong, Whitworth & Co., Elswick, Eng., for placing heavy machinery in erected form, in vessels alongside the wharf. It is mounted on a steel pedestal above the wharf, so as to turn in a complete circle, and has a lifting range of 100 ft. It is hydraulically operated, having two gears of 75 tons capacity each, and an auxiliary lifting gear of 25 tons capacity which has a range of 117 ft.

The Circular Tanks at the Lancaster Filtration Plant.

The water supply of Lancaster, Pa., is drawn from the Conestoga River, a stream subject to frequent and sudden floods, at which times the water carries much loam, clay and vegetable detritus. This supply is purified by a 9,000,000-gal. filtration plant which has been in operation about a year and a half and which consists of a water softening or coagulating system, a series of preliminary filters and a series of final slow-sand filters. There are fifteen preliminary filters, each 6x16x35 ft., and fifteen slow-sand filters, each 6x16x140 ft. The preliminary and the slow-sand filters are of the Maignen type and are very much like those of the 4,000,000-gal. South Bethlehem plant, described in detail in The Engineering Record of July 15, 1905. The tanks into which the water first enters after the coagulant is added, however, where it is agitated and settled and receives preliminary scrubbing are unusual in design and operation. They are designed to remove the bulk of the mud and coagulant before the water reaches the preliminary filters.



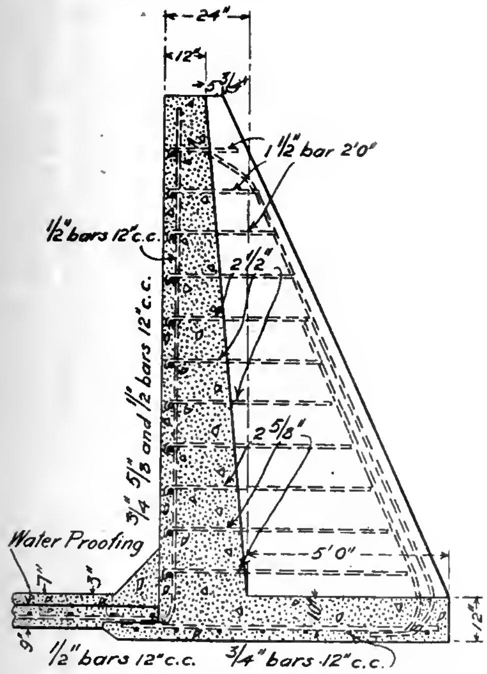
Plan and Section of Tanks at Lancaster Filtration Plant.

At first the reagents used at Lancaster were mainly lime and soda but, as it was considered desirable not to change the chemical character of the water, sulphate of alumina and soda carbonate are now used. These neutralize each other and simply form a coagulating precipitate without making the water harder or softer and without leaving anything objectionable in it. The reagents are added as a dry powder which is thrown into the water by a distributing device actuated by a Poncelot undershot water-wheel operated by the water as it flows into the coagulating basin.

From the coagulating basin the water passes first into a circular agitating tank, 49 ft. in diameter and 10 ft. deep, entering the tank through a vertical 30-in. pipe in the center of the bottom. The tank has three circular concentric baffle walls placed as shown in accompanying illustrations. The first or inner baffle is provided with a series of 8-in. round openings about 6⅓ ft. above the tank bottom through which the chemically-charged water passes into the second section of the tank; the second baffle has openings at the bottom, 6 in. wide and 12 in. deep; and the third has 6 to 9 in. round openings 6 ft. above the bottom; the water leaves at the bottom of the fourth section through a 30-in. pipe that leads to the center of the next tank. The openings in the baffle walls are calibrated so that the

flow through each wall is equally distributed about its circumference as nearly as possible. By the time the water reaches the outlet pipe it has been thoroughly agitated and all the activity of the chemicals as a coagulant has been expended.

The second tank, also 49 ft. in diameter and 10 ft. deep, is provided with a single circular baffle wall with rectangular openings, 12 in. deep and 6 to 9 in. wide, arranged so as to distribute the flow evenly. In this tank the velocity is low and most of the coagulated material, which appears as coarse particles, settles to the bottom while the clarified water passes out through a



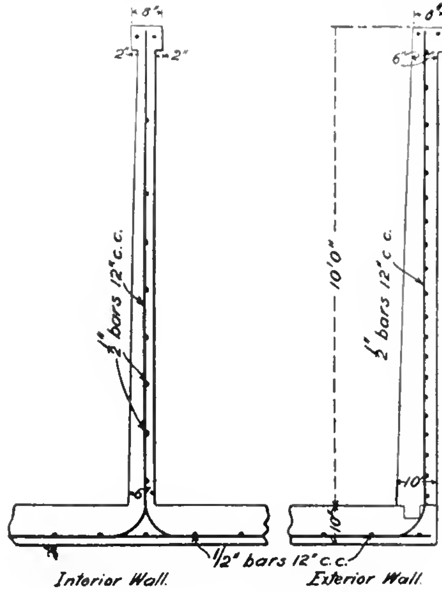
Section of Wall of Pure Water Basin.

30-in. pipe in the bottom of the outside section of the tank and on into two 49x10-ft. tanks without baffle walls. These tanks are preliminary scrubbers and the water is divided equally between them. It enters at the bottom and, being distributed over the floor by suitable concrete drain-tiles, rises through layers of cobble stones, coarse coke and sponge and passes off at the top. By the time the water has reached the surface of these rough scrubbers it is clear enough to be admitted directly to the regular Maignen preliminary filters even during the worst flood periods. There is plenty of room in the coarse material of the rough scrubbers for large deposits of mud and all the circular tanks can go a long time without cleaning. When they are to be cleaned it is done by flushing and shoveling during periods when the river water is clear enough to go direct to the filter plant proper without passing through the coagulating system.

The soil in which these tanks are built is a good loamy clay resting on bastard limestone rock. The excavation was made in original soil. There is now about 5 ft. of earth about the walls.

The circular tanks are made of a mixture of crusher-run limestone, ¾ in. being the maximum size, and Dragon Portland cement in proportions equivalent to 1:3:5, reinforced with New Style corrugated Johnson bars for which the unit working tensile stress assumed was 12,-500 lb. Each bottom slab is 10 in. thick and is reinforced with two series of ½-in. bars on 12-in. centers, 2 in. of the slab being below the reinforcement. The outer walls are 6 and 10 in. thick at the top and bottom, respectively. They are reinforced with ½-in. vertical bars 12 in. on centers, placed as shown in an accompanying section and bent into the floor slab about 18 in., and with circumferential bars, ½ in. to ¾ in., spaced 5 to 9 in. on centers as shown. The baffle walls have ½-in. vertical rods on 16¾ and 19¾ in. centers and ½ in. circumferential rods on 18-in. centers. The openings in the baffle walls were made to come between the rods of both series and the openings for the 30-in. pipes in the floor slabs are surrounded by a flanged metal ring into which the floor slab rods are hooked.

In constructing each tank the floor slab rods were first put in place and wired at their intersections; then the vertical wall rods were put in place and the floor concrete was laid. The vertical rods for the outer walls were held in place during the placing of the floor concrete by attachments to the framework for the lagging. Holding in place the vertical rods of the baffle walls was more difficult but it was managed by wiring the rods together and running guy wires



Sections of Circular Tank Walls.

Coagulating and Softening Tanks, Lancaster Filtration Plant.

to the outer wall forms and to the pipe hole in the center of the floor slab. The floor was laid at one time, a joint recess being provided for the outer wall as shown on the section. No special joint was made for the baffle walls as it was not necessary that these be watertight. When the floor concrete had set enough to hold the vertical wall rods in place the circumferential rods were wired to them, the forms being built up and the concrete poured at the same time. The concrete was very wet and dense and though a Sylvester wash was to have been used it was found to be unnecessary as the tanks were watertight when the forms were removed. The circular framing for the walls was made at a planing mill in 8-ft. sections and ⅞-in. dressed lumber was used for lagging. The surface of the concrete was not treated in any way after the forms were taken down.

The pure water basin is also built of reinforced concrete. It is 100x200 ft. and 12 ft. deep, giving a capacity of 1,500,000 gal. The dimensions of the walls, floor slab and counterforts and the arrangement of the reinforcement is shown in an accompanying illustration. The counterforts are placed 12 ft. on centers.

The Lancaster plant was built by the Pennsylvania Maignen Filtration Co. according to designs prepared by Mr. P. A. Maignen, and has a guaranteed bacteriological efficiency of 97 per cent., a requirement that has been more than fulfilled in regular performance. Mr. W. H. Boardman was chief engineer for the filtration company and Mr. F. H. Shaw acted as consulting engineer for the city. The designs for the reinforced concrete tanks and pure water basin were prepared by Messrs. Webb & Gibson, reinforced concrete specialists, Philadelphia. Messrs. Harmer & Quinn, Philadelphia, were the general contractors, Mr. Chas. Doebler, superintendent of construction.

Canal Transportation in France.

The following report, covering the cooperation of State and communities in the construction of French canals, the cost of constructing them, and the comparative freight charges by canals, rivers, and railways, is furnished by Consul-General Robert P. Skinner, of Marseille:

The systematic effort to improve and facilitate river navigation in France took the form, in 1879, of a general law in regard to railroads, rivers, canals, and seaports. It was rightly considered that these were all branches of the same subject and that there should be a scheme of general improvement harmonizing in every detail. The law of 1879 was, in fact, merely a programme, intended to be executed as the resources of the country might permit, and up to 1890 it had been departed from only to the extent made necessary by the progress in methods of transportation. One of the essential features of the Freycinet programme of 1879 was the standardizing of various types of canals which had been brought into existence through local pressure. M. Freycinet proposed a canal type permitting the utilization of barges 126.31 ft. long by 16.40 ft. beam and drawing 5.9 ft. of water.

Among other projects contemplated in this scheme was the cutting of a canal from the Rhône River at a point near Arles to the city of Marseille, thus shortening the distance between this city and Lyon and making it possible to utilize barges and other craft, which can not with safety navigate in the Mediterranean Sea. The project for this canal has been recast a number of times, and actual work has been commenced only recently. The canal will be 50.33 miles in length, will have a channel 9.84 ft. deep,

and will accommodate barges of 2,000 tons burden. The cost has been fixed at $13,703,000, of which the State is to pay $6,851,000, the town and department councils $2,605,500, and the Marseille chamber of commerce $4,246,000. When this canal was first proposed the Rhone was navigated by steamboats, most of which have been replaced by barges moving in fleets.

Where the French policy of canal, port, and river improvement differs strikingly from that prevailing in the United States is in the matter of original expense. While such works in France are invariably controlled by the State, it is recognized as a fixed rule that the localities through which waterways pass or where ports are created profit to a degree which can not be enjoyed by the community at large, and that these localities should contribute an appropriate part of the primary investment.

In discussing the details of work to be first taken up the Senate committee thus expressed itself: "Priority should be given to enterprises which, while urgently demanded, have also the advantage of an assured financial co-operation amounting to 50 per cent. at least."

The chambers of commerce are usually the instruments through which municipalities contribute, and the obligations so created are usually met by the issuance of bonds, the interest and sinking fund thereof being provided for by the collection of authorized fees, the chamber of commerce being frequently an administrative body. The Marseille chamber of commerce will collect a toll of 2 cents per package upon imported merchandise in barrels, boxes and sacks, and per ton upon merchandise in bulk, as a means of discharging its financial obligation in respect to the Rhone Canal, and it is already collecting fees and rentals with the proceeds of which it maintains certain wharves in a high state of efficiency, for the use of shipping of every nationality.

The length and cost of the French transportation system up to Jan. 1, 1901, were as follows:

Description.	Length in Miles.	Paid by Interested Localities.	Paid by the State.	Total Cost.
Local highways	316,898	$227,740,000	$81,060,000	$308,800,000
National highways	23,656	....	303,975,000	303,975,000
Tramways	2,628	126,608,000	....	126,608,000
Local railroads	2,971	88,587,000	2,509,000	91,096,000
Trunk railroads	23,784	1,920,736,000	834,532,000	2,755,268,000
Rivers and canals	7,397	6,755,000	322,503,000	329,258,000
Ports	......	25,669,000	174,858,000	200,527,000
Total	377,334	$2,396,095,000	$1,719,437,000	$4,115,532,000

The freight embarked on canal and river boats for the past four years was as follows:

	1903. Tons.	1904. Tons.	1905. Tons.	1906. Tons.
Canals ...	18,513,471	18,195,000	18,657,806	18,357,339
Rivers ...	14,617,471	14,243,701	15,119,534	15,381,963

Freight rates by canal are materially lower than rates upon the same merchandise by rail, but the difference is less striking perhaps than an American investigator might expect. On March 23, 1907, the comparative rates per ton from Cette to Toulouse and Bordeaux were as follows:

Articles.	Cette to Toulouse. Rail.	Canal.	Cette to Bordeaux. Rail.	Canal.
Wine	$1.33	$1.16	$2.02	$1.64
Wheat	1.33	1.06	2.02	1.73
Oil	3.38	1.16	4.90	1.73
Petroleum ..	1.33	1.21	2.02	2.02
Phosphates...	1.43	1.16	2.39	1.93
Coal	1.84	.77	2.87	1.45
Tiles	1.96	1.16	2.99	1.93

Nearly the entire freight traffic on the Rhone River is controlled by one company, which enjoys a practical monopoly thereof, but there appears to be no reason why other companies, if equipped with the necessary capital and provided with an efficient fleet, might not enter the field. Although shipments by river to Marseille are transported a much greater distance than shipments forwarded by rail, on account of the absence of the connecting canal now being constructed between Marseille and Arles, river freight rates are nevertheless considerably lower than those quoted by the railway company. The following sample scale of prices prevailed on March 26, 1907, upon the two routes, Marseille to Lyons:

Article.	Water. Per Ton.	Rail. Per Ton.
Soap	$2.07	$2.89
Vegetable oil........	2.99	4.24
Wine in casks........	2.70	3.38
Petroleum	2.70	3.86
Coal	1.54	2.41
Wheat	1.93	2.63

Between Marseille and Lyons canal and river tonnage is always available for any amount of freight that may be offered. The business is not very remunerative on account of the strong competition of the railroad company.

As to whether it would pay to build the French canal system now, had it not been called into being before the existing railways were constructed, can be answered in the affirmative. It is very unlikely that various cities, notably Marseille, would be clamoring at this time for the right to spend their own money upon improved waterways, if they were not convinced of their practical utility. While the French railway system, with the exception of some comparatively unimportant lines, is the result of private enterprise backed by government guarantees, according to the French theory of political economy they belong to the state, and ultimately will be brought under state ownership, as they are already under state control. It is considered that the railways and canals both have their particular function in the modern state, and that the proper equipment for economic development is incomplete without both. Referring to the results already obtained in France from an imperfectly developed system of waterways, the Senate committee said in 1903:

"It is important that we achieve the concordance of the dimensions of intercommunicating canals, and that we select for first execution the waterways yet to be constructed which appear to be of the greatest necessity. It is impossible to deny that traction itself is less costly by water than by rail. The interested localities have the right to demand the connection of existing railways and canals, where such connections would be favorable to the trade of regions not in direct contact with the canals. In nations where canals and railways are in the hands of the state, this has been accomplished already. . . . Where transportation by water and rail are both available, they complement and complete each other, the one transporting heavy materials, the low cost of which is an indispensable condition to the vitality of industries which aliment in their turn the traffic of the railway lines."

A New Type of Current Insulator for high-tension transmission lines was suggested by Mr. H. W. Buck at the recent meeting of the American Institute of Electrical Engineers, which bids fair to materially change present methods of line construction. It consists of a simple form of unreinforced strain insulator with wide flaring petticoats, which are linked in series to support the line wires by a swinging suspension at each pole. At intervals of about every 10 poles, the line is anchored in either direction by the strain links similarly arranged. It is claimed that but 10 towers or poles need be used per mile with this construction, and that the voltage carried is limited only by the number of insulators inserted in the links, only four of the insulators in series being needed for a 100,000-volt line.

The Vacuum Heating System in the Godfrey Block, Grand Rapids.

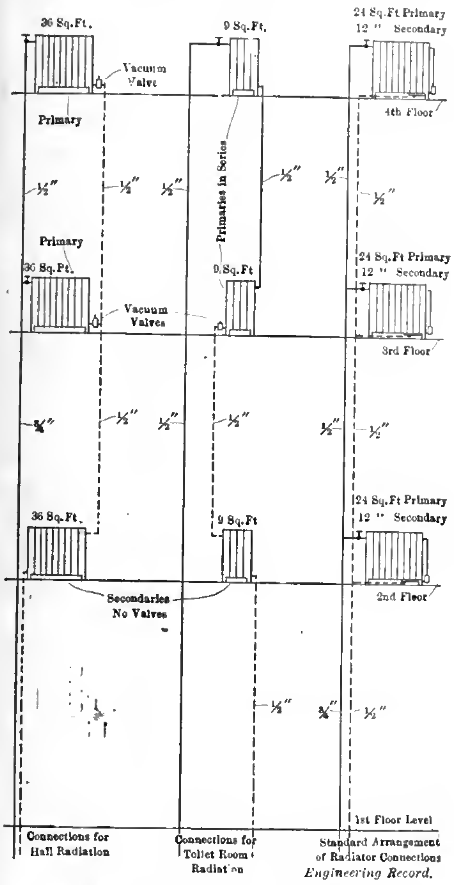
A vacuum steam heating system has recently been installed in the Godfrey Block at Grand Rapids, Mich., which is a departure from the usual arrangement of connections and radiation for vacuum heating. The building is a four-story and basement brick structure having a north and western exposure. It is 27x110 ft. in plan and is occupied by stores on the lower floor and offices on the upper three floors. It has an unusually large amount of window glass exposure, rendering it difficult to heat, and was recently refitted with a low-pressure two-pipe steam heating system having a total of 2,500 sq. ft. of radiation for the entire building, which has a novel system of return connections.

The requirements of the building for heating were for about 400 sq. ft. of radiation on each of the three upper floors, 750 sq. ft. on the first floor and 186 sq. ft. in the basement, in addition to the exposed mains. The distribution of heating surface on the three upper floors is such that there are ten units on each floor, while that upon the main floor consists of nine comparatively large units, arranged so that by supplying five of the first-floor radiators from the basement ceiling main, the upper floor equipment could be supplied from seven riser lines. These risers, as installed, carry from 96 to 386 sq. ft. of radiation each, and are of only ¾ to 1¼-in. pipe, whereas, as ordinarily figured, these amounts would have required 1½ and 2-in. sizes. The return risers are similarly of ½ and ¾-in. pipe, owing to the use of the vacuum system. The supply risers receive steam through a basement main connected to the boiler through a 1½x3-in. reducing valve. This main divides into a 1-in. line supplying a ½ and 1-in. riser at the rear and a 2½-in. main extending around the front side of the basement ceiling and supplying the remaining risers and radiator connections. The return system consists of a vacuum main on the ceiling and ranges in size from a ½-in. line at the extreme end to a 1¼-in. line at the return pump.

The selection of this particular range of pipe sizes is the result of the adoption of the Simonds compound vacuum system, which makes use of the heat carried in the return condensation in special radiation. Secondary radiators are so connected with the vacuum valves of the main radiators that the considerable amount of heat carried in the water of condensation after having passed through each main radiator and its vacuum valve is utilized before it enters the return mains. The water of condensation discharged from radiators in the ordinary low-pressure steam heating system ranges from 208° to 210° Fahr., and difficulty is often experienced with re-evaporation when this heated water passes through the discharge valve into the vacuum of the return line. This difficulty is here utilized by the installation of the secondary radiator units, the steam from the boilers being fed through the usual distribution system to the main radiators while the secondary sections receive the water of condensation which the main sections discharge through the regular vacuum valves. These secondary radiators are in all cases installed in capacities about one-half of those of the main or primary radiator units, it being figured that the heated water passing into the vacuum of the return lines will re-evaporate to a greater or less extent so that the secondary radiation will be of actual value as heating surface. This is borne out in actual experience, the condensation passing from the secondary radiation to the vacuum pump as solid water and no difficulty being experienced with

re-evaporation in the return lines, with consequent necessity of injecting cold water into the pump suction to condense vapor carried through and permit effective operation of the pump.

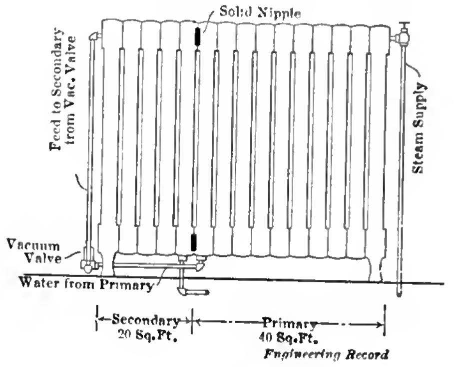
The radiation in the Godfrey Building is, for the greater part, installed on the usual compounded plan, with both primary and secondary sections in close proximity, although there has also been incorporated in this installation an unusual arrangement of primary and secondary radiation separated on different floors. This is carried out in the hall and toilet-room radiation, each of which groups has two primary radiators located on the third and fourth floor levels, which discharge their condensation through a single secondary radiator on the second floor level,



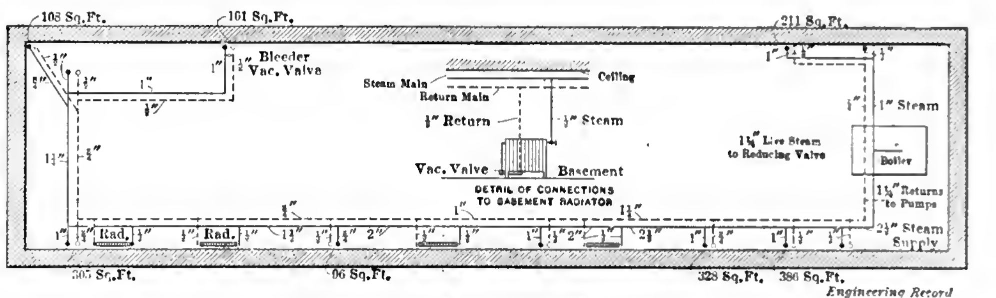
Details of Radiator Connections.

the only difference from the regular arrangement of units being that the secondary radiation is on a lower level to which the water of condensation flows freely. In the case of the hall radiation, there is a 36 sq. ft. radiator on both the third and fourth floors to which steam is delivered directly from the riser lines, each delivering through its regular vacuum valve to a ½-in. return line carried down to the secondary radiator of the second floor level; this return line feeds vapor and water of condensation to the secondary radiator, which is also a 36-sq. ft. unit and thus serves as an effective heating surface equal in capacity to that of the hall radiators above, except for the slightly reduced temperature due to the vacuum of the return system. In the case of the toilet-room units, a somewhat different arrangement was made. Here a 9-sq. ft. radiator is installed in the toilet on each floor, but steam is supplied to them by a ½-in. riser leading to the unit on the fourth floor only. This top floor unit has no vacuum valve, but the return connection is connected directly to the steam inlet of the similar unit on the third floor, and this unit has the regular vacuum valve to serve both units, which discharges the water of condensation and vapor to the second floor unit, as in the preceding case.

In the radiation installed in the various offices, the original arrangement of using separate radiator units for primary and secondary radiation has been dispensed with and compound radiator units installed. These consist of cast-iron sectional radiator units of the usual type, except that one-third of the columns on the return end are isolated from the other two-thirds on the inlet end by solid nipples at top and bottom connections, both sides having inlet connections at the top of the outside columns and return connections at the bottom of the inside columns next to the solid nipple. The arrangement of connections is, as shown in the accompanying detail sketch, for steam supply to the top of the outside column of the primary or inlet end, and return connections from the base of the inside column of this primary end to the vacuum valve which in turn discharges its condensation into the top of the outside column of the return or secondary section. In this section, the condensation vaporizes under the vacuum and effects additional heating surface, after which the water of condensation passes freely to the vacuum return system without encountering further valves or obstructions. This renders the radiators com-



Compound Radiator.



Heating Mains in Sub-basement.

pact, and no difference in appearance from the ordinary units. There is, it is stated, no difficulty experienced in raising the water of condensation from the vacuum valve up to the inlet end of the return side of the radiator units, as it is found that the condensation after passing the vacuum valve into the vacuum of the return line vaporizes partly if not wholly, merely condensing in the secondary section of the radiator to water before entering the return lines. In fact, no difficulty is said to be experienced in lifting the condensation considerable distances, as in the basement radiators the return lines are located on the ceiling and condensation is easily raised from the secondary unit to this level, a rise of about 9 ft.

Steam is supplied to the building by an Atlas internal-fired horizontal shell boiler of the marine type with internal furnace. It is a self-contained unit and is set without brick work, the shell being encased with asbestos block covering. It is of 40 h.-p. rating, being planned for sufficient capacity to operate the heating system on the ordinary method with gravity returns and also another building adjoining. It operates at 20 to 30 lbs. pressure and delivers to the heating mains through a pressure-reducing valve which lowers the pressure to about atmospheric, this being varied from 1-lb. pressure to 4 in. vacuum, according to the heating service required. The vacuum pump is a 4½x5x8 in. Burnham simplex pump which delivers from the return mains to a receiving tank, and from here the condensation is returned to the boiler by a simplex feed pump of similar make which has 3x2x3-in. cylinders.

The results that have been obtained from this system have been very satisfactory, the heating service having proved adequate in all parts of the building. The system as now installed was operated with a fuel consumption of 72 tons of mine run of soft coal for the heating season of 1905-6, while last winter but 69 tons were used. The small sizes of mains for steam supply and return contribute largely, it is thought, to the economy of the system, but, of course, the principle factor of saving lies in the reduction in the secondary radiation of the temperature of the condensation returns to a point where the injection of cold water into the vacuum pump suction, with consequent heat waste, is not necessary for proper operation of the pump. The system was designed and installed by the Simonds Heating & Specialty Co., Detroit, Mich., who control this system of vacuum heating.

Electric Locomotives of the Pennsylvania Railroad.

With a view to determining the type best adapted to pulling its heavy passenger trains through the New York tunnels, the Pennsylvania R. R. has in progress a series of experiments upon electric locomotives. Through the experiments on the West Jersey and Seashore division and the Long Island R. R., the company hopes to determine the general characteristics of the electric locomotive and to secure operating data based on actual service. Of the two direct-current locomotives now undergoing tests, one is equipped with four 350-h.-p. geared motors, and the other with four gearless motors. The gearless locomotive has one of its trucks equipped with two 320-h.-p. motors supported by springs from the main journals and independent of the truck frame, while the other truck has two 300-h.-p. motors rigidly fastened to the frame. In exterior appearance the two locomotives are almost identical. The trucks are of the four-wheel type, having frames placed outside the wheels, with pedestal boxes and adjustable wedges similar to those used in locomotive practice. On account of their short wheel base, the trucks have a tendency to tilt in operation, and thereby shift a portion of the effective load from one pair of wheels to the other. By an ingenious automatic switching mechanism the power delivered by the motor on the heavily loaded axle is increased and the power delivered by the motor on the lightly loaded axle diminished, in proportion to the difference in axle loads. By this expedient the pulling power of the locomotive is increased 25 per cent. The driving wheels are 56 in. in diameter. The cab is entirely of metal. The control mechanism is in duplicate and placed in diagonally opposite corners of the cab. The locomotives are equipped with hand, straight air, automatic and high-speed brakes. The weight of the geared locomotives is 174,100 lb. while that of the gearless locomotive is 195,000.

Book Notes.

A useful summary of some instructive experiments conducted under the direction of the Engineering Experiment Station of the University of Illinois has recently been published by it under the title of "Effect of Scale on the Transmission of Heat Through Locomotive Boiler Tubes." For a great many years it has been generally held that scale 1-10 in. thick required an expenditure of 15 per cent. more fuel to accomplish the same results as clean tubes, and doubling the thickness of the scale doubled the resistance to heat transfer. The experiments described in this pamphlet give materially different results. Some of them were made on a locomotive equipped at first with scaled and then with clean tubes and others on individual tubes procured from railways running through the Central States. They show that the loss in heat transmission with scale up to ⅛ in. thick varies between insignificant amounts to 12 per cent., and depends more on the mechanical structure of the scale than its thickness.

A book useful as a detailed account of the development of public health regulations in the British metropolis is "The Sanitary Evolution of London," by Henry Jephson, of the London County Council. It describes in the first chapter the sanitary measures taken prior to 1855, and gives quotations from reliable publications regarding the frightful state of filth in which a large part of the population were forced to live. It then takes up the progress made in each subsequent decade, explaining how the peculiar municipal subdivision of the district acted as a steady obstacle to progress until means for overcoming it were found. There were public commissions for paving, Mr. Jephson states, others for street improvements, others for lighting, and others even for bridges across the river. All in all, several hundred such commissions had been created without any relation one to the other, and without any central controlling authority, by as many acts of Parliament. They were mostly self-elected or elected for life or both, and were wholly irresponsible to the taxpayers, or to anyone else, nor were their proceedings in any way open to the public. Many of them had large staffs of well-paid officials and there were perpetual conflicts of jurisdiction between them and an absolute lack of anything approaching municipal administration. The development of sanitary improvements from such a condition of divided authority is traced in much detail in this book, and in many places the author's comments on measures and conditions are decidedly interesting, although all readers will not agree with his views. The book is one of those valuable reviews of engineering progress that are all too rarely written because of the great labor involved in collecting and compiling the data. (Brooklyn, 203 Fulton St., A. Wessels Co., $1.80).

One of the most interesting pamphlets relating to street improvements that has appeared in a long time is the "Specifications for Street Roadway Pavements," by Mr. Samuel Whinery. The author believes that in the present state of the art it is entirely practicable to frame specifications for paving materials and methods so that the engineer and municipality may safely assume responsibility for the quality of the work produced. It is his opinion that a contractor who negligently or purposely violates specifications during construction is unlikely to be more faithful or scrupulous in living up to any guarantees he may make with regard to the future, even where the terms and conditions of such guarantees may be clearly defined and indisputable. When his specifications are viewed in this light they are distinctly good, and subject only to the single general criticism of being so detailed that many engineers will probably prefer to abridge them for actual use. In respect to the details, there are a number of points with which The Engineering Record does not agree. It does not believe, for instance, that the contractor should be required to deliver cement for pavement foundations on the work at least ten working days before it is to be used, as the author suggests, for it is just as well at times to keep it in the cars or warehouse until actually needed, for it can be inspected there as easily as in a storage shed on the street. As regards the proposed requirements for asphalt there are details which seem unnecessarily severe and the necessity of specifying anything but the asphaltic cement is certainly open to question. In this respect the new Kansas City specifications will be preferred by many engineers, since their requirements are confined to the asphaltic cement, the material actually used. If the specifications go into the detail suggested by the author they must only be used by someone in close touch with the progress of asphalt technology, and even then the requirements will be open to criticism. For example, the author states that crude asphalt must be refined at a temperature not exceeding 450° Fahr., and material which does not distinctly soften at 185° will not be accepted. As a matter of fact some useful bitumens are injured at 450° and some of the best show no distinct signs of softening at 185°. Again, the section on refined asphalts excludes some of the Cuban asphalts which can be handled satisfactorily with an asphaltic flux. In this section there is also a clause relating to a test of asphalts in water which seems extremely severe in view of the showing made in actual service by asphalts which this clause would reject. In the section relating to flux, the requirement of a specific gravity of less than 0.958 would exclude admirable fluxes with an asphaltic base having a specific gravity of 0.96 to 0.99. In the section on asphaltic cement, there is a requirement regarding viscosity which would throw out material made from California residual pitch and might cause the rejection of good material made from Cuban and Trinidad asphalts. These are a few of the features of the asphalt pavement specifications which are open to criticism and similar comments might be made on the suggested specifications for asphalt blocks, granite and brick. They are pointed out to show the well-defined differences of opinion that exist regarding details of paving lest the reader should regard the specifications, good as they are as a whole, as beyond criticism in detail. (New York, Engineering News Publishing Co., 50 cents).

Letters to the Editor.

The Cause of the Quebec Bridge Failure.

Sir:—I understand that no allowance was made for secondary stresses in the design of the Quebec bridge, and also that the connection joining the lower chord members of the anchor and cantilever arms was rigid. This does not allow the adjoining chords to take their proper position, while the deflection takes place, without developing considerable bending stress in the chords. I would not be surprised to find the secondary stresses caused by this bending to run up as high as 50 or 100 per cent. of the direct chord stress and so might largely have contributed to the failure. I would therefore suggest checking the truss strain sheets for secondary stresses in the chords.

I have had much experience with secondary stresses in bridge members and have found them in some cases of great importance, and therefore would never neglect them unless the trusses were designed to minimize them. Rigid connections between anchor and cantilever lower chords have been used in other important bridges where they have given much anxiety, and I am convinced that they should always be eliminated and a connection designed with both members free to adjust themselves independently on the pin center. In the case of the Quebec bridge the effect of the secondary stresses is greater on account of the great depth of the trusses, and the corresponding considerable deflections of the first and second panel points from the main pier on both sides, tending to produce contraflexure, which, in webs of the depth there existing, develops enormous stresses to augment the primary stresses. This effect becomes less farther from the pier and, beyond the feet of the first diagonals, is not transmitted to the first two subpanels of lower chord. The V-shape member used in the Quebec bridge is, moreover, very difficult to build in the shops, very difficult to check and verify after construction and quite liable to inaccuracies in the angle and bearings, and in exact dimensions, any of which might concentrate the excess load on a very small area until the latter yielded enough to distribute the stress.

Bridge Engineer.

Unit Spiral Tables.

Sir: I have examined with much pleasure the table and explanatory matter for Talbot's Spiral in your issue of Sept. 7, and feel certain that all field men who use this easement curve will find it a great help. As stated in the article the unit table is partially developed in the printed editions of this spiral, and the advantages pointed out, but Mr. Kyle's table is much more extensive. The great advantage, to my mind, of a unit table lies in the fact that it embodies under one series of headings all of the quantities necessary for running the curve, while all other tabulated spirals that I have seen have from a dozen to thirty distinct tables, each one of which is applicable to a certain chord length, though sometimes, also, to the multiples of that length. This advantage was briefly mentioned in your article, but, in my opinion, should be emphasized. There is but one table to turn to and never any danger of taking values that apply to a different set of conditions, a cause for frequently re-running spirals.

Though not thoroughly conversant with the mathematics of many spirals I believe that a unit table like the one you have presented is possible only with a spiral such as Talbot's, in which the chord length can be varied from point to point along a given curve, in the same fashion as a circular curve can be run by setting intermediate points wherever desired.

It must have occurred to many of your readers that the table as set up in the regular edition of The Engineering Record is in rather cumbersome shape for field use, and I hope that you have decided to reprint it, together with the explanatory matter, in handy form. It would do much toward placing in the hands of field men one of the most conveniently arranged tables I have seen.

Very truly yours,

Chicago, Ill. N. E. A.

A Uniform Retardation Brake Gear is in use on the North-Eastern Ry. in England. It consists of an inclined slot mechanism applied to the brake shoes so that, as the grip on the wheels increases, owing to the greater coefficient of friction at decreased speeds, the shoes are drawn away slightly and the pressure relieved somewhat. It is said that the device prevents gripping and skidding. With plain gears the braking pressures are kept well below the weight carried on the wheels, but with this gear they are increased to 160 per cent. of that due to weight and then are reduced automatically as the train stops.

THE ENGINEERING RECORD
Published Weekly by the
McGraw Publishing Company
James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.
MAIN OFFICES:
239 West 39th Street, New York.
BRANCH OFFICES:
Chicago: Old Colony Building.
Philadelphia: Real Estate Trust Building.
Cleveland: Schofield Building.
San Francisco: Atlas Building.
London Office: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.
United States, Cuba and Mexico............$3.00 a year
Canada ....$4.50 a year
Foreign subscription......................$6.00 a year
25 shillings. 25 marks. 31 francs.
Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.
Changes in advertisements intended for a particular issue should reach the office of The Engineering Record on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.
Remittances.—Remittances should be made by check, New York draft, or money order, in favor of The Engineering Record.

Changes of Address.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

Back Copies.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.

Date on Wrapper indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

Club Rate.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. The rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 14,250 copies are printed. Totol circulation for 1907 to date 552,250 copies, an average of 14,533 copies per week.

TABLE OF LEADING ARTICLES.

The Calumet Canal.

The Chicago Real Estate Board has been looking into the project of the Trustees of the Chicago Sanitary District to construct a canal for the disposal by dilution of the sewage of the Calumet district, and its committee appointed to investigate the subject has protested vigorously against the proposition to construct such a branch of the present drainage canal. This Calumet canal is proposed by the Sanitary District trustees on the ground that it is needed to care for the sewage of the district about the Calumet river, that it will furnish a navigable waterway, and that its construction will enable a large water-power to be developed. It is pointed out that these triple aims complicate the problem, originally a purely sanitary one, and do not provide any further improvement of the Chicago river which, in view of the money already spent on the drainage works by Chicago taxpayers, might be considered of considerable weight. Some astonishing figures to show the importance of an immediate betterment of the river are given in the committee's report on the authority of Colonel Bixby. It is stated that in 1889 the tonnage entering the Chicago river was over 9,000,000 tons while in 1905 the tonnage entering both the Chicago and Calumet harbors was only 7,000,000 tons, excluding the shipments of iron ore which did not amount to much on the earlier date. During the same period the tonnage entering Duluth harbor increased from 3,000,000 to 22,000,000 tons, including about 7,000,000 tons of miscellaneous freight during 1905. The tonnage entering Milwaukee harbor in 1905 was at least fifty per cent. more than that of 1893. These figures are asserted by the Real Estate Board to indicate that the interests of the Chicago river as a harbor cannot be neglected upon the supposition that what is lost to the river will be gained through the Calumet; it is claimed, in other words, that so far as any navigation advantages resulting from drainage canal work are concerned it would be far better to concentrate attention on the Chicago river.

Turning from the navigation to the power aspect of the projected Calumet canal, the same arguments are advanced. The Real Estate Board claims that the argument for spending $13,000,000 for the new canal in order to develop power which can be sold for enough to pay interest on the cost of the work, is really as good an argument for obtaining the same amount of power by enlarging the Chicago river. It is true that the cost of the latter work is estimated at $20,000,000, but the additional expense is well worth while on account of the improved navigation facilities afforded, according to the report of the committee. Another aspect of the matter is also brought out in a letter to the committee by Mr. John W. Alvord. "It is a little difficult to see how this project," he writes, "which looks on the face of it to be purely for commercial purposes, can be related to the sanitary problems of Chicago, for which the district was created, and when one considers the risks and disappointments attending a business enterprise of this sort, it seems to be an open question if it is desirable for a public board to commit a municipal corporation like Chicago to a purely business enterprise, which is admittedly entirely unnecessary for the sanitary betterment of this community."

So far as the sanitary aspect of the problem is concerned, attention may be called to the report on the Calumet sewage disposal problem made by Messrs. Hering and Fuller some time ago to the International Waterways Commission and reviewed at considerable length in this journal on February 2 of the current year. In this report it was shown that for the Calumet district there are several methods of sewage disposal as effective as the method of dilution in preventing the pollution of the lake water, the most advantageous one being the use of septic tanks and sprinkling filters. This report is much more encouraging than a good many people in Chicago probably realize. It means that when the capacity of the present drainage canal as a receptacle for sewage has been reached, other methods of disposing of the surplus sewage are available, and if Chicago continues to grow as she has in the past the time is not so far distant when the modern methods must be adopted. It seems hardly conceivable that all the great cities depending in a large measure on their harbors for their prosperity will calmly allow Chicago to divert more water from Lake Michigan for sewage disposal purposes when that diversion means such a lowering of the level of the Great Lakes that navigation will suffer unless costly dredging is undertaken.

The continuation of this method of sewage disposal by Chicago seems likely to become wrapped up in a great project of a Lakes-to-Gulf waterway, and it is pertinent to inquire whether the advocates of this latter project have yet stated where the water for navigating the upper section of this great channel is to come from. If it is to be drawn from the Great Lakes it is surely in order to suggest that its effect on the American and Canadian harbors should be carefully investigated. The great commerce centering in them is an accomplished fact, a matter of pride to those engaged in it, and its injury for the purpose of enabling Chicago to dispose of sewage which can be otherwise handled, or to build a big power station, or to develop an inland waterway which is of problematical value, seems neither wise as a matter of transportation nor necessary as a sanitary measure. The deep waterway convention to be held in Memphis shortly will be well worth watching by the Great Lake cities on account of the facts just stated. The diversion of 10,000 cu. ft. of water per second by the present canal, which was permitted by the Deep Waterways Commission as a sort of moral obligation for not stopping the construction of the drainage canal at the outset, is stated by that Commission to be equivalent to a lowering of the lake levels from 4½ to 6½ in. The tremendous effect on lake commerce of any further lowering by a greater diversion of water is something to be regarded with apprehension.

Another Lesson on Signals.

Last week this journal made some comments on the dangers which lurk in current practice in railway signaling. Following it with frightful rapidity comes the news of another ghastly "accident" on a New England line in which more than sixty passengers were killed or hideously mangled. We all remember General Sherman's characterization of war, but the intentional slaughter of war is a Sunday School picnic in comparison with the awful details of such a tragedy as this. The soldier who follows the flag into the Valley of the Shadow has at least given his life for his country's welfare, but what consolation is it in the last bitter moment to him who is torn and crushed in the shattered wreckage of a train that he has helped to save the expense of a good signal system? In the case before us an express train, late and trying to make up time, met a heavy freight train in the gray mist of dawn in a headend collision. Probably somebody blundered, as is usual in such cases, a telegram went astray or was misread, and the usual result followed. If these collisions were an inevitable part of modern transportation, if they occurred impartially under every system of management and in every country, one might perhaps learn to take them philosophically and, thanking his lucky star for personal escape, go about his business without a protest.

It happens, however, that, as compared with other countries, our own has a sinister prominence in such calamities. The sanguinary casualty list of American railroads rises to near a hundred thousand victims annually. It is probable that accidents will never be entirely averted, yet comparison with records abroad shows that they can be greatly reduced in frequency by proper and usual precautions. There should certainly be means independent of mere telegraphic notice to prevent two trains from meeting on a single track, either in a head or rear end collision. The morning mists in the valleys of northern New

England are not new phenomena taking the unhappy railway men unaware. They are of regular occurrence before a clear autumn day and a known source of danger. They make the regular visual signals of no effect and prevent the trainmen from looking far enough ahead to clear the ordinary danger space. There is no use in writing down the catastrophe as an act of Providence, for there is no Divine law that prohibits the installation of good signals. Rather it must be set down to the blindness of those who will not see and the negligence of those who hold the lives of others cheap when it comes to a matter of business. It is one more evidence of the frightful inefficiency of the methods of signaling and train-dispatching used upon far too many railroads. It is high time for reform and for the introduction of better appliances. It is certainly not impossible to gain a far greater degree of security than now. Whatever system is used it is imperative to employ signals that can be made clear over at least the dangerous space of the train and that cannot be rendered useless by so common a cause as an early morning mist.

The Improvement in the Railroad Situation.

For a year or more engineers have necessarily been impressed by the important influence of public sentiment on the condition of undertakings in which a large proportion of their profession is engaged. Civic pride determines in a large measure the character of municipal works; in a community marked by business strength and public spirit the engineering works are generally planned on a broad and liberal scale and the men entrusted with their execution have the respect and confidence of the public. On the other hand, in cities which are devoid of this civic good feeling, public works are neglected and engineering offices are looked upon simply as political prizes. The sentiment towards public service companies affects engineering in a still greater degree. These companies must operate under franchises and rights of one sort or another granted by state or city legislation, and the feeling of the public toward them manifestly affects the character of the privileges they will obtain. Moreover, public service corporations are still more vitally influenced by the effect of public sentiment on the prices of the securities of such corporations. The great works these companies carry out must be constructed by private capital, and without reasonable security in investments of this nature, people are naturally loath to lend money for such undertakings. The extent to which these considerations influence the engineering profession can be readily understood by an examination of the lists of members of the four national engineering societies; it will be seen that an extraordinary percentage of the members are engaged in enterprises directly affected by public sentiment or in the manufacture of supplies for such works. Under such circumstances it is self-evident that the engineer should study these problems of the relation between the public and public-service companies from a purely selfish point of view as well as on account of his obligations as a citizen of a democracy. The hysterical waves of public antipathy toward all companies engaged in public-service work are unfortunate from every point of view.

It is encouraging to observe how the hostile spirit shown toward railroads and in a somewhat less degree toward street railways during the last two years is now subsiding. There was a time not so very long ago when the railroad official who held any feeling of regard toward the public except as a source of revenue was hard to find. After a street railway or electric lighting company received its charter and franchise it generally assumed toward the public an attitude which indicated its belief that it was engaged in business in exactly the same way as a commercial corporation conducts a department store. The fact that it was operated by public permission in a distinctly public service, affecting the methods of business management which it could rightfully follow, seemed for many years to be overlooked. When the public became dissatisfied with the service rendered, the possibilities of retaliation which the people possessed were overlooked or under-estimated by the companies' officials. The experience of the last two years, particularly the last winter, has shown that the public control of such companies is sufficiently great to thwart methods of management that persistently ignore public rights. From one end of the country to the other it is now recognized by all far-sighted men that the time has gone by when the capitalization of a public service corporation may be safely based upon anything but the cost of constructing the works and meeting the expenses incidental to the beginning of regular efficient service. The day of capitalization based upon maximum earning capacity has gone by.

In an interesting address at the fourth annual meeting of the Association of Transportation and Accounting Offices, Mr. A. G. Briggs, general attorney of the Chicago Great Western Railway, made the following statement: "The railroad company was organized upon the agreement that the stockholders might build, equip and operate the railroad, furnish proper service to the public and charge for that service a reasonable compensation; but always with the reservation, clearly understood, that should the stockholders fail to render proper services or should they charge more than a reasonable compensation for them, the state might, at its option, assert its right to regulate or control the railroads, determine what service should be rendered, how it should be rendered, the terms on which the road should be operated and for what compensation. This reserved right is absolute, limited only by the rule that the state cannot confiscate the stockholders' property or deprive them of a reasonable return on their investment." It is particularly instructive to notice that Mr. Briggs, speaking as a railway man to railway men, refused to consider the recent legislation against railroads and other public-service corporations as the work of demagogues. With some few exceptions, in his opinion, those responsible for these laws did their duty as they saw it. He believed the great majority of officials and legislators have tried to learn and do what is right, and the legislation they passed was due in no small measure to a general public opinion that no reliance could be placed on statements by public-service corporations. Unconscious prejudice is a potent factor in influencing legislation, and the measures of last winter are to be accounted for by it rather than by evil motive. He believed that the wave of public distrust had passed early in the summer, and that it was the duty of everyone connected with public-service corporations to win back confidence in the intention of such companies to render efficient service.

The other side of this matter was stated at some length at the meeting of the American Association of Freight Traffic Officers on September 14, by Mr. Martin Knapp, chairman of the Interstate Commerce Commission. His long connection with that Commission lends particular weight to the opinion, stated emphatically, that the Sherman anti-trust law defeats the purpose for which it was passed, and if it were not violated by the railroads we should have a chaotic condition suited only for savagery. This is an acknowledgment of the necessity of improved legislation deserving careful attention. Mr. Briggs told the railroad men he addressed that the greater good of railroads is in maintaining government inviolate, rather than in escaping temporarily the effects of a single valid law or of several such laws. It was his opinion that whether a law was bad or good the railroads should abide by it until it was repealed or amended. Mr. Knapp, speaking as the public official most directly concerned with enforcing national legislation concerning railroads, stated that the anti-trust law might have been applicable in the old days of stage coaches but was unsuited for present conditions. With railroad men like Mr. Briggs urging obedience to the laws and attention to reasonable public wishes, and officials like Mr. Knapp urging the passage of laws which will be helpful rather than harmful, it seems reasonable to anticipate that before long a more complete appreciation of the necessities and methods of control of public-service corporations will result in more equitable legislation, better service and less public distrust of such companies.

The Protection of Trade Secrets.

The protection of trade secrets was the subject of an important address by Mr. F. P. Fish before the American Society of Mechanical Engineers some months ago and since then several courts have decided cases of this sort. There is one feature of the matter, however, which has only recently been discussed judicially, although it is something that must have frequently been considered by manufacturers. This is the extent of the protection which will be afforded to a company employing a secret process not devised by anybody connected with it and obtained from another source than the original inventor. A case of this nature has recently been passed upon by the New Jersey Court of Errors and Appeals in the Vulcan Detinning Co. v. American Can Co. et al., 67 Atl. Rep., 339. The facts in this case are substantially as follows, according to the statements made by the court. Until about ten years ago the detinning of scrap had not been carried on successfully in this country although such a process was successfully operated abroad. This fact was well known to the dealers in tin scrap who had a large trade with a Flushing establishment as well as with one in Essen. In 1898 a number of American dealers and manufacturers agreed to build a plant for detinning scrap in this country providing a license for using the foreign method was obtained. In order to secure this license Adolph Kern, a dealer in scrap tin, was sent to Europe and obtained the secret from the Flushing company with permission to install it in two plants in the United States. These plants have passed into the possession of the Vulcan Detinning Co., the complainant in this case. The process was discovered by Goldschmidt Bros. and used by them in 1891 in Essen, where it was guarded as a secret. The same process was used at Flushing, where it was also kept a secret, although it had been obtained from the Goldschmidt works clandestinely. The Americans who obtained the secret from the Flushing establishment guarded it zealously. F. A. Assmann, one of the original promoters of the complainant company, was so impressed with the importance of guarding the process that he himself became individually the trustee of a copy of the formula for the express purpose of guarding it for the mutual benefit of himself and his associates. The business was a commercial and practical success from the outset. In 1901 Assmann transferred his personal interest as a manufacturer of tin cans to the American Can Co., the defendant in this case. He became its president and sold to it all of his holdings of stock in the two detinning companies, resigning his directorship in each. He also was the leading spirit in the installation for the American Can Co. of two detinning plants using the process employed by the complainant, and called to his assistance three former employees of the complainant.

The testimony in the case, according to the

decision rendered by the court, admits of no other conclusion than that the detinning plants which came into existence in this way in competition with those of the complainant, are employing the process originally purchased by the complainant which Assmann undertook to safeguard in its interest. That this result was brought about by a breach of confidence upon his part toward his original associates, both as regards the use of the process itself and the enticement of the former employees of the complainant, is stated by the court to be the only legitimate inference that can be drawn from the proofs. That in both of these respects he was acting directly on behalf of the defendant corporation of which he was president is decided to follow as a necessary deduction. The result of such conclusions is to raise the question whether upon such facts the complainant is entitled to any relief, and if so, to what extent.

The defendant's counsel argued that the complainant was entitled to no relief because the secret process it sought to enjoin the defendant from using was not, in fact, a secret, and moreover if it was a secret, the legal title to it did not exist in the complainant. From what has been said concerning the source of the secret, and the organization of the various companies in this country using it, it will be seen that the case is unusually complicated. The court discusses it at considerable length and the various considerations it mentions are of such a strictly legal nature that it is hardly necessary to follow them at length in this place. The conclusion to which they lead is that, entirely aside from the technical secrecy of the process or the abstract question of property in it, the complainant company is entitled to have its former trustee, Assmann, his associates and their servants restrained from using against the interest of the complainant the very process with which Assmann was entrusted for its benefit. The court points out that, apart from the peculiar rights of its discoverer, the secrecy of a process may be viewed in two aspects; first, as having for its object the keeping of the public in ignorance of the nature, source or composition of a commercial product that is put upon the market, and second, as having for its object the prevention of competition by rivals in production. In this case the publication by Assmann of the secret would violate the obligation of secrecy in each of these respects, but, as regards the second, the trust is held to be equally violated if the trustee himself uses the secret to engage in such competition, even though, as would clearly in this case be to his interest, he sedulously keeps the secret to himself, excepting so far as his use of it requires the cooperation of associates and servants. The court decides that when Assmann severed his connection with the complainant and installed the process in question for the defendant corporation as a competitor in production, it is the same in equity as if, without having severed such prior connection, he had broken faith with his fellows by imparting to a rival the secret which he had promised to preserve.

Although the court considers that there is no question about this action by Assmann himself, there is some question concerning the relief the complainant should receive against the defendant corporation for which Assmann was acting when he did the acts that constituted his breach of trust. It is all but impossible, the court says, to avoid the conclusion that the directors of the American Can Co. had actual knowledge of sufficient facts to constitute notice that Assmann held the secret of the complainant's process in a confidential capacity. On the other hand it is all but impossible to demonstrate by direct proof that a corporation has knowledge apart from the knowledge possessed by agencies through which its functions are performed. Hence in such a case the mere fact that the complainant is unable to adduce any corporate resolution of the defendant company expressly asserting its knowledge of the complainant's secret and of Assmann's connection with it does not prevent the court from reaching the conclusion that the defendant had such knowledge, if such is the inference to which the testimony tends by irresistible weight of probability. This consideration brings up another intricate point which the court argues at considerable length before reaching its final conclusion, which is that the defendant corporation is amenable to the same degree touching competition and publication as that already accorded to the complainant with respect to Assmann individually. The court therefore orders a verdict to be found restraining the defendant Assmann and the American Can Co. from using or making public this detinning process.

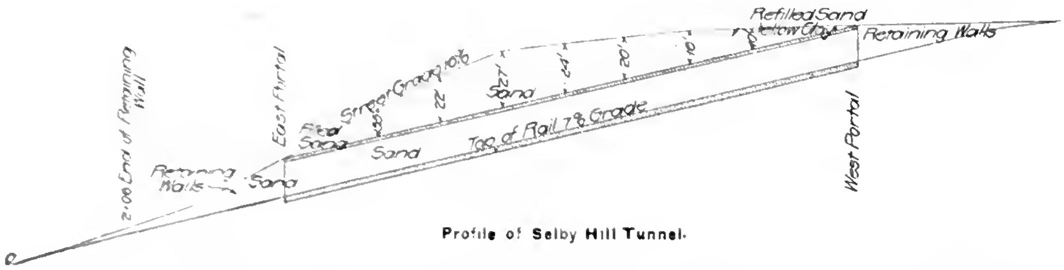
There is one further complication of the case that must be mentioned. There can be no question that Adolph Kern knew of the fact that the process used at Flushing was the same as that employed by the Goldschmidts at Essen and was obtained surreptitiously from them. It was held in one of the lower courts where the case was tried that this knowledge on the part of Kern, who became an agent of the incorporators of the complainant company, must also be imputed to that company, which therefore came into the court with "unclean hands." The Court of Appeals points out that there is a nice distinction in this matter. That the knowledge possessed by an agent but not acquired by him while acting for his principal will, under certain conditions, be imputed to the latter, is in the nature of a presumption indulged in by courts in working out the rights of litigating parties. The Court of Appeals points out that it is never a rule of evidence by which the actual possession of knowledge by the principal can, in point of fact, be established. On the contrary an essential part of the presumption in question is that the principal is ignorant of the knowledge that has been casually acquired by his agent. Hence, by the hypothesis, the principal is not only ignorant of the knowledge thus acquired, but, if such knowledge involves a fraud, the principal is innocent of such fraud. He may be bound by it in the sense that his legal rights may be determined with reference to the knowledge with which he is thus chargeable, but his conscience is void of offense, and hence it cannot be said with propriety that his hands are unclean, for "unclean hands" within the meaning of the maxim of equity that "one who comes into equity must come with clean hands" is a figurative description of a class of suitors to whom a court of equity as a court of conscience will not even listen, because the conduct of such suitors is itself morally reprehensible as to known facts.

Taking the case as a whole, it seems to be one of those which deserve a careful consideration by members of the engineering profession who have to do with inventions and their commercial use. As Mr. Fish pointed out in his address to which reference has already been made, the practice is growing of relying upon trade secrets rather than patents in certain kind of manufacturing. Cases involving trade secrets are bound to come up more frequently in engineering work and it consequently behooves engineers to keep in touch with the legal opinions concerning such matters. On the facts as presented in the opinion of the Court of Errors and Appeals, there can be no question that the decision just reviewed is in accord with principles of equity, particularly in view of the fact that the original inventor of the secret process had refused to take part in establishing a factory in America on the ground that it would be commercially impracticable.

Notes and Comments.

Publicity is again being given in the New York papers to the attempts of speculators to force the Board of Water Supply of New York to pay unnecessarily large sums for land needed in connection with the new Catskill water works. In this connection it might be pointed out that soon after the work in the Catskills was inaugurated the property owners likely to be affected by it were informed that if they cared to rely upon the Board of Water Supply and its representatives for fair treatment they would probably receive far better returns for any of their property needed for the works than they were likely to obtain by any other course. Events indicate that this is true. Those property owners who did not give up title to their land will receive from the commissioners the same sum for the same class of land as the speculators will get who bought property for a much lower price from the original holders. It is very unfortunate that this unwillingness to rely on the fairness of the commission has existed along the line of the new works, but those who have held it must thank themselves alone for the unfortunate results of their poor judgment.

The Battery Tunnel connecting the lower end of Manhattan with Brooklyn is rapidly approaching completion, but not rapidly enough to satisfy many people who wish to use it. Consequently there is a good deal of newspaper criticism of the work which is likely to cause some misapprehension concerning it. The tunnel is a part of a contract awarded by the late Rapid Transit Railroad Commission to the Rapid Transit Subway Construction Co., a subsidiary company of the Interborough Rapid Transit Co. operating the subway. The Construction Company has until May, 1908, to complete the entire contract. It is to its interest to get the work done as rapidly as possible in order that the Interborough train service may be started. It sublet the work in three sections. That in Manhattan has been finished and in operation for a considerable time. That in Brooklyn is well on toward completion although extensive modifications of the plans have delayed it. The tunnel under the East River is almost finished. It presented a number of new engineering problems and, like most subaqueous tunneling, developed difficulties which could not be foreseen. Concrete piles driven under the tubes where they cross fine sand have been carried down 75 ft. in places by the contractors in order to provide an additional safeguard, although Mr. George S. Rice, the chief engineer for the Commission, considered them unnecessary. The tubes have been reconstructed wherever the subcontractor deviated too much from grade, and there is now the same clearance for the cars in these tubes that has been provided in other parts of the subway. The same people who are the general contractors for the work will also have to operate the trains through the tunnel, as before stated, and consequently they have spared no expense to secure substantial and proper work. Unless something now unforeseen arises, which is always possible before the final completion of any subaqueous tunnel, trains will be running before the end of the contract time. Mr. Rice stated recently that cars might be started in one of the tubes in October although this was more likely to take place later, probably some time in November. In view of all the difficulties and new problems that have been encountered, this will be a surprisingly good showing. If new difficulties arise it is to be hoped that the Public Service Commission will disregard any clamor based on ignorance of these difficulties and will take a firm stand for the completion of the work in the best possible manner before authorizing trains to be put in service.



Profile of Selby Hill Tunnel.

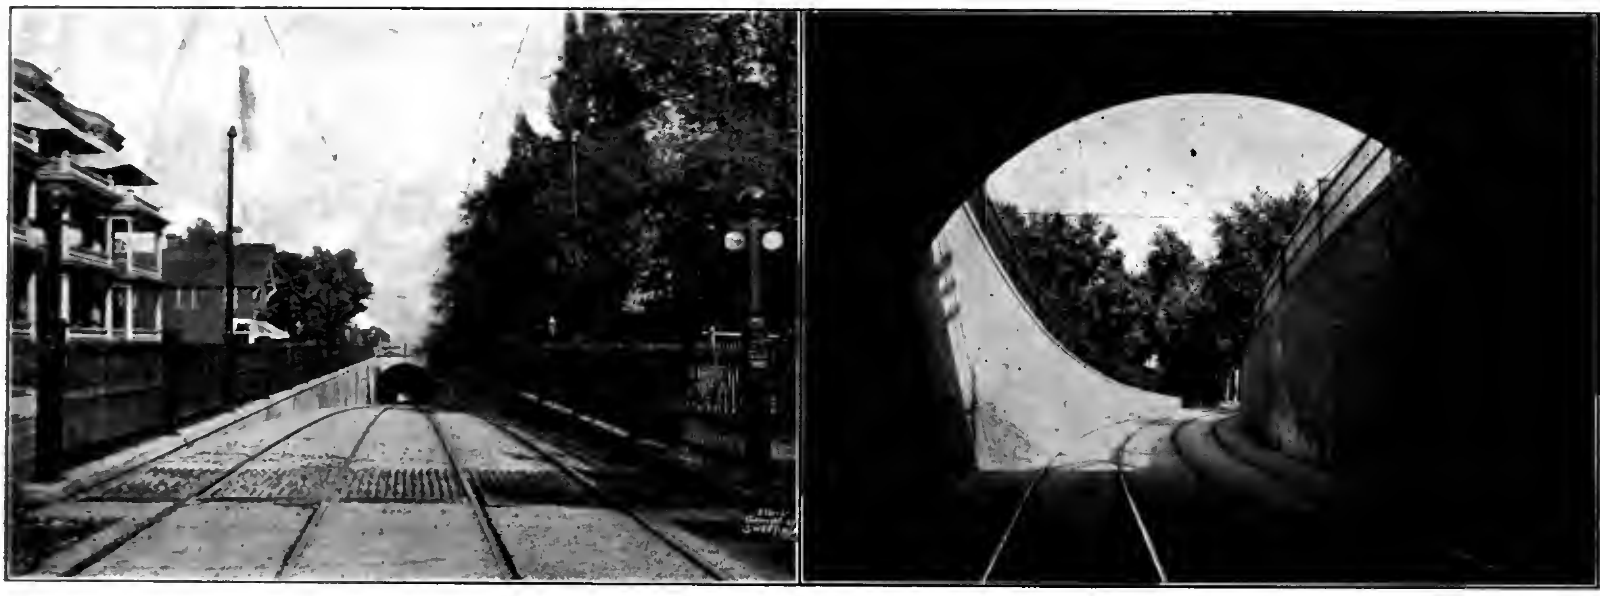
THE SELBY HILL STREET RAILWAY TUNNEL, ST. PAUL, MINN.

The Twin City Rapid Transit Co., of St. Paul and Minneapolis, has recently completed and placed in service a subway tunnel which greatly reduces a steep grade on one of the most important street railway lines in St. Paul, and eliminates the necessity of a counterweight formerly used to handle cars up and down this grade. The new tunnel is on Selby Ave., a short distance from the business district of the city. At the location of the tunnel the grade of the street was 16.5 per cent for several hundred feet, the business district being 125 to 150 ft. lower than the residence sections at the top of this hill. The cars of one of the three interurban lines between Minneapolis and St. Paul, as well as local cars, were operated over this steep grade, on which the counterweight device had been used track. The approaches are so arranged that after the backfilling has all been placed, the street will again be opened for traffic at practically the original grades.

The approaches are between reinforced-concrete retaining walls, which vary from 3 ft. to a maximum of 20.5 ft. in height. Where these walls are less than 6 ft. high they are built as gravity-section structures. Above that height they are vertical, reinforced-concrete slabs, having a horizontal slab footing, and buttresses, 2 ft. wide and 6 ft. apart on centers, on the rear side. The approach to the lower portal of the tunnel is at one side of the street, a roadway parallel with it connecting with the street over the tunnel. The approach to the other end of the tunnel is at the middle of the street, but a 13-ft. tained on a screen with 3/4-in. meshes being used. In all 10,400 cu. yd. of concrete and 55,000 bbl. of cement were required.

The details of the reinforcement of the tunnel section are shown in an accompanying illustration. The arch has two sets of 1 1/8-in. round rods, alternating with girder rails, all of which are spaced as shown. The rods in the side walls have their lower ends imbedded in the invert, and extend up into the arch, overlapping those in the latter in such manner as to produce continuous reinforcement. The invert is reinforced with two layers of old rails, placed transversely. The rails in the lower layer are 28.5 ft. long and are placed 4 ft. apart on centers; those in the upper layer are 28 ft. long and are 12 in. apart on centers, their tops being 1 in. below the surface of the invert section.

The tracks in the tunnel have 80-lb. T-rails attached to creosoted ties with screw spikes. The ties and rails are imbedded in concrete to within 1 1/4 in. of the top of the ball of the rail, the concrete being finished to a smooth surface to form the floor of the tunnel. The floor between the rails of each track is practically flat, transversely with the tunnel, and between the tracks is depressed only slightly toward the center line. Connections to a drain are made at intervals of 200 ft. in the tunnel so the floor can readily be flushed clean, thus avoiding any difficulty from



Approach to Upper End and Exit from Lower End of the Selby Hill Tunnel at St. Paul.

since electric traction was substituted in 1898 for the existing cable line on this street. The counterweight device consisted essentially of a traveling cable and a counterweight in a conduit below the street surface, and two grip cars, which were used to haul the street railway cars up and down the steep grade. The number of cars passing over this line became so great that the counterweight could not handle them fast enough to avoid delays. In order to eliminate the delays due to the auxiliary apparatus, and to obtain other operating advantages, the decision was made to build a double-track tunnel from the base of the hill to a point far enough back on Selby Ave. at the high level to obtain a satisfactory grade.

The total length of the improvement required in the grade reduction is 1,700 ft., including the tunnel and the approaches. An approach, 230 ft. long, leads up to the portal of the tunnel at the bottom of the hill. The tunnel is 920 ft. long between portals and has an approach 320 ft. in length at the upper end. The lower approach is on a curve with a 500-ft. radius, but otherwise the alignment of the improvement is straight. The grade of the new track is uniformly 7 per

drive was obtained on each side of it, so, on the whole, the street is much improved for highway traffic as compared with the old arrangement. The tops of the walls of the approaches and the portals of the tunnel are 0.5 ft. above the street grade, and are surmounted by a 6-ft. ornamental-iron picket fence, in order to prevent accidents.

The tunnel has a double-centered arch, with a span of 23 ft. at the springing line and a rise of 11.5 ft. The clearance at the center line of both tracks is 14.5 ft., while the center height is 16 ft. 10 in. The arch is 24 in. thick at the crown, and the bench walls are 4 ft. thick. Unlike most tunnels of this type that have been built the invert is perfectly flat, having a thickness of 2 ft., exclusive of the concrete in which the track structure is imbedded. The tunnel section proper required 9.782 cu. yd. of concrete per linear foot.

The concrete in the invert, in the side walls of tunnel up to the skewbacks of the arch and in the retaining walls was mixed in the proportions of 1:3:5. That in the arch was made in the proportions of 1:2:4. Owl cement, sand and run-of-the-crusher stone, with no pieces exceeding 2 in. in the extreme dimensions, were used in the 1:3:5 mixture; the stone in the arch was screened,

dust, or odors from refuse that would collect in stone ballast. At the same time the track structure is believed to be of such design that the concrete in which it is embedded will not have to be diturbed for a long period.

A 15-in. sewer pipe was laid under the invert, along the center line of the tunnel, from the entrance of the upper approach to the lower end of the improvement. An opening covered with a grating is placed across the end of the upper approach to intercept storm water and divert it into this sewer. Similar openings at other points in the approaches and the tunnel provide inlets to the sewer for storm water and for water used in flushing. The ground water back of the tunnel and retaining walls is also drained into this sewer through 4-in. laterals, which are placed 20 ft. apart on both sides of the main drain.

A four-way duct for cables is imbedded in the concrete along each side of the tracks, manholes being provided on these ducts at both ends and at the middle of the tunnel. Connections between the trolley wires and the cables in the ducts are made through conduits imbedded in the tunnel arch. The tunnel is lighted by 32-candle power incandescent lamps, spaced 10 ft. apart along the

connected to the cables in the ducts through conduits buried in the tunnel arch.

The construction of the tunnel was handled entirely in an open cut, 34 ft. in width, the maximum depth of the cut being 52 ft., and the average about 30 ft. The hill through which the cut was made consists almost entirely of a coarse glacial sand, containing some boulders and small stone. As the sand was practically free from clay, it would flow easily when dry. When the street was originally graded it was cut down 15 to 25 ft. below the natural surface on one side for a distance of 250 ft., toward the lower portal of the tunnel. A heavy masonry retaining wall had been built along that side of the street to hold back the ground, which continues to rise until a surcharge of from 10 to 30 ft. over the wall is produced within a short distance back from the street.

Forms and Centering for the Tunnel.

The deepest cutting for the tunnel was required along this wall, the top of the latter being 30 to 60 ft. above the bottom of the cut, while its base was directly at the edge of the cut. The work was successfully completed under these difficult conditions, however, practically no movement of the wall, or of the high bank back of it having occurred.

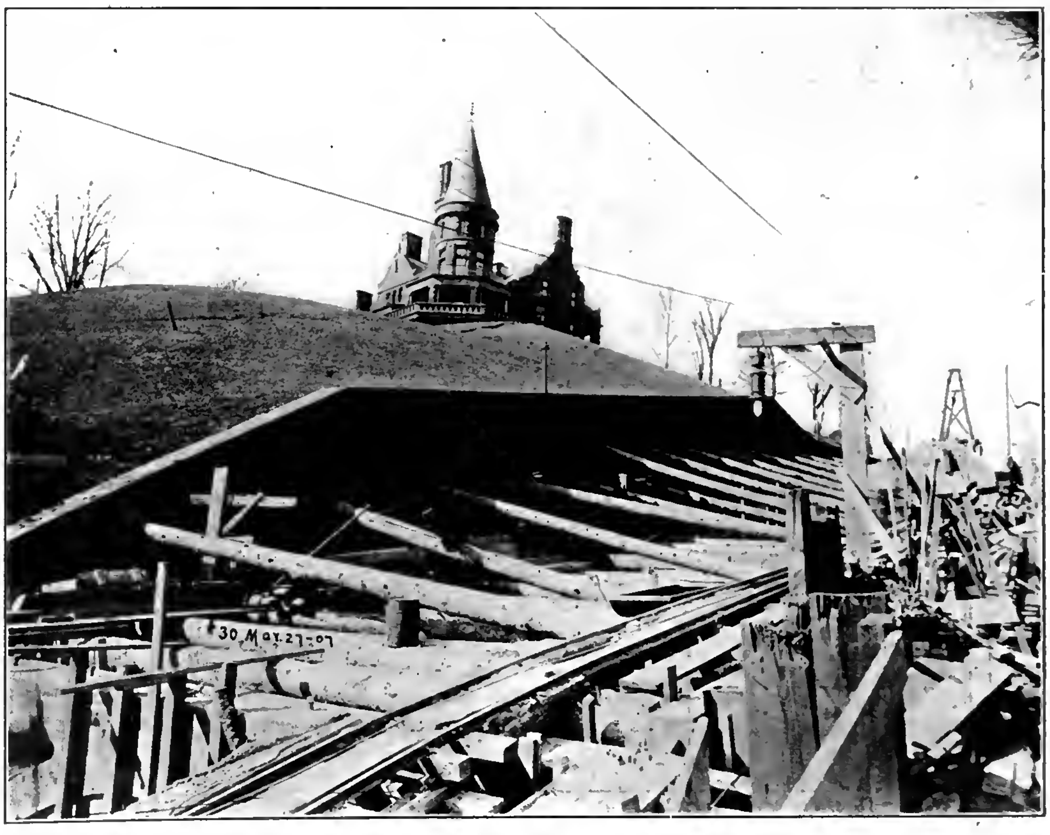
The excavation was started at both approaches and carried toward the middle. The material removed from the excavation was hauled away in 6-yd. dump cars handled by a motor-driven work car, until the amount removed was approximately equal to the quantity which had to be wasted. Most of this material was taken out of the approaches and was loaded into the dump cars by hand. Some of it, however, was taken from the tunnel cut, and a part of it was loaded into wagons by cableways.

Two cableways each having a span of 500 ft., were set up over the longitudinal center line of the tunnel. The two head towers of these cableways were close together near the middle of the tunnel, one tail tower being just beyond the portal at one end and the other beyond the other portal. After the excavation for the approaches had been made and the retaining walls of the approaches had been built, the excavation and concrete work on the tunnel were handled so material removed from the cut at one point could be placed by the cableways as backfilling on a completed section of the tunnel, or could be stored in convenient piles, from which it would afterward be readily available for backfilling. As the excavation in the portion of the work spanned by the cableway at the upper end of the tunnel was considerably lighter than in the part spanned by the other cableway this portion was completed first. The cableway at that end was then placed on the same towers with the other cableway, after which the two worked in conjunction. Buckets with a capacity of 21 cu. ft. each were used in connection with the cableways, which handled nearly 50,000 cu. yd. of material during the progress of the work.

The cut had to be closely sheeted and heavily shored from end to end, owing to the nature of the sand through which it was made, and the necessity of protecting the adjacent property. The sheeting consisted of 4x6-in. timbers in 22 and 26-ft. lengths. Against this sheeting were placed horizontally 12x12-in. waling, or ledger timbers, spaced 6 ft. apart on centers. The waling timbers in the corresponding rows were braced across the cut by poles, 10 to 14 in. in diameter, and 35 ft. long. The cross braces were spaced 6 ft. apart along the waling timbers, thus making a brace at each corner of every 6-ft. square on the side of the cut. The sheeting was driven by hand in advance of the excavation, to a depth of from 8 to 26 ft., and when the excavation had reached that depth, a second set of sheeting was started inside the lowest waling timber for the first set, and was driven to the bottom of the cut. The bracing timbers were wedged in place as the excavation was made, light vertical braces being nailed to them near the middle to prevent sagging.

The 6x6-in. sheeting was replaced for 250 ft. along the base of the high retaining wall by heavy round piles, 26 to 46 ft. long, which were driven closely together. Since the edge of the cut had to be made close to the base of the wall these piles were driven within 18 in. of the latter. As the excavation was made in this section of the trench the row of piles were braced against the sheeting on the opposite side with the regular heavy poles. Inclined braces, with one end against the sheeting on the opposite side of the trench, were also placed against the wall at various points. After the sheeting and bracing had been built up in this manner, the braces being placed as the excavation was made, the tunnel was built and the backfilling placed on it without injuring the high retaining wall or adjacent property in any way.

In all, approximately 1,000,000 ft., board measure, of timber was required in sheeting and shoring the tunnel. Practically all of this was handled by the cableways, which greatly facilitated the speed with which the heavy braces and timbers could be delivered and placed.



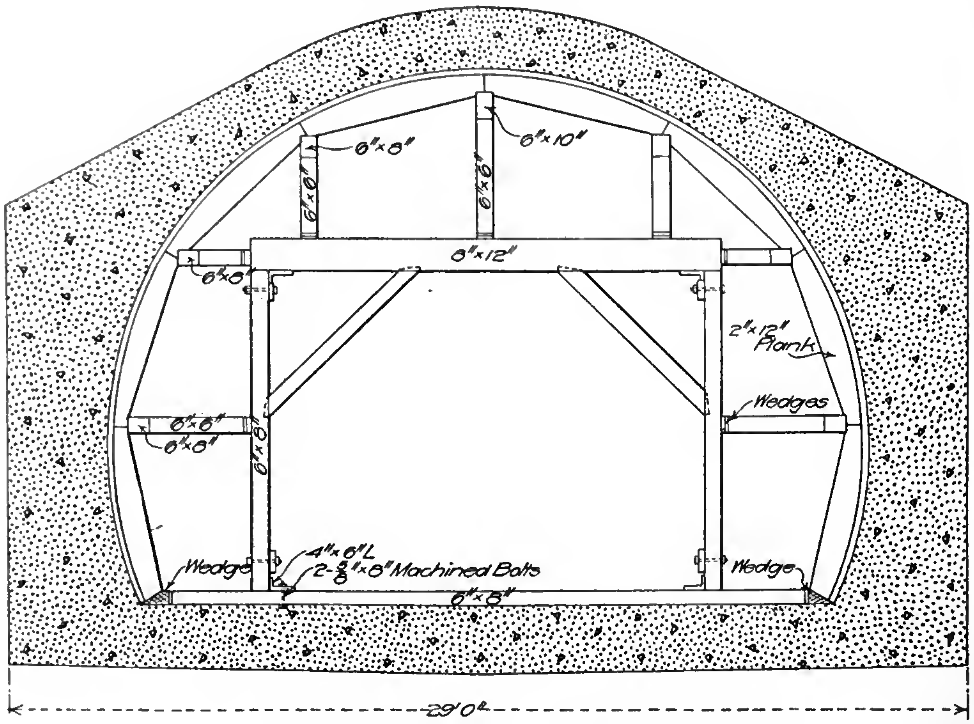
Bracing against High Retaining Wall during Construction.

The great pressures brought on the sides of the cut by the loose sand precluded any possibility of removing the bracing or sheeting as the concrete work progressed, without the load on each brace being transferred to another support capable of carrying this load. A system for building the tunnel section was developed, however, which not only provided for the transfer of the loading on the temporary braces, but also greatly simplified the centering for the tunnel arch. As soon as a section of the excavation was made ready for the concrete, the invert of the

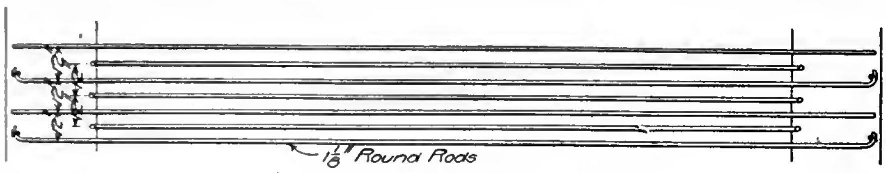
tunnel was laid nearly to the tops of the upper layer of reinforcement rails in it. Heavy concrete posts 4 x 4 ft. in cross-section, and reinforced with old steel rails, were built against the sheeting on both sides of the trench at the same time the concrete was placed in the invert. These posts were placed between the vertical rows of temporary braces and were 6 ft. apart on centers, a section of the two lower 12x12-in. waling timbers, 4 ft. long, being embedded in each of the posts. The posts were cast in rough plank forms, and were built enough in advance of the first work on the side walls of the tunnel to permit them to set for several days. They were held at the bottom by the invert and at the top by a temporary timber cross brace between the two corresponding posts on opposite sides of the trench.

Timber bents were then erected on the invert in such position as to form a center for the forms of the walls and the arch of the tunnel. These bents were 12 ft. wide and 11 ft. high. They were built with a 6x8-in. sill, two 6x8-in. plumb posts and an 8x12-in. cross brace at the top. The bents were spaced 6 ft. apart on centers, being directly opposite the vertical 4x4-ft. concrete posts. When they had been erected as far as the side walls were to be built at that operation, the lowest row of temporary sheeting cross braces between them were removed one at a time, transferring the load on the bottom of the sheeting to the concrete posts. The inside forms for the walls up to the springing lines of the arch, 5 ft. above the invert, could then be set and braced at the top and bottom against the bents of the centering, the sheeting of the trench forming the outside forms. After these wall forms had been filled, enclosing the lower ends of the concrete posts, the concrete in them was allowed to set for a few days. The cross braces between the second row of walings from the bottom were then removed, the load on the sheeting carried by these braces being transferred to the concrete posts. The arch forms were next erected on the bents of the centering up to a height of 11 ft., or just under the third row of temporary cross braces, and the walls built up to that height. When this concrete had set, the third row from the bottom of the temporary cross braces between the sides of the sheeting, and also the temporary braces between the tops of the concrete posts, could be removed and the balance of the arch built.

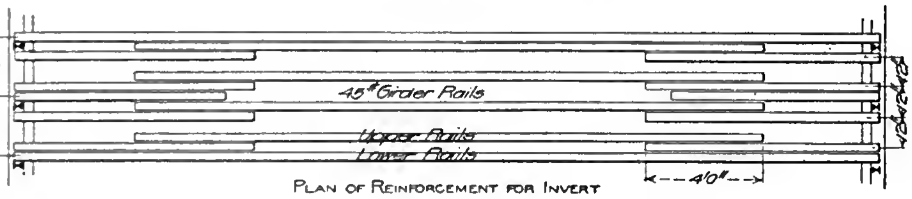
In all this sequence of operations no part of the sheeting was at any time unsupported. At the same time, the centering and forms for the concrete were erected practically without interference and the concrete could readily be placed. The temporary braces were also all saved, although the waling timbers and sheeting had to be left in place, which would have been required in any case. On the other hand, comparatively little extra work, or extra concrete was required by extending the limits of the walls to permit the construction of the 4x4-ft. concrete posts which temporarily carried the load against the sheeting.



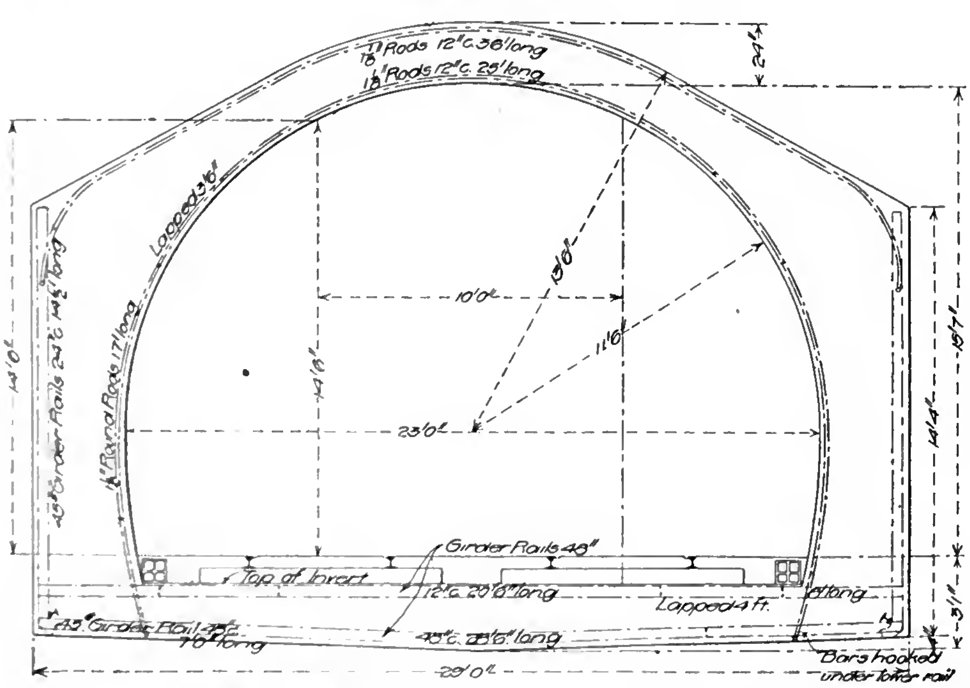
Centering and Forms Used in Constructing Tunnel.



Plan of Reinforcement for Arch Ring



Plan of Reinforcement for Invert



Transverse Cross Section of Tunnel Showing Reinforcement.

The forms for the tunnel had ribs made of 2x12-in. plank cut to a template to conform with the curve of the arch. These ribs were each in six sections, a section on each side extending up to the 5-ft. level of the walls, a second section on each side extending to the 11-ft. height, and two top sections in the closing part of the arch. They were spaced 2 ft. apart on centers and were lagged with 2x4-in. timbers. Ordinarily, the forms were permitted to remain in place at least 14 days before the centering was removed. The exposed surface of the concrete was all spaded carefully in the forms, with the result that a very uniformly good finish was secured.

Two concrete mixing plants, each containing a Smith mixer, were set up at the start of the work, one near each tunnel portal. The concrete materials were delivered to these plants by the work cars of the street railway company, over tracks which had been laid up to them. The concrete was handled from the mixers in 1-yd. Pettela narrow-gauge dump cars. For most of the work, two narrow-gauge tracks were laid longitudinally on the upper row of cross braces in the trench, one track toward each side of the latter. The cars from one mixer plant could be pushed along these tracks by hand, but at the other end of the work the tracks were on a grade, so the cars were handled by a hoisting engine set at the top of the grade. The concrete was dumped from the cars directly into place in the tunnel section.

The concrete work on the tunnel was carried forward in sections of various lengths, depending on the manner in which the excavation could be prepared. Backfilling was not placed on the arch until the concrete was at least 10 days old. The material from the unfinished sections of the

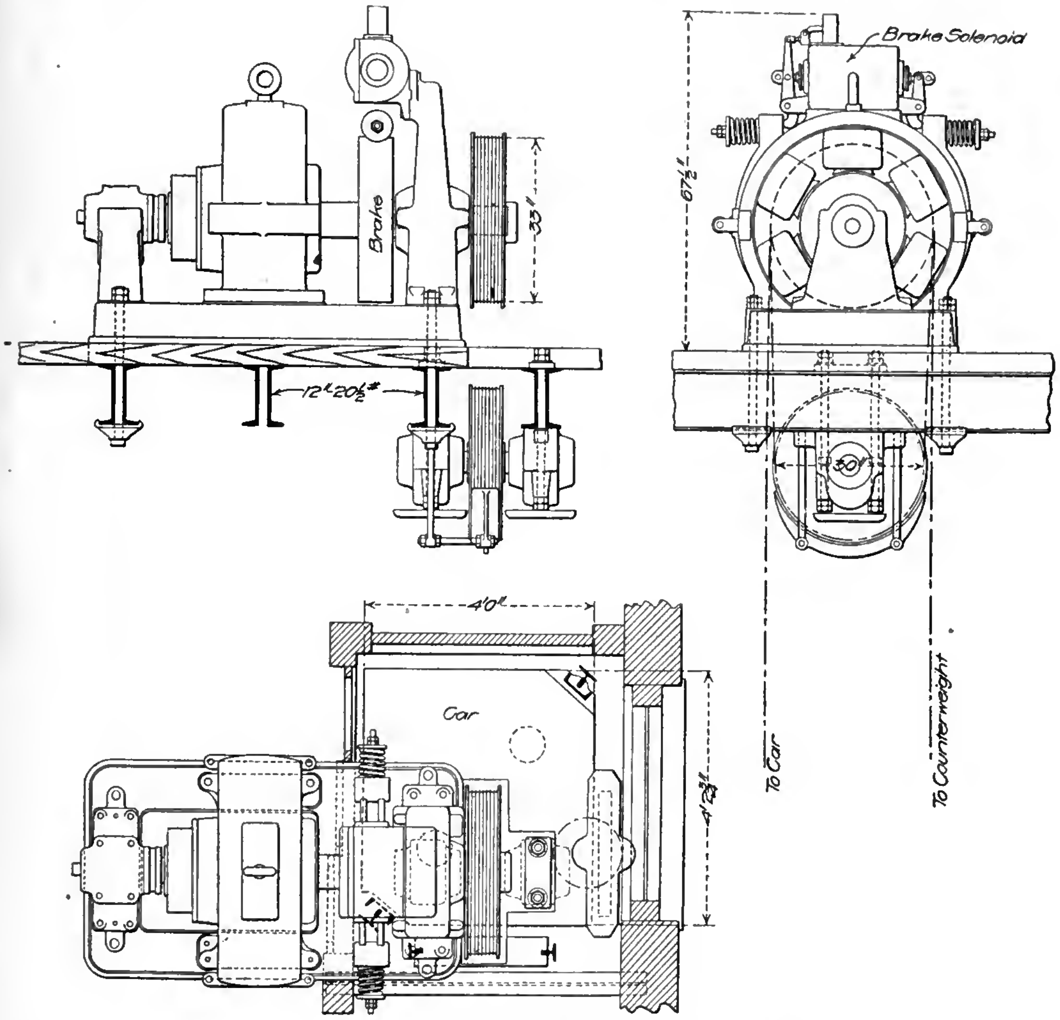
trench was generally piled on the finished concrete work by the cableways. The excavation was planned so very little of the material had to be handled twice, the backfilling being carried forward from both ends toward the middle of the tunnel. Approximately 4,000 cu. yd. of material had been stored on both sides of the trench in a street which crosses the tunnel about midway, and was used to close the final section. This stored material was entirely out of the path of the cableway, but was very economically handled back into the trench by a drag-scoop arrangement that was adopted. A double-drum hoisting engine was set up near the edge of the trench, close to the pile of material. A cable on one drum of this engine was rove through a block on the opposite side of the trench, and then carried back to the front end of the drag-scoop bucket, which had a capacity of 1½ cu. yd. Another cable on the second drum of the engine was rove through a second block on the opposite side of the trench, from which it was carried to a block in the rear of the pile of material and then to the back end of the bucket. The latter could thus be pulled back and forward from the storage pile to the trench very rapidly, discharging its load into the trench. Four men were required to operate the outfit; a driver for the hoisting engine, a signal man and two men to guide the scoop bucket as it was being filled. When the outfit was working to its full capacity it would handle as high as 250 cu. yd. in 10 hr.

The tunnel was designed by the engineering department of the Twin City Rapid Transit Co., of which Mr. George L. Wilson is engineer, and was built under the direction of that department by Mr. George J. Grant, general contractor of St. Paul. Mr. Charles R. Shepley was engineer in charge of the design and construction for the company. Prof. F. H. Constant, professor of structural engineering, University of Minnesota, assisted in the design.

The Electric Elevator Equipment for a Tall Office Building.

An 18-story office building has recently been completed at No. 1 Wall St., at the corner of Broadway, in New York City, which is a very unusual structure, occupying a ground plan approximately 30 x 40 ft. in size and rising to a total height of over 220 ft. above the sidewalk. It has the distinction of occupying a site for which a greater price was paid per square foot than has ever before been given for a building lot in New York City. Owing to the greatly restricted floor plan, an interesting feature is the interior arrangement of the building and the methods of communication between floors. As the available interior space on each floor averages but 28 x 37 ft., in which is included the elevator shafts and stairway enclosures, none of the floors are subdivided, each of those above the ground floor being devoted to a single large office, while the ground floor and basement are rented for store purposes, the basement communicating directly with the uptown platform of the Wall St. station of the Subway and serving as one of the station entrances. This interior arrangement obviates entirely the necessity of corridors on the upper floors and leaves the space that would otherwise be thus occupied available for office purposes, except on the ground floor, where an entrance corridor is necessary, and on the 18th floor, where there is a corridor for access to the upper works of the elevators. Stairway communication between floors is afforded by a line of stairs in a narrow enclosure at the rear corner of the building, having an inside measurement of 6 x 10½ ft.

Three elevators have been installed in a shaft 17 ft. long by 5 ft. deep, at the rear of the building, which is enclosed by wire glass partitions throughout its height, the elevator doors opening directly into the offices on the various floors. Two of the cars are arranged to travel from the basement to the eighteenth floor, a rise of 217 ft., 1½ in., while the third travels from the first to the eighteenth floor, a rise of 200 ft. 3½ in. The elevator mechanisms are each designed for maximum capacities of 2,000 lb., the machines being capable of moving the cars at a maximum speed of 500 ft. per minute with loads up to 1,500 lb. The cars are, of course, owing to the limited space available, of comparatively small size, having outside dimensions of 47½ x 51 in. The hatchway doors at each floor are of the double-telescoping type, giving an unobstructed opening of 38 in.



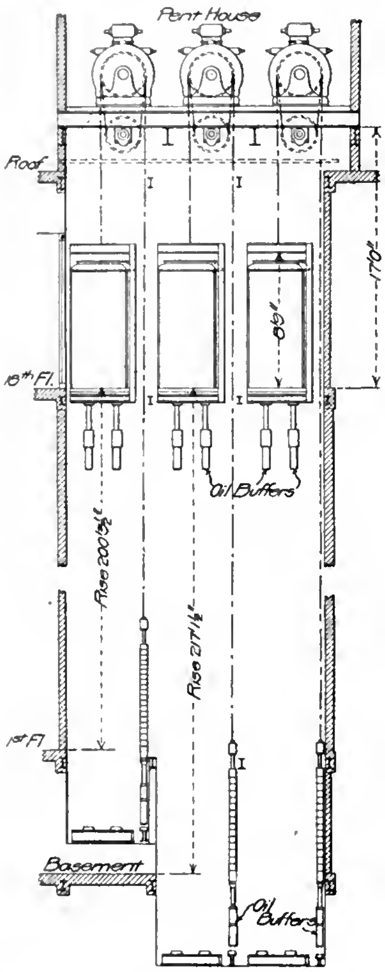
Traction Elevator Machine and Its Location over Hatchway.

Considerable interest is attached to this installation for the use of the Otis traction type of electric elevator machines, these being the first high-rise machines of this type that have been installed in New York City. This type employs a cable drive in its simplest form, entirely devoid of gearing, the elevator cables merely passing over a driving sheave which is mounted directly on the motor shaft, and are thus driven by the adhesion imposed by the weight of the car and counterbalance weights. The cables pass from the car over the driving sheave, thence for additional adhesion down under an idler sheave immediately below, and again up over the driving sheave, being attached at their other ends to the counterbalance weight. The speed of the car is thus always equal to the circumferential speed of the driving sheave. The motors are of a special slow-speed design, operated by the improved type of Otis magnetic control for rapid acceleration, and the two half wraps around the driving sheave give all the adhesion necessary for ordinary elevator service. The equipments are thus of the simplest possible form and specially adapted for high lifts and high speed, the height of lift being limited only by the practicable length of cable. This type of machine has, in fact, been adopted for the extreme high rise elevators in the 42-story section of the new Singer Building in New York City, and of the 45-story tower of the Metropolitan Life Insurance Building.

The elevator machines are, in this installation, located at the top of the elevator shafts in a pent house above the roof. This is, however, an arrangement to which this machine is particularly adapted and is an advantageous one, the machines being so located over the elevator shafts that the cables pass directly from the cars to the driving sheaves carried by the motor and then over and directly down to the counterweight, the motor shaft and sheave, in other words, displacing the overhead work of the usual construction and thus rendering all other sheaves unnecessary, with the exception of the idler sheaves immediately below the driving sheaves by means of which the second wrap around each driving sheave is secured for additional adhesion. The main bearings of the motor together with those of the idler sheave are the only frictional points encountered in the machine. The machines are self-contained, each combining on a single bedplate the motor driving sheave overhanging at one end and the brake mechanism, making a total weight of about 14,000 lb. Support was provided for the three units by a simple framework above the elevator shaft which is enclosed in a pent house that affords protection for the shafts and control mechanisms. The framework consists of four pairs of 12-in. 20½-lb. channels, which are so located upon cross girders supported by the building framework as to form bolting slots for the motor bed plates and the suspended idler shaft; the idler is hung directly below the driving sheave so that its support is a simple matter, as indicated in the elevation drawings of the machines at the top of the shaft and their methods of support.

The remaining structural features of the elevator equipments do not differ, except as affected by the location of the machines at the top of the shaft, from usual elevator practice, the usual form of T-rail guides being used for both cars and counterweight, while the speed of travel is limited by the usual form of Otis elevator governor. On account of the form of drive used and the location of the machines, however, these governors are made double-acting, arranged to operate the safeties in either direction of car travel, both upward or downward. The car safeties or guide grips are also arranged to be operated by emergency levers in the cars, if necessary. Furthermore, the ropes are not connected positively to the driving sheaves and there is no fixed relation between the position of the car and the position of the driving machinery. The limit stops, which prevent overrunning the limits of travel, consist of special switches at the top and bottom of the shafts, which are operated by cams upon the cars that act upon the control system. In addition to these provisions, there is an extra precaution taken in the attachment of oil buffers to the bottoms of the cars and counterweights, which are arranged to bring them to rest at the lower limits of their travel independently of all other devices; the efficacy of this means is evident from the fact that, if all other safety devices should fail, either the car or counterweight buffers would strike the impact blocks at the bottom of the shaft and prevent further descent so that continued motion of the elevator machine motor would result only in lifting the suspended weight sufficiently to allow slippage of the ropes.

The elevator machine motor is a six-pole direct-current motor of special design for the required capacity at the slow speeds of operation necessary, arranged to operate normally at 60 r. p. m. It is wound for operation at 250 volts, current being supplied to the building from the Edison street service. The controllers consist of series of magnet switches, mounted on switch panels with the resistances, near the machines in the pent house at the top of the shaft, and have the usual features of utilization of the increasing counter-electromotive force of the motors, in starting, for operating accelerating magnets to cut out gradually the armature resistance and finally introduce resistance in the field circuits, and retarding magnets, similarly used for slowing down in stopping. The holding brakes on these machines are of a special design, with double-acting solenoids above the outer main bearing caps which operate specially designed shoes that act upon large drums on the motor shafts. The brake shoes are leather lined and carefully fitted to the drum, and are operated by a special toggle motion requiring but a very slight movement of the solenoid core to grip the drum firmly. The solenoids are operated in conjunction with current limit switches which allow comparatively heavy currents to pass through them during the action of releasing the brake, but reduce the current flow to a fraction of its initial value while the shoes are merely held in release position, against the pressure of helical springs in compression.



Traction Elevators in No. 1 Wall Street Building.

Locomotive Smoke Prevention has been demanded in so many cities of late and is so desirable for the comfort of passengers that it was thoroughly discussed at the recent Chicago convention of the Traveling Engineers' Association. The unanimous sentiment was in favor of a brick arch for preventing smoke and protecting tubes. It was stated to assist materially in mixing the inflowing air with the gases of combustion, thus supplying oxygen and preventing the formation of smoke. The hot brick also help maintain proper combustion temperature when the engine is standing and gases are still coming from the coal.

Factory Lighting.

In a paper with the above title, read before the Ohio Electric Light Association, at Toledo, last month, Mr. A. P. Biggs pointed out that from the standpoint of illumination, the lighting of factories may be divided into space and applied lighting. For general space and floor lighting there must be some large source of artificial light, and the sources now available are the electric and gas arcs, the Cooper Hewitt and the Nernst lamps. The incandescent lamp in large sizes is still inefficient as compared with these others, and in ordinary sizes does not give the necessary illumination.

An arc requires minimum cost for installation, has the greatest efficiency per watt expenditure and lowest maintenance cost. The unsteadiness of an arc is not serious in space lighting, and while the shadows from a single arc are apt to be annoying, the arc on the whole is the best unit for such work as above noted.

The Nernst lamp is desirable in small space lighting, in low-ceiling machine shops, and in foundries. In one instance where the Nernst lamp is giving excellent results, the lamps are spaced from 8 ft. to 10 ft. apart at a standard height of 9 ft. The light is soft and pleasant, and energy consumption low.

For particular application of artificial light, single incandescent lamps are the sources used. Although the installation of a lamp at each machine in every kind of business is not sanctioned by all illuminating engineers, it has the sanction of custom, the recommendation of the wiring contractor, and enjoys the hearty endorsement of those responsible for getting the same amount of work out of the machine by artificial light as is expected by daylight.

In a shop having low ceilings and much window surface, illumination may be good from natural sources for the first six months or so, but after that, by continuous process, the windows, ceilings, walls, posts and everything blacken and cease to let in or to reflect any light. The lighting installation fares the same way, and the workman shades his eyes by covering the lamps with anything available, until there is almost no light available.

An example of shop practice with individual lamps—uncommon because definite data accompany it—was presented by Mr. K. C. Keech, before the Chicago Section of Illuminating Engineering Society in May last. A bare lamp, 13 ins. above the face-plate of a drill press, and 7 ins. from the center, gave 3.7 ft.-candles at the center of the face-plate. The dirtiest lamp in the shop when substituted, gave 1.55 ft.-candles, while a new clean lamp in the socket gave 5.7 candles.

When the customer gives us the opportunity of making recommendations upon his equipment, we generally advise him to place at every machine a drop or bracket lamp with reflector, and that he use 8-cp lamps wherever possible. Often, to satisfy the customer that the economies pointed out are worth securing, we loan him a half dozen styles of shades and reflectors, and he purchases when he has determined the kind most suitable. Further—and here the policy of the company may seem heretical—space lighting is often disposed of by advising and urging the use of gas arcs. All possible short-hour burning is turned over to the gas company, and the electric light company is relieved from the "lighting bill" complaint which formerly afflicted us for several months each winter. As this policy results from our differential rates, its presentation may be comforting only to those who make high prices per kw-hour for lamps burned but few hours per year; unless the "Flat Rate" man wishes to mend his way.

The usual factory lighting can be considered by central-station men as none other than unprofitable business, which is to an extent a necessary evil. By reason of its character, it requires all of the attention and all of the equipment which more respectable branches of the industry necessitate, but refuses to make adequate return on the investment and work to supply its need.

The assumption is not to be made that the Detroit Company is securing proper and adequate return for its service in this branch of lighting. The company has certain rates and is, as a public service corporation, required to furnish and does furnish service for all customers. Further, it is needful that this unprofitable business have a fairly low rate in order that we get the profitable business that goes with it.

The rates at which this class of lighting is sold in Detroit are as follows:

First—Open Order—Sixty hours' use per month of the demand at 16 cents per unit, balance at 4 cents per unit. This agreement is not a contract, having no definite term.

Second—Demand Contract—Thirty hours' use per month at 16 cents per unit, balance at 4 cents per unit; minimum bill 30 hours' use per month of maximum demand at 16 cents; term, one year.

The following discounts for prompt payment are allowed on both agreements: On bills less than $50, 10 per cent; on bills of $50 and less than $100, 15 per cent.; on bills of $100 or more, 20 per cent.

Under "open order" we furnish standard incandescent lamps and renewals—and trim and care for arc lamps and Nernsts owned by the customers. Under "demand" we furnish all incandescents, arcs, Nernsts, renewals and maintenance.

The "open order" is the most common prescription for factory lighting. It cares for that class of customers whom we term "short hour," who use our service as auxiliary to sunlight and daylight; who have a few places which, due to poor

construction of building, blackened windows, or later construction by their neighbors, need light occasionally during the day, but whose principal service is from dusk to 5:30 p. m., and who either cannot or will not make nor pay us for making the investment necessary for good lighting.

The "demand contract" is suited to the lighting conditions of but a small portion of factories, inasmuch as it is designed for the satisfaction of long-hour burners. The factory whose conditions are met by it is probably one in which there is a requirement for a large number of individual lamps, and for small lamps in isolated parts of the factory, for which there is necessity for service all through the day.

To illustrate that under our rates factory lighting is unprofitable to us, the following cases have been figured to show cost to consumer under "open order" and under "demand contract," and the amount the business should have brought in in order that it might just begin to be profitable, the later amount being arrived at as fixed charge per kw-year plus operating costs per kw-hour:

				Earnings	Income per Year	
	Kw.-h.	Connected Kw.	Demand Kw.	Open Order.	Demand Contract.	Minimum Allowable.
1..	4,330	29.0	12.0	$552.00	$632.00	$780.00
2..	8,163	36.6	13.5	916.00	815.65	973.89
3..	1,800	5.6	2.2	220.00	157.00	172.30
4..	6,850	30.6	22.2	884.00	1,061.70	1,410.80
5..	10,410	26.3	17.6	1,168.70	875.80	1,262.80
6..	3,052	16.6	9.16	416.70	492.93	500.40
7..	1,644	5.1	2.81	226.72	170.25	201.10

Nos. 1, 2, 3, 4, 5—On Open Order, 60 hours' use of the demand.

No. 6—On Demand Contract.

No. 7—On Open Order, 60 hours' use of connected load.

The first three calculations are for a carriage manufacturer, in successive stages of his business. For two years he did all his lighting by clusters; at the end of that time, by reconstruction of building, the electric lighting was reduced from 13 kilowatts demand to 2 kilowatts, and all general floor lighting was done by gas arcs. Only on this third year, after the changes had been made which took from us the pleasure of serving 650 lamps, did we make any profit on the business.

The fourth and fifth calculations are successive years in a cigar factory—a six-story building lighted throughout by incandescent lamps. At the end of the first year given, the customer was persuaded to change 300 individual lamps from 16 candle-power bare to 8 candle-power lamps with reflectors. Demand was reset and he was billed upon 60 hours' use by its readings—as he was an open-order customer. He saved considerable and we only lost 10 per cent. on the lighting business, against 60 per cent. the year before. His motor business in the last year amounted to 30,800 kw-hours, with a demand of 11.6 kilowatts.

The sixth is a manufacturer of shirt waists, skirts, etc.; has all electric equipment, using electric arcs for general floor lighting. His lighting business, which was on demand contract, lost us but $8. During this year we had the profit from the sale of 20,000 kw-hours for motors with demand of 8.5 kilowatts.

The seventh, which is a bathtub factory, has wood-working, sheet metal and brass foundry departments. For space lighting gas arcs are used, and the business gave us some respectable return.

As a public service corporation having established rates we must sell at these rates whether the customer causes us to lose on service or brings us revenue from it. We tell customers that by our experience his lighting will be cheapest for him, say, on demand, but inform him that there are so many conditions of surroundings, location of lamps, faults of building design, amount of natural lighting, etc., that he must fix his conditions and try it out for himself. Usually we install such service on open order—if we find later that demand contract rate will be to the customer's advantage, we offer it to him.

Our rates are based on customer's demand even when the open order is taken. If demand is same as connected load, and the customer signs the open order, we will bill him at 60 hours' use of the connected load at 16 cents. If his installation is greater than his demand, we install demand indicators and bill on showing of indicators. If he has many empty sockets in his installation, we install demand indicators, and probably bill on connected load until demand shows that customer has fitted empty sockets with foreign lamps and would have us continue to bill him without increasing his rate.

By the same method of figuring as used above, a business begins to be profitable to us when the customer has paid for 480 hours' use of demand per year at 16 cents, say, 40 hours per month. As an approximation—to get at classification of business as profitable or unprofitable—the consumption of energy per year of factories as found in several customers' ledger accounts, has been divided by 12 times demand, giving hours' use of demand per month. All of these factories are operating on a regular 10-hour day.

No. of Cases.		Average Hours' Use of Demand per Month.	
5	Bakeries, Wholesale	107	
8	Brass Works	57	
2	Breweries	85	
2	Brush	12	
4	Candy	51	
3	Chemical	10	
7	Cigar	29	
9	Clothing	37	(5 cases average 11.9)
3	Engravers	70	
3	Harness	35	(2 cases average 11.9)
1	Knitting	9	
14	Machine Shops	31	(7 cases average 13.4)
3	Paper Box	13	
4	Printing	20	
8	Sheet and Metal	18	
3	Sheets	33	(2 cases average 13.7)
2	Toys	31	
1	Upholstering	4	
1	Wire Works	12	
6	Woodworking	24	(4 cases average 11.10)

From their nature, several kinds of business are invariably profitable. The wholesale bakers use some lighting for 24 hours per day. Breweries have many small motors about their establishments which are shut down about 4 p. m., and the lighting load up to that time continues quite uniform throughout, making the lighting demand negligible.

Machine shops and brass works need electric lamps for individual machines only, and give a good lighting load summer and winter. The clothing manufacturer, whose record makes the best showing of his class—to our way of thinking—in the above list, has on each machine a movable arm carrying a lamp of low candle-power with parabolic reflector, permitting operator to bring source of light close to work without unpleasant effect on eyes; all his space lighting is by gas arcs.

We persuaded one customer operating a brass foundry to put in gas arcs for all lighting, and further satisfied him that, with little hardship, his air compressor could be shut down in the afternoon at such times as would prevent any increase of total load due to shop lighting. As a matter of general policy, in addition to giving other advice, we recommend to the manufacturer that a fraction of the amount spent this last year for lighting be turned over to a window cleaner and a man with a hand-pump and a tank of whitewash, expecting that both of us will then be satisfied with his factory lighting.

Our conclusions are: That an electric light company cannot afford to take on all factory lighting offered to it; that it is obliged to take a certain amount which is inherently unprofitable; that it should minimize this amount (first) by advising the customer how to reduce his demand by utilizing light to best advantage; that is to say, by good illuminating engineering; (second) advocating the transfer to daylight hours of any motor load that can be dispensed with during the evening hours, and (third) by passing over to the gas company such factory space lighting as can be profitably furnished by gas arcs, retaining for electricity the long-hour localized lighting.

It is worth while to note that the new metal filament incandescents may modify these conclusions. They will not change the rates of demand to sales, but they may make gas so comparatively expensive as to put it out of competition either partially or altogether.

In a paper with a similar title, J. T. Kermode stated that many manufacturing concerns are vacating their old premises to enter buildings of more modern construction, with saw-tooth roofs and windows on practically four sides, which is evidence that better lighted workrooms are essential and that the demand for a higher standard of artificial illumination is rapidly increasing.

The short-hour use and usually heavy demand on the station peak has brought about a condition where there is some question as to the advisability of factory lighting from a supply company's standpoint; it is, however, very important when combined with the supply of electricity for motors. In conjunction with this latter business considerable work has been done in Cleveland, where it has been the policy to make surveys, plans, specifications and to obtain bids for this class of wiring with special reference to the best and most economical method of illumination for the various kinds of work in different processes of manufacture.

The average factory requires artificial light during 10 to 20 per cent. of the working hours, not including overtime or night shifts; therefore, the illumination should be sufficient and the lamps so arranged that the quality and quantity of work accomplished during these hours can be as well and economically done as that which is performed by daylight.

The amount of light required varies, first, with the size of room, relative position of machines and the general shop conditions, and, second, with the character of work to be done. The arrangement that will effectively light a clothing factory cannot be efficiently applied to industrial plants, where the atmosphere is filled with smoke and dust.

Experience has taught that no general rule can be laid down to govern the many different situations that present themselves, but each factory must be studied separately to determine the amount of light, style of illuminant and the method of its installation, to give the best results.

For instance, large units cannot be successfully operated in roundhouses or car shops. The principal parts of locomotives that need special attention are so located, that, to be of value, the source of light must be reflected from each side of the engine. Five 100-watt Gem lamps, spaced 15 ft. apart, at an elevation of 7 ft., will light in a very satisfactory manner one side of two engines. Oil torches so commonly used in cabs, boiler and floor pits, can be conveniently done away with by the use of portable incandescent lamps

In foundries, forges, steel mills, structural iron works and boiler shops, where the walls are dark and the work does not require concentrated light, a lamp is needed that will give good general illumination Enclosed arc lamps, giving a white light, combined with shadows, are undesirable for this class of work, as the dark walls and dense atmosphere absorb a large percentage of their penetrating powers

The color and brilliancy of light produced by the flaming arc has attracted the attention of many manufacturing concerns, and, notwithstanding the cost of lamps and carbons, they are being extensively used to light large areas

In a large mill operating steel presses, 16 enclosed arcs were installed. On account of the dense atmosphere these lamps were hung below the tops of the presses, resulting in heavy shadows being cast around each machine. The 16 enclosed arcs were recently substituted by six flaming arcs. With slight changes in the wiring these arcs were placed 22 ft. from the floor, resulting

in the entire shop being flooded with a warm, bright light.

The use of flaming arcs reduced the connected load, and averaging two hours use a day, these lamps would save 234 kw-hours per month, which at the usual prevailing rate for energy would more than compensate for the cost of carbons, without considering the increased amount of illumination.

It is generally conceded that the best uniform illumination can be obtained by distributing small units over the space to be lighted, but this is not always practical, for one must consider the building construction, and purpose for which the space is to be used.

The use of higher candle-power arc lamps for factory lighting is rapidly increasing and the advantage that can be obtained by their use and efficiency must be recognized. The efficiency with which the light is produced and utilized, are two important factors, with which a supply company is intimately concerned.

In machine shops it is common practice, together with large units for general illumination, to furnish each workman with a single incandescent lamp, which when new, and at average height from his work, usually gives a fair amount of light. Oil and dust soon reduces the illumination one-half.

But it is not expected that the amount of work should reduce in the same proportion. Some reasons why this practice has become so popular are:

First. That up to a few years ago the majority of industrial shops were equipped with generating apparatus, but the cost of electric lighting was charged against the operation of the shop, and not against the cost of electricity, as it should have been.

Invariably, I have found, that where light is obtained in this manner, the generators, feeders and branch circuits are heavily loaded with inefficient apparatus and there is no incentive to economize.

Second. Wherever a large installation is necessary, the manufacturer usually employs a man to look after the operation, repairs and additions to the electrical equipment.

These men, as a rule, are not familiar with the improvements that are continually being made on the various devices that go to make up a modern electric installation. Consequently, inefficient light facilities are unintelligently installed.

Third. Employees have been educated to believe their work cannot be successfully performed unless each individual is furnished with an incandescent lamp, and realizing the flexibility of electricity, it seems comparatively easy for one to convince the foreman that an additional lamp should be added here or there, resulting in an over-lamped room for the number of machines operated and also in a poorly lighted room at an excessive cost.

In machine shops where lathes, drill presses, planing machines, milling machines, screw machines, punches, etc., are used good general illumination of uniform intensity is required. Nernst or Gem lamps are well adapted for this class of lighting.

The size and number of lamps to be used depends upon the size of the room, height of ceiling, color of walls, location of machines, belts and shafting. In estimating the size and number of units it might be of service to consider 50 watts per operator, or machine, as an average amount for all ordinary machine work and general illumination. For special machines or work needing bright light, individual incandescent lamps with reflectors should be used. Machines that are automatic in their operation are many times provided with unnecessary individual lamps. Appreciating that these machines do need good light for changing their adjustment, the use of portable lamps that can be connected to receptacles near each machine will, if intelligently used, save energy.

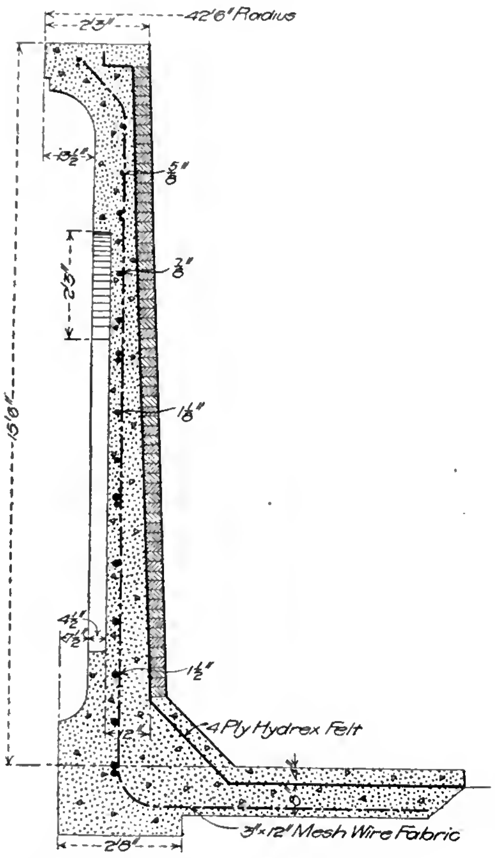
The general evenness of illumination with the absence of glare, together with the easy shadows and searching quality of the light produced by mercury-vapor lamps makes them especially adaptable for factory lighting by direct current. Unfortunately the alternating-current lamp up to the present time has not been successful, due to its inability to readily start.

Manufacturers of clothing require an even, shadowless, well diffused light of considerable brilliancy. Nernst lamps with prismatic reflectors can be utilized for this purpose with a comparatively low consumption per operator.

The difficulties that exist in factory lighting are familiar to all men engaged in the sale of electricity and it should be the duty of each central station to educate its men to successfully overcome these conditions by encouraging the use of lamps, shades and reflectors that have been produced for scientifically converting wasted energy into useful light. Recent discoveries in the production of electric lighting are of revolutionary nature, the same principles which have been utilized in the cheapening of gas light, that is, the use of the peculiar properties of rare earth and metals, have been appropriated by the electrical interest and the recent developments indicate the efficiency of electric lamps will be doubled in the near future.

Recently I have read an article in which a supply company recommends the use of gas for factory lighting that they might be successful in retaining power business.

Is there a more exaggerated case of false economy than that of requiring people to work by poor illumination? In comparison with the cost of labor, the cost of lighting is trifling. Take, as an illustration, the case of a skilled workman receiving $3 or $4 a day (say, an average of 30 cents an hour or ½ cent a minute), figure the cost of a 16-cp lamp burning 10 hours, and see how many minutes of the man's time it requires to pay for the light. Yet there are thousands of skilled mechanics handicapped with insufficient and ill-directed light.



Section of Wall, Cos Cob Reservoir.

A Concrete Power-Plant Reservoir.

A 600,000-gal. reinforced concrete reservoir, 80 ft. in diameter and 15 ft. deep, of attractive appearance, has been constructed for the New York, New Haven & Hartford R. R., at Cos Cob, Conn., in connection with the power plant described in The Engineering Record of Aug. 17, 1907. The reservoir is founded on solid rock and is without any surrounding fill, thus making some exterior embelishment very desirable. Accordingly the wall was designed with a cornice and a slightly projecting base and the flat belt between was relieved with a series of arched indented panels, forty in number, giving somewhat the effect of an arcade. The general appearance of the exterior of the tank is shown in an accompanying illustration.

The concrete wall has the form and dimensions shown in an accompanying sketch and has a 4-in. lining of brick laid up in cement mortar to protect the waterproofing coat. It is reinforced circumferentially with steel cable, varying in diameter from 1½ in. at the base to ⅝-in. at the top, forming a continuous spiral with 12-ft. splices made with sixteen Crosby clips where the ends of two sizes of cable are joined. The pitch of the spiral varies somewhat, as indicated on the drawing, but is in general about 1 ft. Inside the cable spiral is a continuous sheet of 3x12-in. mesh Clinton wire fabric, placed in vertical strips which extend 6 ft. into the floor foundation.

The inlet and outlet pipes are 10 and 12 in. in diameter, respectively, and enter through the floor of the tank near the east wall. Water-tight connections were secured where the pipes passed through the waterproofing by clamping a sheet of lead between two flanged screw sleeves, as shown in an accompanying sketch. Just outside the tank wall the two pipes enter a concrete valve chamber, 5⅔x11⅓ ft., in the top of which is a 30-in. manhole. A 3-in. steam pipe leading from the power house through the valve chamber into the tank and half-way across the floor, with a perforated upturned end, is provided for keeping the water above the freezing point in cold weather.

The natural surface of the granite outcrop on which the tank is built sloped considerably to the north. To make a level foundation the rock on the south side was blasted out and transferred to the north side, the rock fill being thoroughly compacted and grouted with cement and sand mortar until it was a practically solid mass.

The wooden form for the exterior surface was built complete from the foundation to the coping and around the entire circumference of the tank. Screw hooks were then driven into the inner surface of this form, properly spaced to support the cable spiral. The cables were then hung on the hooks, the proper spacing between these points of support being maintained by wire ties, and upon the cables was wired Clinton electrically welded wire fabric in vertical strips as indicated on the drawings. The interior of this form, with the cables hanging on the hooks before the wire ties or wire fabric were attached, is shown in an accompanying illustration. The vertical supports for the inner forms were erected after all the reinforcement was placed and were wired to the outer forms at the proper distance. The concrete was prepared in a mixer placed just outside the tank, and delivered to place in 1-yd. skips by a guyed derrick placed in the center of the tank and operated by a hoisting engine which was outside the enclosed area. The derrick cables were run through the wall, the holes being filled after the forms were removed. The inner form was

built up a few feet at a time as it was filled with concrete, which was placed very carefully to insure the filling in of all spaces between the cables, wire fabric and forms.

About ten days after the filling of the wall forms had been completed the forms were removed and the derrick was taken out of the tank. The floor was then concreted to an even surface and a 4-ply waterproofing coat of Hydrex felt was applied to the inner surface of the wall in vertical strips and to the tank floor. Hydrex compound was used to cement the layers of felt together.

A 4-in. protective covering of concrete was laid over the floor of the reservoir on the waterproofing coat and extending a little way up the side to give a footing for the 4-in. brick wall lining. The bricks were laid with cement mortar with a solid backing of mortar between brick and waterproofing.

The reservoir was designed and built by Messrs. Westinghouse, Church, Kerr & Co., of New York, engineers and constructors of the power house.

The 600,000-Gallon Reservoir at Cos Cob Power Plant.

Electrical Equipment for Suburban Lines.

Electrical equipment for the suburban lines in Oakland and vicinity belonging to the Southern Pacific was ordered recently. The service given is distinctly of a suburban rapid transit character. The commuter traffic is confined largely within a radius of about seven miles, and the different roads conducting this service converge at Alameda Mole where they connect with ferryboats to San Francisco. The stations on the suburban lines average four-tenths of a mile apart, and the system as a whole is said to do a larger suburban business in number of passengers carried than any other in the country, the Illinois Central suburban lines out of Chicago alone excepted. The electrical equipment now decided upon will consist of multiple unit trains with from three to twelve cars per train, made up in the usual combination of motor and trail cars. The cars seat 80 passengers each. Eighty motor cars have been ordered and each will be equipped with four General Electric 125-h.p. motors. Direct current will be employed and overhead catenary construction will be installed. The power station will be equipped with two 5,000-kw., 25-cycle, 13,200-volt, three-phase units, the contract for which has been awarded the Westinghouse Machine Co. Parker boilers have been ordered for the plant and Worthington condensers and auxiliaries.

Electricity for Cement Plants.

A paper read before the Association of American Portland Cement Manufacturers by Mr. J. B. Porter, of the Light and Power Department of the General Electric Company.

The applications of cement have been so enormously increased in the last two years as to almost justify the name for the present period as the cement age. This increased demand and the high prices which have been maintained have created a large number of new companies, and have stimulated the remodeling of old plants to increase their output. It is predicted that the total output of cement for 1907 will equal, if not exceed, 60,000,000 bbl.; yet this supply, it is claimed, will fall far short of the demands.

The object of this paper is to point out some of the special advantages of the electric drive in the manufacture of cement, both in economy and flexibility. From the economical standpoint the savings of one cent per barrel on a 1,000-bbl. plant would justify a first cost of over $50,000. Economy in the manufacture of cement is so closely connected with flexibility that it seems almost one and the same thing. Economy to cement manufacturers means continuous operation, and continuous operation is contingent on flexibility.

There are few if any plants which are not making good profits under the present condition of prices; yet there are any number of plants which are producing cement at a high cost of manufacture because of the inefficient layout of their plants and the uneconomical transmission of their power.

The cement industry has been very conservative in the adoption of electricity for the transmission of power; yet in most other lines of manufacture, mechanical transmission has been superseded by electricity even at great expense, and the results have proved that the electric drive has either increased the output, simplified the process of manufacture, improved the economy, or made easy the superintendence of the plant. Many Western cement plants are already driven throughout by electricity, and yet in the East, the cement manufacturers use the electric drive only where the mechanical drive is impracticable.

The cement industry opens a large field for the application of electricity. The simplicity of the manufacture of cement permits a division into different departments in such a manner that each department can be regarded as a unit, having its local manager who is held responsible for its satisfactory operation. With the electric installation, a ready record can be kept of the power consumed in each department, and the superintendent can easily locate the department responsible for any decrease in output for each day. A record of the power consumed in each department shows at a glance whether the consumption is above or below normal, and any deviation should require a satisfactory explanation or should indicate that the machines are not operating satisfactorily.

The profits in the cement industry demand the continuous operation of each machine at its full load; to obtain this, it is necessary to have flexibility in the power applied, and electricity permits of greater flexibility than any other mode of operation.

The installation in the power house of two or three generators insures a constant source of power for each and all departments. The switchboard, if properly subdivided and arranged with one feeder panel for each department, each panel equipped with indicating ammeter or recording wattmeter, furnishes a constant indication of the power consumed by each department, and a record of these readings gives a ready reference to the operation of each department. Each department may be operated by one or more motors; if more than one motor is used, the group drive should be made as flexible as possible so that part of the load, if necessary, can be thrown from one motor to the other, or the groups entirely separated from the others so that part of the department will always be in operation.

The output of a plant is based on the output of each kiln and the number of kilns installed; this department is the very heart of the industry and the successful manufacturer should provide every means known to keep his kilns running and crowd them to the limit of complete calcination.

To accomplish this there are three different methods of control, variation of the speed of the kiln, variation of the feed of raw material, and variation of the coal feed for combustion.

All these variations should be under the hand of the operator at the point where he can watch the calcination and change any or all of these to accomplish the most satisfactory results; here the application of the electric motor should play an important part.

Where it is necessary to use a number of crushers arranged in groups, the most flexible arrangement would be to select a motor of about 150 to 200 h.p. and drive from a line shaft, each pulley on the shaft to be equipped with a friction clutch. If the number of crushers requires more than one motor, put in another line shaft so arranged that it can be connected to the first line shaft by means of a friction clutch. Should it be necessary to add more groups, this can be easily accomplished by placing the crushers either in parallel or series, whichever arrangement will enable the feeding and taking away of the material to be more concentrated.

The power house, if properly designed, should permit the shortest steam transmission from boilers to engines, and the building should be so constructed that if it becomes necessary to increase the number of units beyond the capacity of the building, the end of the latter can be taken out and an extension made for both boiler and engine rooms without interfering with the continuous operation of the plant.

Electricity permits the grouping of the buildings for each department in the most convenient sequence without being obliged to take into consideration the source of power, and also permits the shortest transmission of the manufactured material from one department to the next. If possible, the building for each department should be constructed similar to the arrangement of the power house so that extensions may be added.

Up to the present date it has been almost impossible to obtain satisfactory tests even on motor-driven machines in cement plants, as the power required to start some of the machines is so great and changes so quickly that it is hard to take a reading; and the running power is so small in comparison that manufacturers have been compelled to use motors of large horsepower ratings in order to be on the safe side. There is now on the market a curve-drawing meter which automatically records the power consumed, and it is to be hoped that tests with it will put the consumer in a better position to specify motors nearer the running horse-power of the machine than they are at present.

For best results, motors, both direct and alternating current motors, should be run as near their most economical point as possible, which naturally is full-load rating. It is not always possible to take these points into consideration, as the limiting feature is the starting torque, which is generally from two to three times greater than the running torque required for most cement machines, yet with these curves, it will probably not be necessary to install a 150-h.p. motor to operate a continuous load of 65-h.p. as many of the plants are doing to-day.

The belt drive is generally considered the most satisfactory for transmitting power from the motors to the machines. It often happens that crushers get clogged and it is practically impossible to furnish sufficient power to start them again without cleaning them out. The belt drive relieves the motor from the enormous shock consequent on the stoppage of the machine and the belt would probably slip before the circuit-breaker could act, giving a double protection and also giving a protection to the cement machines that it is impossible to obtain from a mechanical drive, as there is no flexible arrangement that would automatically shut down the machine, mechanically driven, when excessively overloaded. The belt drive also relieves the motors from the consequent jar of heavy starting loads. At one cement plant where a crusher was driven automatically, a large-size shaft was twisted off by the clogging of the crusher with a sledge-hammer head. It is almost improbable that such an accident could have happened had this crusher been driven by a motor with an automatic circuit-breaker.

Until recently, it has been the practice to equip manufacturing plants with 220-volt direct current, chiefly on account of the great advance that has been made in that line of apparatus and especially where variable-speed motors were needed for certain machine tools where the requirements are such that the direct current motor is more advantageous.

The alternating current has many special advantages in the equipment of cement mills. The motors that are exposed to the cement dust are so simple in their construction that they do not need protection except dust guards for the bearings. The spare parts are so few as almost to be left out of consideration. The wiring and automatic protecting devices are enclosed in such a manner as to eliminate any sparking and consequent fire risk, and the motors are rugged and better suited to heavy overloads.

The alternating current permits the transmission of power at a higher voltage than is advisable with direct current, which will greatly reduce the cost of installation. It was estimated in one plant of several thousand horse-power capacity that the use of 600 volts instead of 480 volts showed a saving of over $8,000 on the installation alone.

For ruggedness, simplicity and continuity of operation, the turbine-driven generator has no equal. This point is well illustrated by the following quotation from a letter of one of your members operating a cement mill in the West: "The 800-k.w. turbine now in operation is giving splendid satisfaction and there is no question in my mind but that this type of power equipment is far and away the best for cement mill practice. We have had absolutely no difficulty of any kind or description in starting or operating this machine, and, from our experience so far, we are inclined to think that when once properly adjusted, the turbine will practically run without mechanical attention indefinitely." This letter refers to an alternating-current turbine-driven generator and was written entirely unsolicited. It was a comment on the turbine, while the letter was begging the manufacturer to improve their promise of shipment on a new turbine of larger capacity.

With the mechanical drive properly subdivided, dependence must be placed on one engine for one or more departments. Electricity gives two or three prime movers from which to draw power.

If one line shaft distributes the power in any one department, and it generally furnishes power to more than one department, any accident to that shaft might tie up the whole production of the mill. With electric distribution properly subdivided, it would practically be impossible to so cripple the plant.

A line shaft has to be installed not only of sufficient capacity for the total maximum load but with a big margin of safety, and this entire mechanical drive has to be run continuously whether one or all the cement machines are in operation. With the electric installation, the power is drawn only for the machines in operation and the efficiency of the plant is practically maintained.

Even if the kilns were driven by a separate engine and an independent shaft, any tie-up of either of these means of power distribution would shut down and seriously cripple the day's production. A delay of one hour on ten kilns would mean over $150 wiped out of the profits for the day, and it is seldom, if ever, the repairs can be made in one single hour with the facilities at hand. The electric drive in this department would save many hours of anxiety. Mechanical transmission cannot give you the flexibility or the output you can obtain from the electric drive.

Engineers ask how the electric can be as cheap or as economical as the mechanical drive. The dynamic power of the engine has to be converted to electric power with a generator and back again with a motor. That is perfectly true, but the commercial operation of a plant is a practical operation. With the mechanical drive, the plant is started and everything made to run smoothly, the load is thrown on and a lot of money and time spent to make tests on engines to ascertain the efficiency, which makes a fine showing. Take the same plant after a year's run and find what an enormous increase is demanded to accomplish the same result. It has been necessary to patch up here and there and to do it in the shortest possible time, for the plant must run, and instead of twenty or thirty per cent. loss in the mechanical transmission, this figure will be found enormously increased, although there is practically no means of knowing this except from the coal pile or more tests.

The electric transmission depreciates with far less rapidity than the mechanical, and any change or patchwork in the plant changes only a small percentage of the gross output of the power station. The instruments showing the power consumed are always visible and any increase in the demand for power is shown immediately; this fact alone would justify the electric drive where it is so important to operate continuously and to anticipate and to avert any trouble.

It is practically impossible for an electrical engineer to make satisfactory recommendations of electrical apparatus in a cement plant or any other kind of manufacturing plant without being perfectly familiar with the conditions under which the electric motor is to operate. This requires the hearty co-operation of the superintendent of the plant with the electrical engineer.

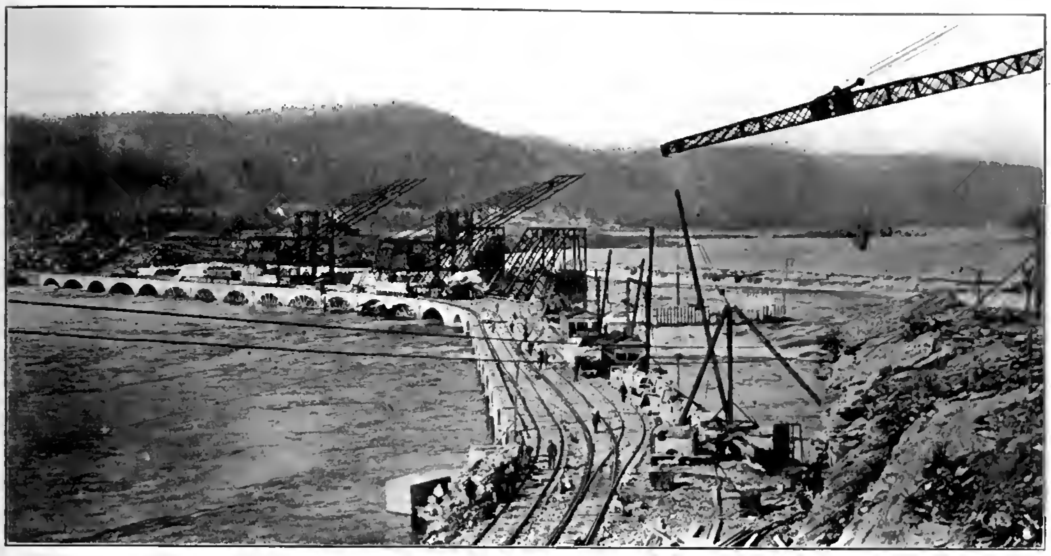
The keen competition of the present period demands the highest quality, together with the greatest output of material with the least possible cost. To be in a position to stand this competition, it is necessary for all manufacturers to use every means possible to bring their plants up to the highest points of economy and efficiency. It requires a man of strong character to seize the proper opportunity (which is generally dull times) to make these changes in his plant, in anticipation of the increased demand which will result from an inactive period.

A card index should be made of all generators and motors installed, and a record of any repairs or tests should be kept on these cards, the dates always being specified. The meters on the switchboard should be read at stated intervals during the day and night, and a regular record made and filed away for reference. These records will appeal to engineers, superintendents, managers and boards of directors; and such a file of records, if intelligently used, will put the cement industry on a scientific and economical basis heretofore unknown.

Boston Street Cleaning has been investigated for a citizens' committee of that city by Mr. R. T. Fox, whose work in Chicago was described in this journal on May 25, 1907. He found that the men he watched loafed a quarter of the time and cost of keeping horses was about twice that paid by business firms.

The Hydro-Electric Plant of the McCall Ferry Power Co.

There is now under construction at McCall Ferry, Pa., a hydro-electric plant having many unusual features in both design and methods of construction. It is on the Susquehanna River about 25 miles from Chesapeake Bay. The possibility of obtaining power from the lower Susquehanna has been realized for many years, but not until the McCall Ferry Power Co. began constructing its plant were any definite steps taken to profit by it. The originator of the project now being developed was Dr. Cary T. Hutchinson, who retained the late George S. Morrison,



Construction Bridge and General View of Site.

and in 1902 established gauging stations near the site of the plant now building to obtain definite information of the river conditions. Mr. Morison carried his work so far as to determine the site for the station, and the final studies and surveys resulted in the acceptance of this site.

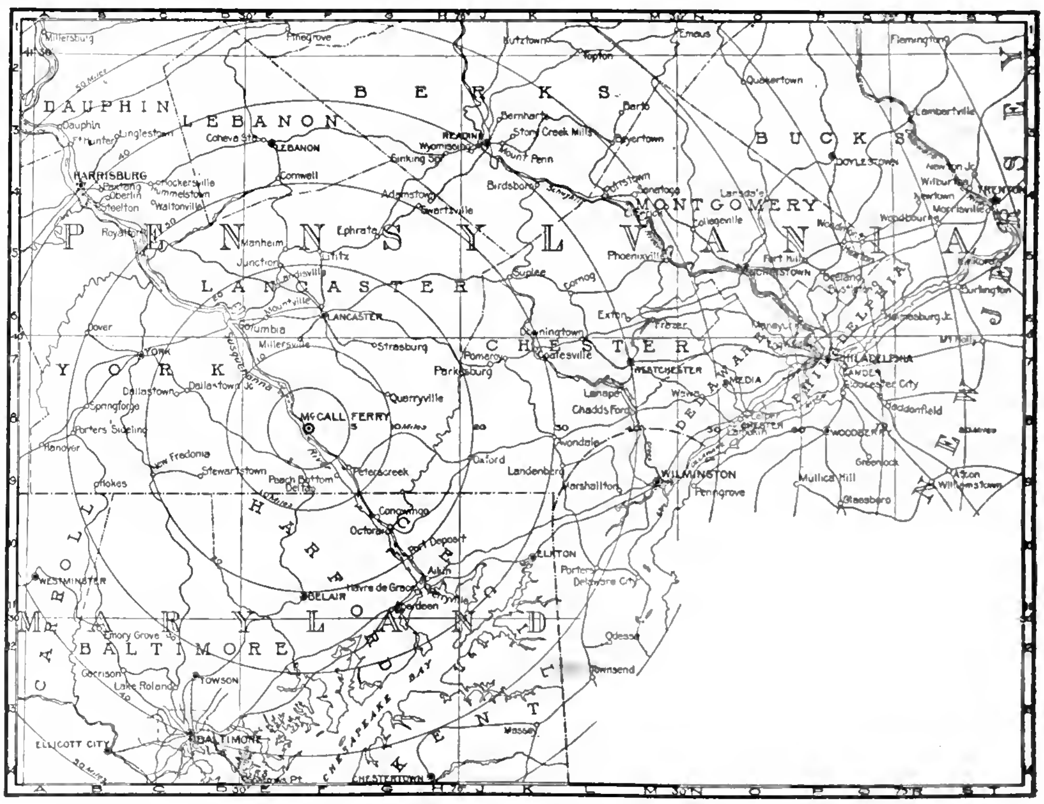
The situation of McCall Ferry is exceptionally advantageous for a large power plant, being in the center of a large well-developed manufacturing district and a short distance from tidewater. Within a radius of 60 miles are Philadelphia, Harrisburg and Chester, Pa., Wilmington and Dover, Del., and Baltimore, Md., and within 20 miles are many cities with populations ranging from a few thousand to 50,000, such as Lancaster, York and Columbia, Pa. The head of Chesapeake Bay, moreover, within 30 miles of the plant, offers in many small cities desirable factory locations accessible to large vessels. The present use of electric current for lighting, traction and manufacturing within a radius of 60 miles of McCall Ferry is great and the constantly increasing demand insures a large market. The McCall Ferry plant which is now making contracts to supply power in this territory has been designed for a nominal capacity of 100,000 h.p., half in an initial installation and the remainder developed by additonal units as needed. The total capacity for peak loads is 135,000 h.-p. on the turbine shaft.

Before the organization of the McCall Ferry Power Co. there were a number of plants projected at different points in the river both above and below McCall Ferry, which had secured water rights, and options on land. These developments were smaller than the station now being built, and the present company, having bought the rights of the smaller companies, was able to consolidate all the projects into two large ones. A possible site for another plant of 100,000 h.-p. exists at Conowingo, Md., 14 miles below McCall Ferry, and is controlled by the same company.

Hydraulic Conditions.—The Susquehanna River has a drainage area of 27,400 square miles, the larger part lying in Pennsylvania. Its watershed includes the steep slopes of the Allegheny Mountains, which cause sudden rises of rather frequent occurrence. The river occupies a deep valley, and for 125 miles above its mouth has an average slope of 3½ ft. per mile, the fall at McCall Ferry being 8 ft. per mile. The conditions on which the design of the plant is based have been studied at Harrisburg since 1890 and at McCall Ferry since 1902. The records thus obtained show that with the adopted head of about 55 ft. the flow of the river assisted by an adequate storage capacity can be depended upon for the continuous development of 100,000 h.-p. The storage will be secured by a lake 6 miles long and 4,000 ft. wide, formed by the dam. The discharge necessary to develop the normal rating of the plant on a 12-hour load is 10,000 cu. ft. per second, corresponding to an average run-off on the catchment area of 0.47 cu. ft. per second per square mile, the drainage area above McCall Ferry being 26,766 sq. miles. The discharge at peak load will be 27,000 cu. ft. per second. The flood flow considered in making the plans was about 671,000 cu. ft. per second; the record of the highest flood, that of June, 1889, corresponding to an average runoff on the drainage area of about 25 cu. ft. per second per square mile. The floods come with great rapidity, the flow in the river frequently jumping from 30,000 to 100,000 cu. ft. per second or over. The necessity of providing carefully for these conditions is further emphasized by the large amount of ice carried toward the end of the winter, much of it in large, thick cakes.

Dam.—The plant and dam are built at a point where the river is about 2,600 ft. wide, and divided into two channels by Fry Island. The east or Lancaster channel is about 900 ft. wide, and the west or York channel about 1,200 ft., and the island about 500 ft. The stream is only 400 ft. wide a short distance above the dam, but the depth and swiftness of the current forbade construction there. The present site offers a ready means of handling the flow during construction by reason of the two channels. Above and below McCall Ferry the river is dotted with small islands and crossed by ledges, on one of which the dam rests. The water a short distance above and below it is very deep. Another such ledge crosses the river at Cully's Falls, and a channel had to be cut through it for the tailrace. The rock, though hard, is considerably eroded and fissured.

On account of the floods, the dam has been constructed as a spillway throughout its entire length of 2,350 ft. The dam extends only 600 ft. across the Lancaster channel, the remainder of the channel being spanned by the power house. Its crest is 45 to 50 ft. above the average summer water level. The section has been calculated for a head of 17½ ft., above the crest corresponding to a flow of 304.7 cu. ft. per second per linear foot of the dam, a quantity equal to the maximum recorded flow of the river. The section was calculated on the assumption that the weight of the masonry was 135 lb. per cubic foot and the weight of the falling water over the dam, and the pressure of the water on the apron were neglected. The base of the dam is uniformly 65 ft. wide, below a point 51 ft. down from the crest of the dam. Where the dam crosses the island, the ledge rises to within 41 ft. of the crest, necessitating a change in the section, which was made



Map Showing Location of McCall Ferry.

by retaining for the lower part of the apron the same curve as was used elsewhere, the only difference in the two sections being in the length of this lower curve of the apron. The front face is vertical.

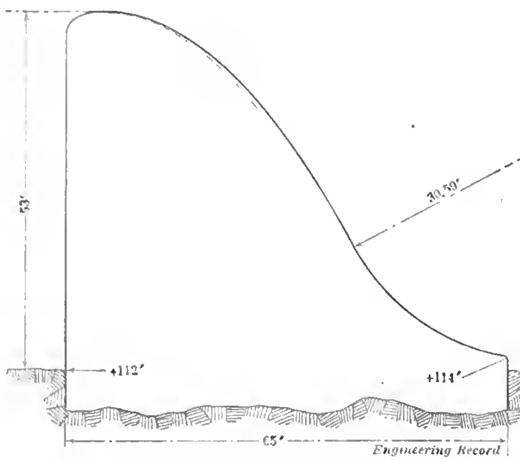
The dam is 1:3:5 Portland cement concrete with pudding stones up to 1 cu. yd. in size. Atlas and Giant cement are used. The sand is coarse and very clean, secured from a bank at Charlestown, Md. The stone is a very hard trap, weighing 193 lb. per cubic foot, used without screening, and contains pieces running up to 7 in. in length. The pudding stones are of the same rock, which is obtained at a quarry operated by the company at Conowingo, Md. These stones, forming 20 per cent. of the total yardage, are placed not closer together than 8 in. and 2 ft. back from the surface of the concrete. The amount of material in the dam is 174,000 cu. yd.

Power House.—The power house occupies the eastern part of the east or Lancaster channel, and stands at an angle of 42 deg. with the face of the main dam. In front of it is a forebay, where the racks and screens are located, and the entrances to the chutes for disposing of any ice which gets into the enclosure. The conduits leading to the turbines start immediately back of the inclined racks. They are built entirely of concrete, no steel being used either for reinforcing or for the intakes or draft tubes. The ten turbines are beneath the power house floor, five on each side of the two exciters in the center of the building. South of the power house is the transformer house, carried by arches spanning the draft tube outlets in the tail race.

The front wall of the forebay is carried on eleven arches, the crowns of which are 6 ft. below the crest of the dam, and 1 ft. below the low water level, so that they will always be submerged. Back of the arches and carried on inclined piers are the screens, and back of them are the gates closing the intakes to the turbines. The screens are built in panels 10 ft. wide and 11 ft. high, four tiers to a unit. They have frames of 10-in. channels, supporting the screen bars, which are 7/16x4½ in., with 2-in. spaces between them. Instead of using gas-pipe separators, as is generally done, the bars will be kept apart by plates ⅜ in. thick, which have notches cut in them of the thickness of the bars. The strips of metal between the notches are bent over the rods on which the bars are hung, thus holding the latter apart. The frames slide in cast iron seats bolted to the noses of the inclined piers. This arrangement allows the screens to be withdrawn for repair and cleaning by merely catching them with a line from the crane, and pulling them out. Within the forebay are two chutes for disposing of any ice that may get by the exterior ice protection. One of these chutes 6 ft. square is located between the two exciters at the center of the power house, and the other measuring 8x10 ft. at the east end of the forebay.

The gates closing the intake conduits are 16 ft. high and 6 ft. wide, and are raised and lowered by the large traveling crane in the screen and gate room. An auxiliary gate also lowered and raised by the crane is cut into the main gate, and can be opened so as to equalize the pressure in the forebay and the intake conduits.

The intake conduits for the main units start in three openings separated by piers each 6 ft. wide and 16 ft. high. Eight ft. back from the gates these three passages merge into one which is 15 ft. wide, and for a short distance 13 ft. high, expanding as the conduit forms the turbine chamber to a height of 33 ft. There are two draft tubes one leading from each wheel of the unit. These draft tubes join about 20 ft. from the unit, but are here divided by a vertical wall, the discharge outlet into the tailrace of each unit being composed of two passages, each 13 ft. wide and 15 ft. high. This arrangement of the draft tubes, since they are constructed of solid concrete necessitated very complicated form work, especially since it was necessary to have easily curving surfaces which would offer little or no resistance to the flow of water. The exciters are located in the center of the power house with five main units on each side of them. The intake conduits and draft tubes for them are 6 ft. square in section.



Section of Dam.

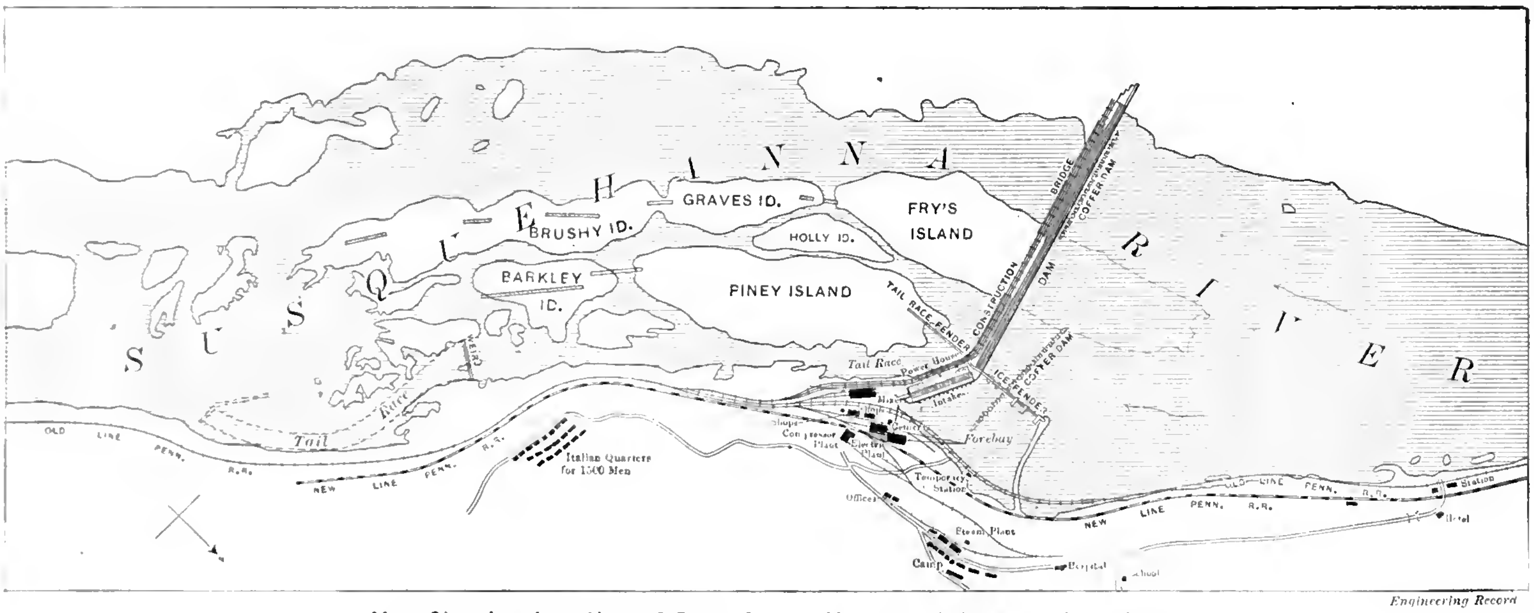
Each turbine is set in the concrete chamber without the usual steel or iron casing. Each chamber can be closed independently of all the others, and after being closed by the gates in front of the intake conduits and the stop logs at the ends of the draft tubes can be drained through outlets leading to pumps installed for that purpose.

Below the power house floor runs a chamber parallel to the length of the power house in which will be installed the pumps for draining the wheel chambers and the turbine-driven oil pumps for supplying the thrust bearings with oil.

The turbines are of the vertical shaft, inward and downward flow, Francis type, made by the I. P. Morris Co., Philadelphia. There are 10 main units each capable of developing 13,500 h.-p. under a head of 53 ft. with the gates open 80 per cent. at 94 r.p.m. Each turbine when run at its rated load will take about 2,700 cu. ft. of water per second. Each turbine has two separate wheels mounted on the same shaft, the latter being of forged steel, 20 in. in diameter. The upper wheel discharges through a steel casing leading to the draft tube while the lower wheel is set immediately over the draft tube pit, and discharges into it without the medium of a casing. The wheels are about 10 ft. in diameter.

The weight of all the moving parts of both generator and turbine is carried on a thrust bearing which is supplied with oil from pumps driven by small turbines. Separating the oil pumps in this manner from the main units allows the oil in the thrust bearing to be put under pressure before the unit is started. The thrust bearing which carries a total weight of 335,000 lbs., is supported by a lens-shaped casting set into the concrete. The exciters, also made by the I. P. Morris Co., have a capacity of 1,000 h.-p. and are of the same general type as the main units.

Ice Protection.—The large amount of ice which has to be disposed of and its long continuance each winter has necessitated special precautions for protecting the plant and turbines. It is aimed to keep the entire enclosed forebay free from ice and to accomplish this an outer forebay is provided and separated from the main river by a series of submerged arches and timber cribs, which form racks holding in place floating booms. This ice protection is 630 ft. long, and stretches from the point where the main dam and the power house join to a ramp 300 ft. long built out from the shore. The concrete ice protection consists of 3 submerged arches each having a span of 68 ft. with 8-ft. piers between them. The crowns of the arches are 2 ft. below the estimated low water elevation so that the arches are always submerged, the ice and floating debris being thus stopped and floated toward the dam, where a special runway for this purpose has been constructed between the main dam and the power house. The top of this concrete structure rises to a height of 22 ft. above the crest of the dam and 4½ ft. above



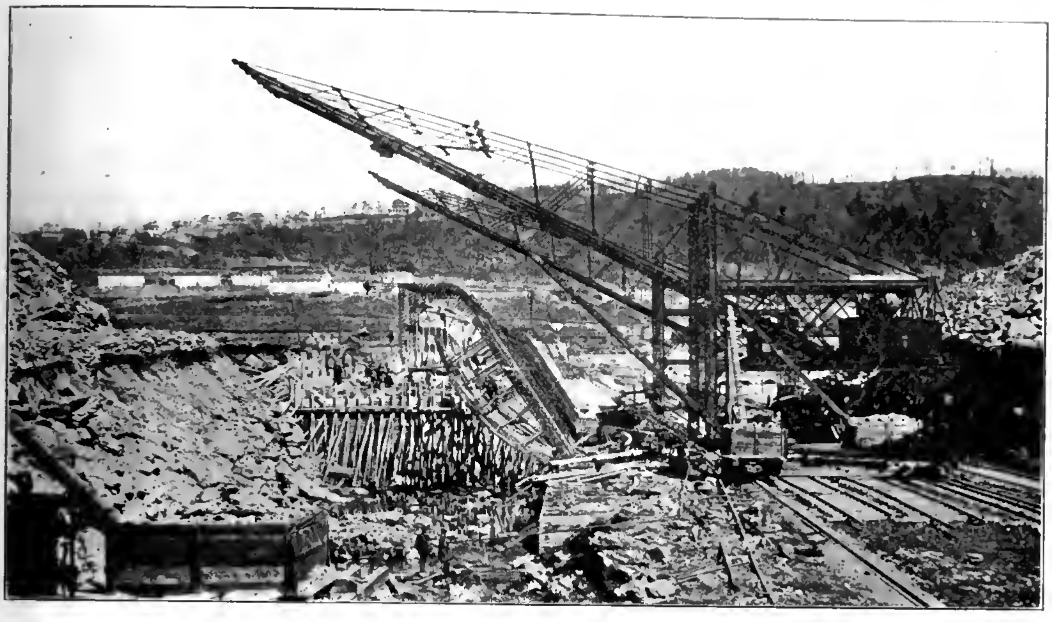
Map Showing Location of Dam, Power House and Construction Plant.

the high water elevation. The top is 6 ft. wide and the back face has a batter of 4 in. to the foot, the piers at rock foundation being 30 ft. long. The space between the concrete structure and the ramp is occupied by four timber rock-filled cribs, spaced 104 ft. apart and supporting floating booms. These cribs are 24 ft. wide and 16 ft. long on top, the length increasing with the depth, being 64 ft. at the foundation. The floating stop logs between the cribs are made of three layers of six 10x12-in. timbers each. They are bolted together with spaces between them so as to make the boom 7 ft. 8 in. wide and 3 ft. thick. The boom slides in recesses in the timber cribs, rising and falling with the stage of the water above the dam. The direction of the ice protection is parallel to the flow of the river so that the flow will assist in carrying the ice and debris toward the main dam and over the runway.

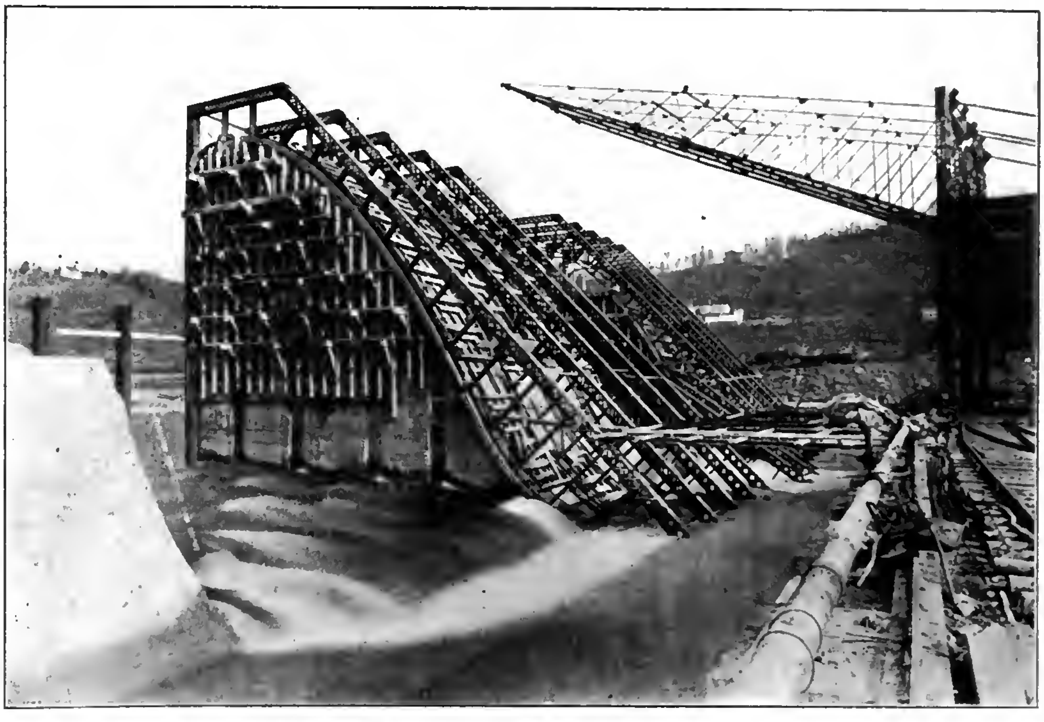
In addition to this ice protection, a spillway has been provided between the power house and the shore for disposing of any ice which forms in the forebay or finds its way into it. This spillway 40 ft. wide has the same elevation as the crest of the main dam. Separating it from the power house and protecting the latter from the ice passing to the spillway is a wall 8 ft. thick reaching above the high water elevation. This spillway cuts off the power house from the shore and access between them is had by a bridge 5 ft. wide, and by a tunnel 14 ft. wide and 16 ft. high running through it. The tunnel is laid with a standard gauge track which extends 55 ft. inside the power house, allowing the machinery to be handled directly from the cars by the power house cranes.

Tailrace.—The tailrace, 3,000-ft. long, is nothing more than the former bed of the Lancaster channel, lying between the east bank of the river and the chain of islands south of Fry Island. This channel presents a very curious formation. The bed is of solid gneiss, with benches on either side submerged at the original condition of the river from 7 to 10 ft., and having between them a channel about 100 ft. wide and from 80 to 90 ft. deep, with vertical walls. This unusual depth continues until near the point where the tailrace flows into the main channel of the river. A ledge of rock is here encountered through which a channel 1,000 ft. long and varying in width from 150 to 300 ft. is being blasted. In order to prevent the river from flooding the tailrace by flowing through the openings between the islands which separate the two channels, rock filled timber cribs are being thrown across these openings, and carried above the highest level which the water in the channel can reach. At the point where the rock ledge obstructs the channel near the end of the tailrace a concrete weir will be built, with its crest at the same elevation as the top of the draft tube outlets, so as to preserve a water seal for the turbines.

In order to prevent a large volume of the water which comes over the dam from finding its way at once into the tailrace, and thus raising the level of the latter, a deflecting dam 576 ft. long starts at the junction of the main dam and the power house, just opposite the beginning on the upstream side of the ice protection, and runs over to Piney Island, which lies south of Fry Island. This dam will be built of solid concrete, using pudding stones and the proportions which were adopted for the main dam. Its crest will be at the same level as the power house floor, 14 ft. below the crest of the main spillway. With this dam, and the crib work between the islands below the plant, the water coming over the main dam, is confined entirely to the western or York channel, allowing the Lancaster channel to be used for the tailrace. The low water level in the latter will be about 15 ft. below the water level in the spillway channel immediately below the dam.



Excavation for Dam on Fry's Island.



Pier Sections of Spillway Dam Showing Steel Forms.

Construction.—The preliminary work such as the erection of the camp and cutting the timber on the side hills was begun in Nov., 1905, and in the following January with a full force. Work on the dam was started on Oct. 25, 1906. It is expected that the plant will be in operation in June, 1908.

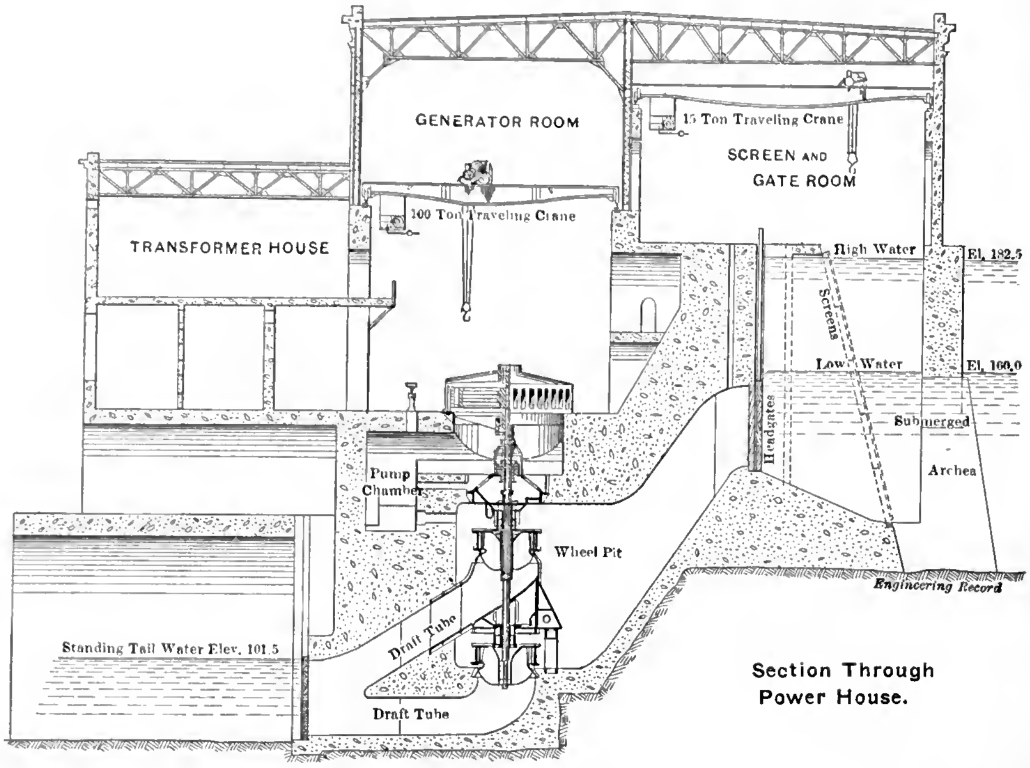
Construction was first started across the Lancaster channel, which carried the greater volume of water and in which the power house is located. On account of the rapid rise of the river, and the large discharge during high water, the problem of constructing the dam was a serious one. To have provided against the maximum flood during construction would have involved great expense, while any less provision meant the occasional stoppage of the work, and the probable loss or damage of the construction equipment and the partially completed work. After a thorough study of all the conditions it was decided to construct a cofferdam sufficiently high to prevent being overtopped by a flood less than 60,000 cu. ft. per second. Since the inception of the work, daily reports regarding the weather conditions on the watershed have been received from the weather bureau at Harrisburg, and when a flood above 60,000 sec. ft. is on the way preparations are made to meet it. Such a case occurred on Mar. 15, 1907, when a flood of 320,000 cu. ft. per second swept over the work. Warning had been received and everything movable in the path of the water was moved to a place of safety, and work carried on without interruption until within an hour of the arrival of the flood, when the remaining equipment was run to cover. The flood did no damage to the partially completed dam and power house, but carried off four standard gauge tracks laid with 60-lb. rail which were on the construction bridge below the dam.

Cofferdam.—The first step in the actual work of harnessing the river consisted in building the cofferdam, a rock filled timber structure 1,000 ft. long and about 300 ft. up the river from the site of the dam. Soundings had been made across the channel at the places where the cribs were to rest, and where these did not give a satisfactory description of the bottom, divers were sent down to get more accurate information. The bottoms of the cribs were then framed on shore to fit the rock foundation on which they were to rest, and after having a few courses of timber built upon them were launched, towed into position, and held there by cables anchored on shore. They were then built up in the usual manner, the tim-

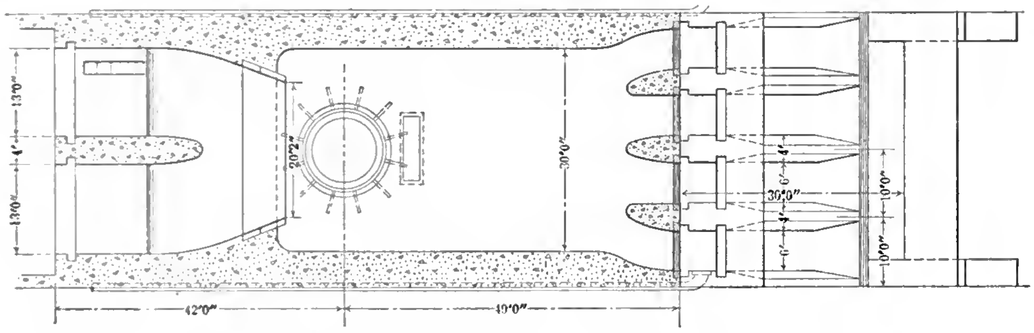
bers, which were 8x10 in., being drift bolted together with 7/8-in. drift-bolts, 30 in. long. The materials were conveyed to the cribs by means of a Lidgerwood cableway with a span of 1,200 ft. over the site of the cofferdam. In addition to this means of conveyance, a standard-gauge track was carried out and extended over each separate crib as soon as completed, and on it was run a traveling stiff-leg derrick. Rock was placed in the cribs to sink them as the timber work was carried up. The cribs were 16 ft. wide and varied in length, in multiples of 8 ft. from 24 to 40 ft., being built in bays 8 ft. square. The deepest crib was about 30 ft. below the original low water level.

The openings between the cribs were closed with stop logs, and in front of them were placed two rows of 2-in. timber sheeting, breaking joints. The careful placing of this sheeting is largely responsible for the remarkable tightness of the cofferdam. The separate planks were driven to the bottom, rammed slightly, and on being drawn up showed by the bruising of the ends how they were to be cut to fit the rock bottom. After being shaped they were again put in place and rammed, and withdrawn a second time to determine whether further fitting was necessary. Against the sheeting was thrown the strippings from the excavations for the dam and power house, a mixture of sand and loam, and on top of this a quantity of rip-rap.

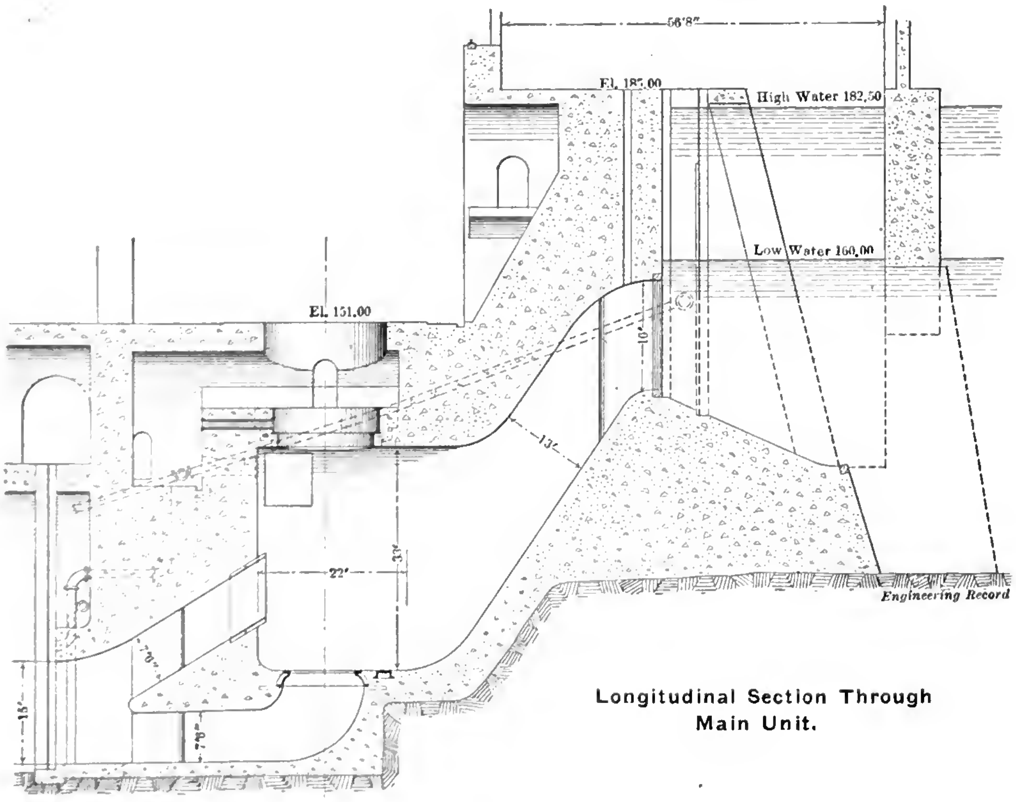
As soon as the cofferdam was sealed the dam site drained of itself. In order to determine the tightness of the work, the leakage was measured over a weir. The results were remarkable, for though there was a head of 22 ft. on the cofferdam for the greater part of its length of 1,000 ft., and the rock foundation was fissured and eroded, the leakage was only 1 gal. per second, at the present time after being overtopped by numerous floods the leakage is carried away by a 6-in. pipe.



Section Through Power House.



CROSS SECTION THROUGH C.L. OF CONDUITS



Longitudinal Section Through Main Unit.

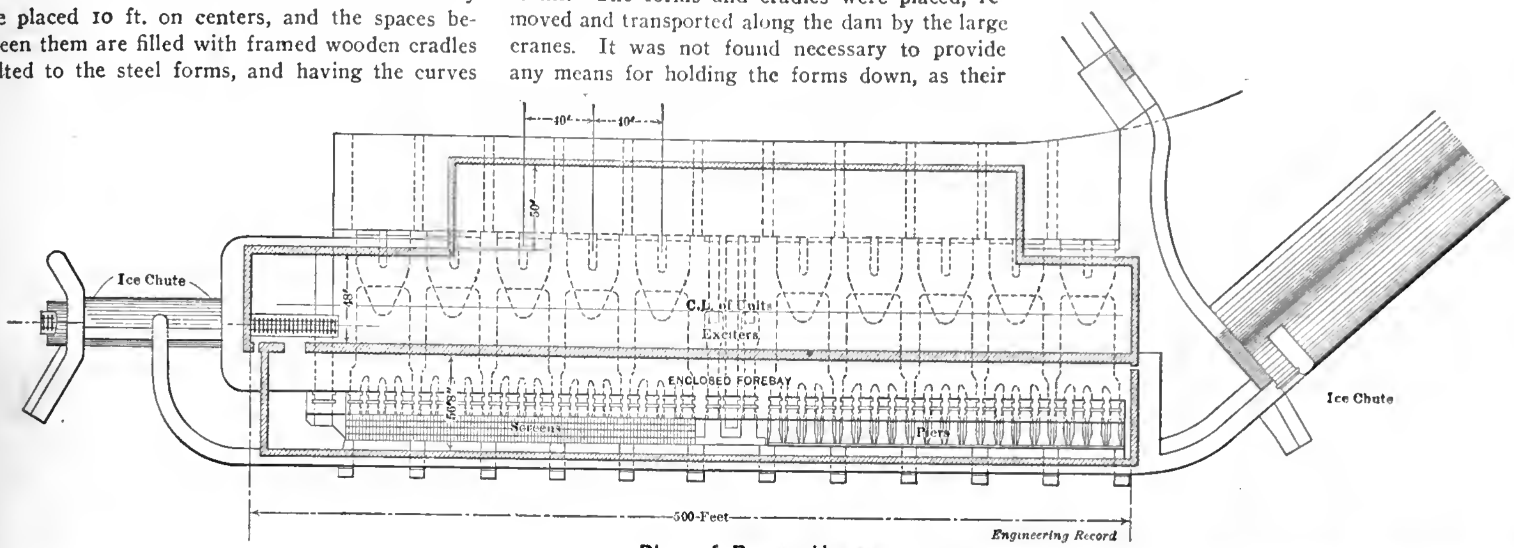
Foundation.—It was found that the rock bottom for the foundation of the power house was of the same hard gneiss which had been examined, before the work commenced, on the banks of the river and the islands near the proposed site. Near the western end of the power house, howver, the rock became more dense, contained less mica, and finally merged into a very hard and dense trap, quite similar to that quarried at Conowingo, and used in the concrete and for pudding stones. Examination showed it to be a dike which ran to Fry Island and then disappeared. Both the trap and gneiss were excellent foundations for the heavy structures and test holes drilled the whole length of the work showed the same high quality of rock for a depth of 40 ft. below the river bed. The surface rock which was considerably eroded and fissured was removed, and at the shore end of the power house about 50,000 cu. yd. of the solid rock had to be taken out. The surface of the rock was then thoroughly cleaned, and a layer of cement grout spread over it preliminary to placing the concrete. The amount placed at any one time was governed by the strength of the forms, very close supervision being given so as to guard against bulging. The bond between successive sections is secured by inbedding pudding stones in the surface of the work which is to be left to set. When the next course is added, the surface is first thoroughly swept with wire brushes, and then washed. Cement grout is spread over the surface, and the concrete work continued.

Forms.—The forms for the turbine intakes, and chambers, and draft tubes are quite complicated as everything is built of plain concrete. The forms are carefully designed and built by experienced form builders. Those that can be transported are put together on a framing platform adjoining the carpenter shop, and are carried to the work on flat cars, and set in place by means of cranes. In order to fashion the complicated curves on many of the forms, sheet iron and bass wood are used, the latter being bent into shape after being steamed. The forms are very heavily braced and tied across when possible by iron rods, as any bulging or displacement would result in altering the carefully designed water passages, and cause a loss of head by obstructing or changing the course of the flowing water.

The forms used on the dam are deserving of special attention and represent one of many instances on this work of the skillful design of construction equipment. Unlike the general run of large contracting plants which contain many makeshifts built primarily for some other class of work, much of the equipment here is of orig-

inal design, and well adapted for the work. The entire method of construction and the means for carrying it on show a well considered plan which was fully determined before the work was started. The length of the pier sections of the dam correspond with the most efficient working capacity of the bridge cranes, and the spacing of the structural steel forms, has likewise been fitted to these cranes so as to profit by their full capacity.

The forms for the dam consist of structural steel bracing completely spanning the section of the dam, and resting on two shoes, one on the upstream and one on the downstream side. They are placed 10 ft. on centers, and the spaces between them are filled with framed wooden cradles bolted to the steel forms, and having the curves the forms above the crest of the dam. At the shore of Fry Island, where the section was changed, the steel forms could not be used because of the warped surface connecting the sections. Wooden-braced forms were therefore put in place and the value of the steel forms was demonstrated by the difficulty experienced at this point. The steel forms were used on the island section by merely unbolting the rafter at the center and allowing the two parts to overlap and pass each other, the lower part of the apron having the same curve on both sections, thus obviating the necessity of having two distinct sets of forms. The forms and cradles were placed, removed and transported along the dam by the large cranes. It was not found necessary to provide any means for holding the forms down, as their house and dam is decidedly novel, and has proven economical and satisfactory. Before work was started on either structure a plain concrete bridge 1,060 ft. long and 50 ft. wide, containing 16,000 cu. yd., was built across the Lancaster channel to Fry Island, parallel to and 16 ft. from the downstream edges of the dam and power house. The York Channel now being closed by the coffer dam, the bridge is being extended across it, making the total length about 2,300 ft. The arches of the bridge immediately in back of the openings between the pier section of the dam have the same span as that opening, 40 ft., so as to dis-



Plan of Power House.

River Side of Concrete Mixing Plant.

Draft Tubes Looking from Tailrace.

of the surface of the dam. The steel forms consist of a post with a total height of 57 ft. supporting a rafter which runs over the apron, and rests on a shoe at a horizontal distance of 68 ft. 2⅞ in. from the shoe under the post. Beneath the inclined rafter is carried a 12-in. 20½-lb. channel having the exact curve of the apron. On the bottom of the chanel is a 2-in. timber, bolted to it, and having a width of 1 ft. 9½ in. Bolted to this strip are uprights 3 in. wide and 6 in. high on each side, having bolt holes through them by which the cradles are fastened between the steel frames. The cradles are each 8 ft. 2⅜ in. long and 4 ft. 2¾ in. wide, and each one is numbered according to an erecting diagram, for its proper place on the dam. On the channel sections the dam is being built in 40-ft. piers, with 40-ft. openings between them. For these piers five of the steel forms were used and braced together by diagonals, and by a large box beam connecting weight alone was sufficient, but wires were passed through the dam, tying the vertical post and the rafter together to prevent the latter from bulging. An additional advantage of the steel forms lies in the saving in instrument work, it being necessary to set only the shoes with transit and level.

The cofferdam in the York channel is now completed and sealed, the flow being diverted through the openings between the pier sections of the dam across the Lancaster channel. The remainder of the dam will be built behind the new cofferdam and carried up in the manner followed with the Lancaster section, leaving 40-ft. openings. These openings will then be closed alternately in the two channels by stop logs and the concrete carried up behind them, the flow being diverted alternately to the two channels.

Construction Bridge.—The method of carrying the materials to their places in the power charge readily all the water coming through the openings. Back of the piers, however, and alternating with the 40-ft. arches are 32-ft. arches, the discharge through them not having as high a velocity as that coming unchecked through the larger openings. The arches back of the power house have spans of 35 ft., this being the width of the draft-tube discharge passages into the tail race. This end of the bridge is to be part of the permanent construction and will serve as the foundation for the transformer house. The disposition of the remainder of the bridge has not yet been determined.

Cranes.—On the bridge are laid four standard gauge tracks, and spanning them with a gauge of 44 ft. are three large traveling cranes. The clearance under the latter is 16 ft. 3 in., so that cars and engines can pass beneath them. Each crane has four outriggers with a horizontal reach of 94 ft. and a capacity of 5,000 lb. at the end of

each outrigger. The carriages are operated independently of each other, and each crane is consequently the equal of four separate cranes, each with a capacity of 5,000 lb. The outriggers extend out beyond the upstream face of the dam and can deliver buckets, pudding stones, forms and necessary materials to any part of the work. The carriages run down over the tracks beneath the cranes and take the materials direct from the cars. The outriggers are spaced 10 ft. on centers to agree with the spacing of the steel forms and thus are enabled to deposit four buckets of concrete or place four pudding stones at a time. They are moved along the bridge by the dinky locomotives. The hoisting engines for the carriages are operated by compressed air, supplied from the main compressor plant.

The cranes on the bridge are used in placing materials in the power house as well as in the dam, but for building the former two additional cranes of special design are used. They consist of a tower 125 ft. high running on a track with a gauge of 45 ft. and carrying outriggers hinged 90 ft. above the top of rail. Each tower has two outriggers 135 ft. long with a capacity of 5,000 lb. each at the end, and since these can be carried horizontal as well as at an angle with the horizontal, the maximum reach is equal to the length of the outrigger. These cranes are placed on the upstream side of the power house, and the outriggers extending across to the tracks on the construction bridge, handle materials from the downstream side of the structure. As in the case of the cranes on the bridge they were designed especially for the construction of this plant.

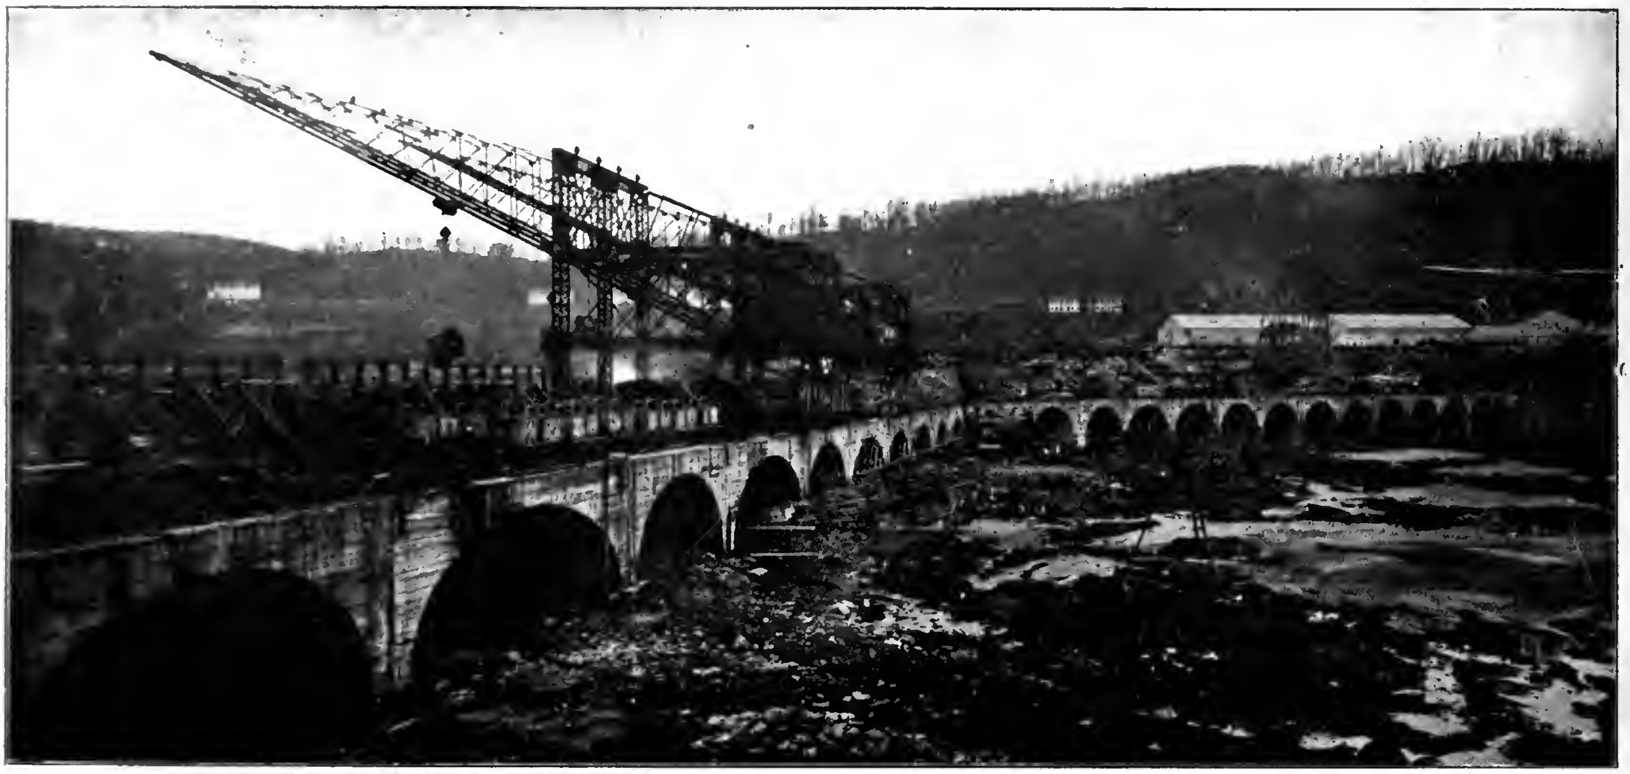
Concrete Mixing Plant.—The concrete mixing plant is placed on the Lancaster shore, near the beginning of the construction bridge. It is 200 ft. long and 90 ft. wide, divided longitudinally into four rows of bins, over each of which runs a standard gauge track. These bins which are 16 ft. deep are divided into smaller compartments by partitions 12 ft. apart. Three of the bins are used for storing stone, and the fourth for sand, while the cement is kept in a bay 25 ft. 8 in. wide running the entire length of the building, and served by a special track outside the plant. The passage of the various ingredients through the building is entirely by gravity. Beneath the bins and across the width of the plant directly under the discharge gates run tracks of 3-ft. gauge, on which the charging cars are operated. These cars are of the bottom-dump type, and run to hoppers which discharge into the mixers. The latter, of which there are eight, are placed 25 ft. on centers, and dump into 1-yd. buckets carried on flat cars on standard gauge tracks which lead to the construction bridge.

The materials are brought into the mixer plant in standard bottom-dump gondolas with a capacity of 100,000 lb. each, and unloaded into the bins. Charging cars having a capacity of 1 cu. yd. each are run successively under the discharge gates of the cement, sand and stone bins, and then carry the aggregate to chutes leading to the mixers. The discharge openings of the bins are closed with sheet steel sliding gates operated by compressed air. A rod connected with the piston of an air cylinder runs beneath each transverse row of bins and slides through U-bolts fastened to the under side of the sliding gates. When it is desired to secure a charge from a bin a pin is slipped through a hole in the rod immediately in front of the U-bolt of the door to be operated. Compressed air is admitted to the proper end of the cylinder and the door is opened. Closing is effected by slipping the pin in a hole in the rod on the opposite side of the U-bolt, and admitting the air to the opposite end of the cylinder. There are two narrow gauge tracks to each mixer, parallel to each other and served by a distinct transverse row of bins, so that while the car on one track is discharging into the mixer, the car on the other track is being charged with the ingredients for the next batch. The charging cars have been divided into two unequal compartments, one of which holds the proper amount of sand and cement for a batch and the other the proper amount of stone. Steam-driven Smith mixers with a capacity of 1 cu. yd. each are used.

The plant has a capacity of 2,400 cu. yd. in 10 hours. The storage capacity is about 5,700 cu. yd. of stone, 1,100 cu. yd. of sand, and, together with an auxiliary storage house, 70,000 bbl. of cement.

The track in front of the mixers runs directly to the construction bridge, and has a switch to an outer track at the end of the plant away from the bridge so that an engine bringing in a string of empty buckets, does not have to set them out on a siding in order to pull out the train of loaded cars. Should it be pushing the empties, it runs on the outside track beyond the mixng plant, then takes the switch to the track in front of the mixers, and pushes out the loaded cars. In pulling empties from the bridge, the dinky pushes out the loaded cars, and drops the empties in passing the mixers.

Auxiliary Plant.—The auxiliary plant connected with the work embraces a power house, machine shop and carpenter shop. The power house contains two Sullivan compressor outfits, with a capacity of 600 h.-p. supplying 3,800 cu. ft. of air per minute at a pressure of 100 lb. per square inch. The plant and camp are lighted by electricity, the current being furnished by a G. E. alternator. Steam for the engines and for heating the camp is supplied by four 150-h.-p. Atlas boilers. The machine shop contains 5 forges, a steam hammer, two engine lathes, two drill presses, two punches, a shaper and some smaller machines. The carpenter shop contains a swinging crosscut, a circular and a band saw. The augers used both in the shop and in the field are driven by compressed air. A number of small saw mills were used in cutting up the timber which originally covered the hills on both sides of the river, the timber for the cofferdams being all secured from this source.



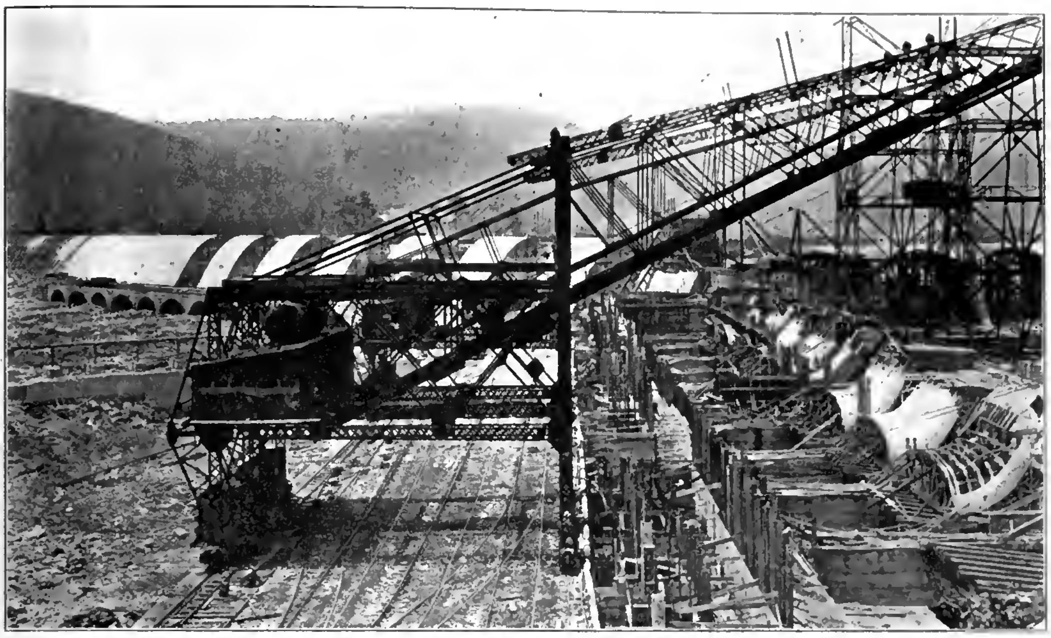
Looking toward Lancaster Shore Showing Dry River Bed, Construction Bridge and Plant.

Five standard flat cars are used on the work, 55 concrete cars carrying two 1-yd. buckets each, 16 mixer charging cars, twenty-five 6-yd. dump cars, 4 dinky standard-gauge locomotives, one 45-ton Baldwin yard engine, 4 narrow-gauge dinkies with a supply of 4-yd. narrow-gauge dump cars, 25 Ingersoll compressed air drills, 12 traveling derricks and one 12-in. and two 20-in. Morris centrifugal pumps. The concrete cars were all built on the work, the dump cars by the Western Dump Car Co., and the traveling derricks by the American Hoist & Derrick Co.

The amount of freight coming to the plant, about 50 cars per day, consisting of supplies, equipment, and construction materials has resulted in the running of a special freight train every day by the Pennsylvania R. R. to handle the business. The tracks in the power company's yard are well maintained with the result that there has never been a derailment.

Quarry.—The quarry at Conowingo, Md., is equipped with four 7-ton Lidgerwood cableways, each with a span of 550 ft. across Conowingo Creek. Rock is being taken from both sides of the stream for a stretch of 1,000 ft., the cable-

ways being mounted on tracks so that they can be moved to cover all parts of the work. The rock is hoisted by the cableways in skips and put into dump cars for transportation to the crushing plant, or into 50-ton gondolas for delivery to McCall Ferry. Six 10-ton traveling derricks are used in handling the material immediately alongside the railroad tracks. Thirteen Ingersoll-Rand, 15 Little Jap, and 4 Little Wonder drills, the latter made by the Hardsocg Wonder Drill Co., are being used. There are in use 3 dinky locomotives, one 45-ton Baldwin yard engine, twelve 12-yd. dump cars, six 7-yd. dump cars, and two No. 8 Austin gyratory crushers.



Dam, Power House and Large Crane, McCall Ferry Plant.

Miscellaneous.—The backing-up of the water by the dam will flood the present right of way of the Pennsylvania R. R., and the power company is therefore building a new line for the railroad, 13 miles long, at an elevation from 20 to 30 ft. higher than the present grade. This work is being done under contract by H. S. Kerbaugh, Inc.

When the work was started there were no accommodations at McCall Ferry or in the neighborhood for the large force required in building the plant. The company, therefore, built a camp and installed a steam heating system, electric lights, running water in all buildings, and sewerage and fire protection systems. About 1,500 men are employed, 400 of them being at the quarry at Conowingo.

The total yardage of concrete including pudding stones, in the power house, dam and construction bridge will be 330,000, about half of which has now been placed. The total rock excavation amounts to 200,000 cu. yd. The cost of the entire plant including property and the new line for the Pennsylvania R. R. will be $10,000,000.

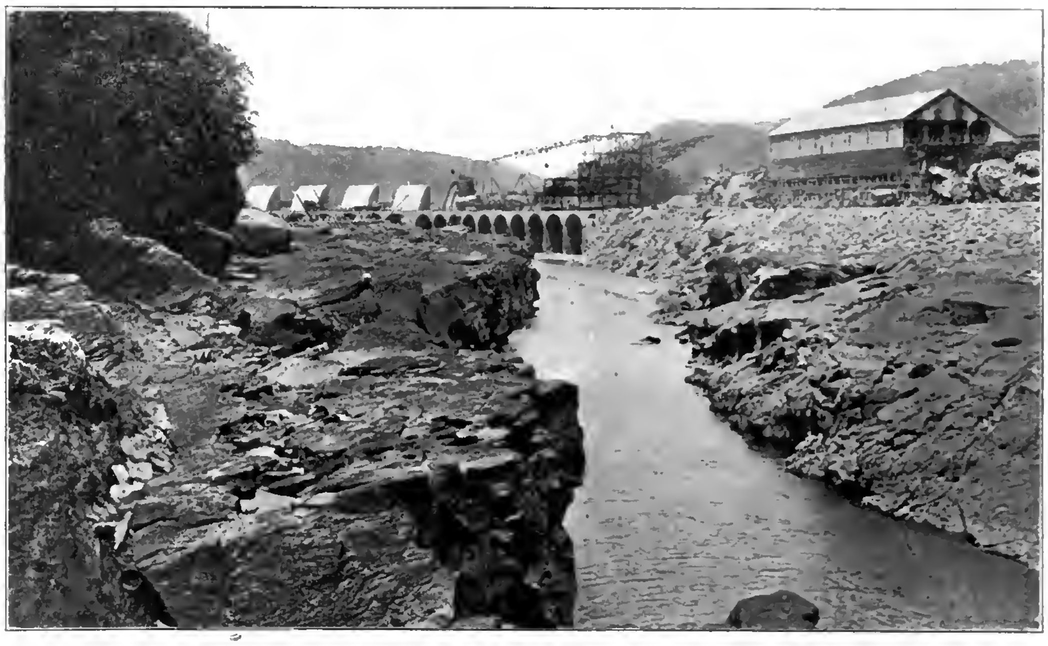
The work is being done by day labor. The New Jersey Bridge Co. built the bridge cranes and the steel forms for the dam, and the Baltimore Bridge Co. the tower cranes.

Dr. Cary T. Hutchinson is chief engineer of the McCall Ferry Power Co., and Mr. Wm. Barclay Parsons is consulting engineer. Mr. Hugh L. Cooper is the hydraulic engineer and designed and is constructing the hydraulic plant on an administration basis and no work is being contracted. Mr. B. R. Value is the engineer in charge of construction.

RAILROAD TIES for use on the lines of the Italian state railways will in future be preserved by the Rueping process. The government recently entered into a contract with the owners of this preservative process whereby all of the ties are to be treated.

Cost-Keeping as an Aid in Managing Men

Engineers are better qualified to act as managers of large enterprises to-day than they were formerly, owing to the development of cost-keeping and cost analysis, according to a paper on cost-keeping as an aid in managing men, recently published in the "Proceedings" of the Pacific Northwest Society of Engineers. The author, Mr. Halbert P. Gillette, chief engineer of the Washington Railroad Commission, first points out that before the development of methods of cost-analysis, the successful manager of men was usually one who relied mainly on his knowledge of human nature and his ability to hold men to his tasks. They were drivers, and only men willing to play such a role were successful as a rule. Of late years, however, engineers have been rising to the head of one undertaking after another, who have generally achieved their success through ability to get at the cost of each kind of work and study methods of reducing the expense of each item.



Natural Tailrace Channel and Mixer Plant, McCall Ferry Plant.

To most people, a cost-keeping system means nothing but a sort of bookkeeping, and they are unable to understand how a bookkeeper can develop into a successful manager. But the truth is that modern cost-keeping involves cost analysis, and cost analysis involves a study and comparison of the relative economy of men and of machines, and a study of relative economy leads to improvements, both in machines and the methods of using them. Cost-keeping has for its main object the determination of the efficiency of men. A proper system of cost-keeping tells daily what each workman or each gang of workmen has accomplished. It is better than a foreman, for it cannot "stand in" with the men. It is better than a foreman, for it costs you less and it tells more. A cost-keeping system tells who are good men and who are lazy men. It shows whom to discharge and whom to promote. It tells whose wages are too high and whose are not high enough. And, finally, it leads to that ideal condition of industrial organization known as profit-sharing. When a manager has learned, by cost-keeping, that certain men or groups of men produce more than others, he soon perceives that the advantage of stimulating them to further use of brain and muscle by paying them a bonus for each unit produced in excess of a prescribed minimum. The men respond to this stimulus, and often in a remarkable degree.

A proper system of cost-keeping shows the material used and the labor performed every working day. The day is the unit of pay for work done, and it must be made the unit in measuring work wherever the work is of such nature as to permit daily measurement. Often it is not practicable to make accurate daily measurements of work accomplished. Then it is usually possible to estimate the output approximately. For example, to measure the yardage of concrete placed in a day may not be readily done, but the number of sacks of cement used each day can be recorded, and the yardage of concrete thus estimated closely. It is in devising methods of approximating the output that an engineer has a chance to use his ingenuity and his engineering knowledge.

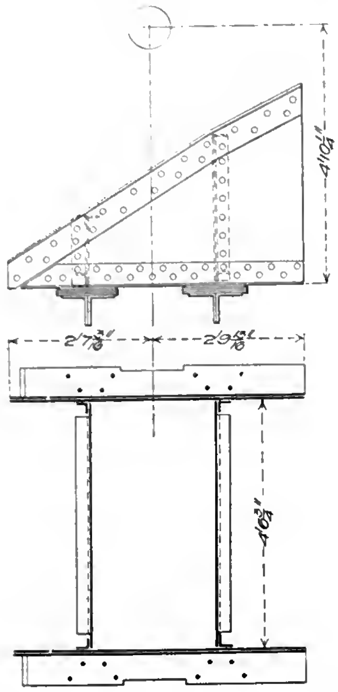
Second only in importance to securing records of work done is the devising of ways that enable the manager quickly to compare results day by day. All engineers have been trained to depict mechanical measurements and formulas graphically by the aid of charts, diagrams and curves. Hence it is second nature for the engineer to plot a "cost curve," which shows at a glance the unit cost of each kind of work for each day or each week. When a marked fluctuation occurs in the cost curve, indicating a rise or fall in the unit cost, then it is that the manager can usually visit the work to advantage. His very coming at such a time is in itself a spur to the men, for they realize that he is keeping in constant touch

with their progress, and immediately notices an increase or decrease in output.

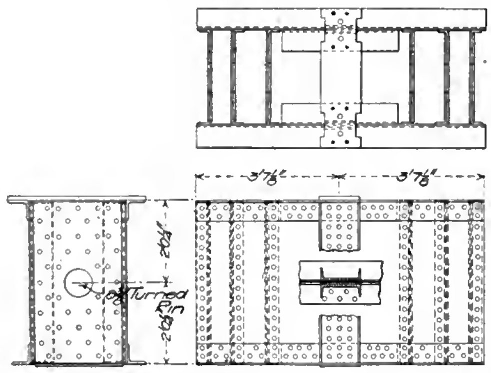
By the modern method the contractor receives a daily report of work done at every cut. In rock the report shows the number of linear feet of holes drilled, the pounds of explosive used, a chart of the location and depth of drill holes, carloads of rock hauled away, and such other details as are needed to determine both progress and economy of work done. Instead of the old progress profile, he has a mass diagram which indicated the total number of cubic yards in each cut, or in each group of cuts. On this mass diagram the amount of material removed each day is indicated, and, since the diagram is drawn to scale, the areas show at a glance the total work to be done, the amount done to date, and the amount remaining to be done. On a large mass diagram of the whole excavation it is well to indicate the points that should be reached at the end of each week, if the contract is to be finished within the time limit. Similar mass diagrams show the yardage of masonry and other diagrams are prepared for the quantities of other items in the contract.

Diagrams of this character possess two decided advantages over the tabulated reports from which they are prepared: First, they permit of quick comparisons of progress by days, by weeks and by months. Second, they insure that no reports are omitted or sent in incomplete. It is easy to overlook the omission of a certain daily report, when examining a pile of such reports, but on a diagram no such omission is possible.

In the prosecution of my present work of appraising the value of the railways of the State of Washington, I have gone through innumerable records of the cost of bridges, culverts and other structures. It has been noteworthy that the cost of a very large percentage of structures has exceeded the engineer's estimates; and, in such cases, the engineer, or the superintendent, tries to explain the cause of the excess cost. The records show, in most cases, that neither of them knew what the cause was until after the work was finished. No better example could be found of the

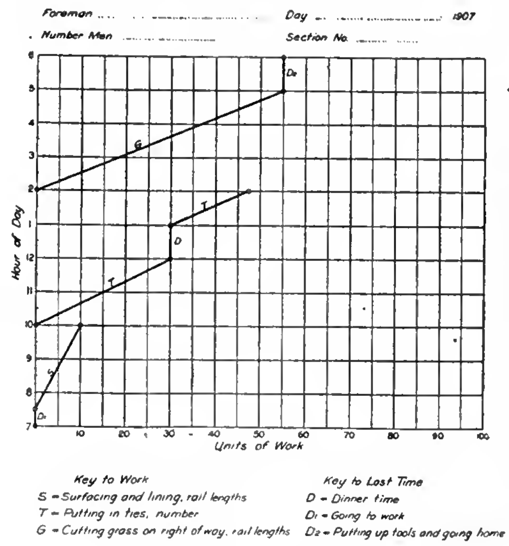


Filler between Inclined Chord and Bottom Girder, Quebec Bridge.



Bearing Girder under Bottom Girder, Quebec Bridge.

day and the progress from hour to hour. The diagram, or form, is a proposed card to be used by section foremen, and it shows the day's work done by a gang of section men. The vertical lines, or ordinates, show the hours of the day from 7 A. M. to 6 P. M. and the intermediate quarter hours. The horizontal lines, or abscissas, show number of units of work accomplished. The black circles are holes punched with a conductor's punch. The lines connecting the punch holes can be ruled in after the day's work is done. This particular card shows that the gang of men arrived at the site of the day's work and started in at 7.30 A. M. At 10 A. M. they had completed 10 units of work, and the key letter *S* on the straight line between 7.30 and 10 A. M. is found to be the number of rail lengths of track surfaced and lined. At 10 A. M. the gang began putting in ties, as is indicated by the key letter *T* on the straight line between 10 A. M. and 12 M. Then the curve of work rises vertically from 12 M. to 1 P. M., indicating that no work was done during the noon hour. From 1 to 2 P. M. the work of



Section-Gang Work Chart.

inefficiency resulting from a lack of the use of modern methods of cost-keeping. Indeed, I may go a step farther and say that practically all the railroads of our country are poorly managed in nearly every department, simply because they cling to out-of-date methods of cost-keeping. Usually, however, they pride themselves upon the completeness of their records, but, as compared with the methods of cost-keeping used by up-to-date manufacturers and contractors, the average railroad is in the kindergarten class. Occasionally you will find a division superintendent who has charts made showing the daily movement of freight trains over a division. But I know contractors who have similar charts made every day which show the movement of every wagon load to the nearest five minutes of time. They can tell you not only the distance traveled and the number of trips made by each wagon, but each delay and the cause thereof. Surely if it pays to watch the movement of wagons with such care, it will pay to watch the movements of trains in a similar manner, and to study and compare results with even greater care. Yet, so far as I can learn, the details of train movement are not ordinarily plotted and studied with anything like the minuteness which a cost-analysis engineer employs in managing the movement of dirt trains over a narrow gauge temporary track.

For the purpose of indicating the degree of refinement of cost-keeping which certain contractors employ, I present herewith a diagram which is susceptible of wide application. It is like the log of a ship, in that it shows the events of each

putting in ties was continued. At 2 P. M. the gang began cutting grass, as is indicated by the key letter *G*, and quit at 5 P. M., having cut grass for a distance of 55 rail lengths. Then the curve of work rises vertically from 5 to 6 P. M., and the key letter *D* shows that this hour was lost in picking up tools and going home.

It will be noted that a card of this sort gives a perfect log of the day's work, showing all delays, their cause and duration, and number of units of work accomplished. On the back of the card a series of key letters should be printed so that the foreman can indicate on the curve of work any kind of work done, and the units in which it is measured. The rail length is a convenient unit for certain classes of work, the distance between telegraph poles may serve for other

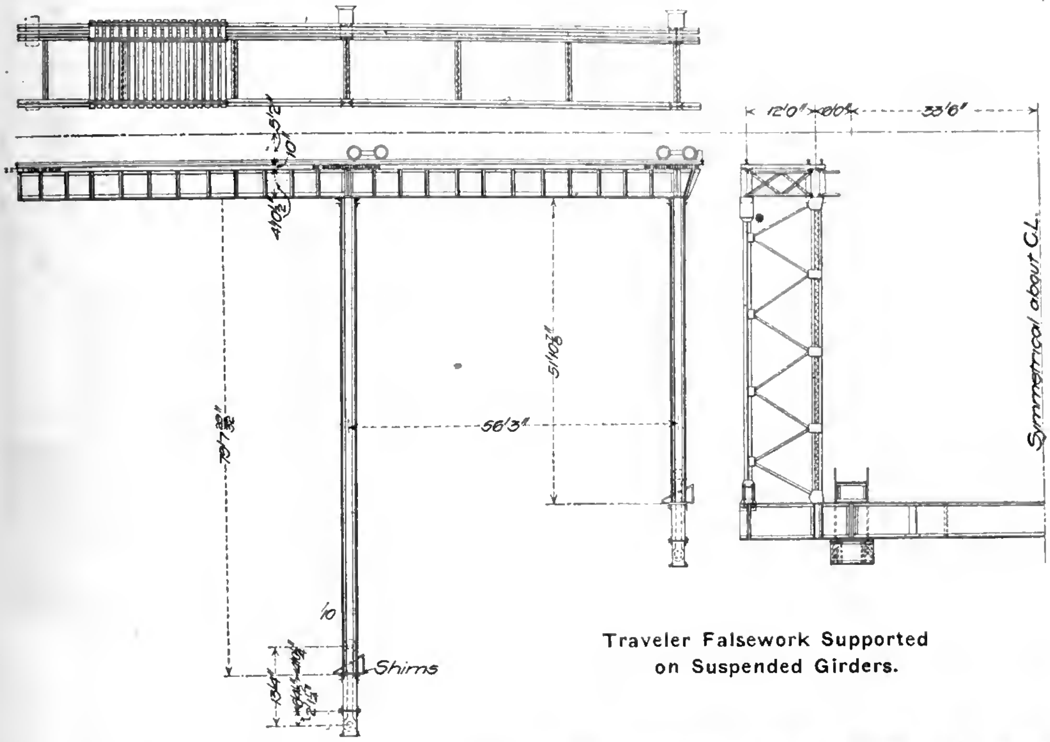
classes. Incidentally all telegraph poles on each section should be numbered consecutively. Then the foremen can be required to report the exact location of the work by writing the number of the pole on the curve of work diagram. With a system of this sort, and by paying section foremen about 50 per cent. more than is the present practice, it would be an easy matter for any engineer to increase the average output of section men by 100 per cent. over present outputs.

The card shown herewith is obviously applicable to innumerable kinds of construction or manufacturing where men work as individuals or in gangs. It becomes complicated when a gang under a foreman is split up into smaller gangs which are continually shifted from one kind of work to another. But such shifting is usually unnecessary, and can be obviated, as a rule, by the use of better judgment in the management of the work. Indeed, the very objection to the use of such daily card reports points the way to better management by indicating the lack of reason for using small units that putter away time.

There is a rapidly growing demand for engineers who can devise and apply a modern cost-keeping system. Indicative of this fact Mr. Gillette stated that within the last few months he had many inquiries from very large contracting firms, as well as from engineering departments of the federal government, for names of competent cost-analysis engineers. These inquiries are coming in with increasing frequency, showing that the value of the services of a cost-analysis engineer are being recognized. Frequently, however, the salaries offered would be no inducement to an engineer having a satisfactory position; but the chances for advancement in salary is infinitely greater than in the ordinary lines of engineering professional work. Moreover, the chance to become a partner in a firm is much better where a man is engaged in studying labor costs with a view to reducing them than it is where he is engaged in studying designs with a view of saving materials. Few men are capable of judging the true worth of the engineer who saves money by an economic design of a bridge or by the economic location of a railway. But no man is so blind as not to be able to see the ability of the engineer who reduces the cost of excavating rock by 10 cents a cubic yard, or who effects an increase of 5 per cent. in the tonnage hauled over a given division. Hence, it will always be more profitable to be a cost-analysis engineer than to be a designing engineer or a locating engineer.

The Suspended Falsework of the Cantilever Arms of the Quebec Bridge.

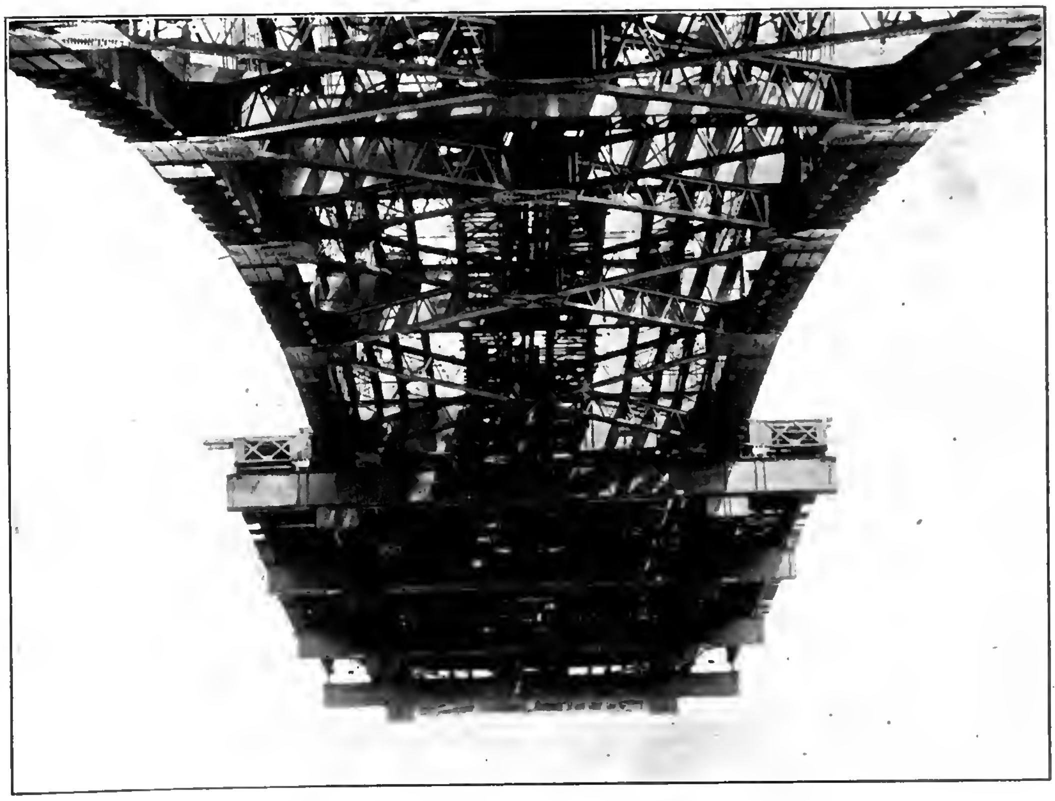
The recent collapse of a part of the Quebec Bridge gives added interest to anything connected with the design and erection of that structure. In earlier articles concerning it attention has been called to many of the details and to the carefully developed field methods. One of the most interesting parts of the erection was the use of suspended falsework in connection with the river arm, which will be described in this article.



Traveler Falsework Supported on Suspended Girders.

The 560-ft. cantilever arm of the Quebec Bridge had trusses 67 ft. apart on centers and 315 ft. in maximum depth erected by the same great gantry traveler which had already been used for the erection of the south anchor arm. The traveler, which was illustrated and described in The Engineering Record of March 4, 1905, weighed with its equipment about 2¼ million lb. and had a Z-shaped longitudinal elevation, with a 54x103-ft. tower, 212 ft. high and a 66-ft. forward overhead cantilever. It moved entirely outside the finished superstructure with horizontal and vertical clearances of 79 and 202 ft. respectively. It moved on two 12-ft. gauge tracks 91 ft. apart on centers, at roadway level, one track 12 ft. outside the center line of each truss. For the anchor arm these tracks were supported on two lines of steel falsework towers erected on shore between the main and abutment piers. The south cantilever arm had been and the north cantilever arm was to be erected by the cantilever method self-supporting during erection at a maximum clear height of about 150 ft. above the high water of a maximum depth of 200 ft. The support of the traveler tracks in the same manner as for the anchor arms was, of course, impossible and a system was devised of suspending them from the cantilever trusses in a novel and ingenuous manner which, before it proved to be successful, was considered by some bridge engineers to be impracticable and was undoubtedly without close precedent for its magnitude and the details of its construction.

The cantilever arm falsework consisted essentially of two sectional steel viaducts, about 80 ft. in maximum height, supported on each side of the cantilever arm on the cantilever ends of box plate girders suspended from the lower chord pins of the cantilever trusses. Each viaduct was made with three lines of longitudinal girders supported on transverse bents each composed of two vertical posts 12 ft. apart on centers; the bents being spaced 56 ft. 3 in. apart longitudinally to correspond with the panel points of the cantilever trusses. The vertical bents diminished in height from the piers to the extremities of the cantilevers but the box girders supporting them were duplicates for all points so that only four of them and four full sets of longitudinal girders were required. This provided one panel more than was necessary for the support of the traveler and permitted the removal of the rear panel and its re-erection in front, panel by panel, as fast as the traveler progressed. The total weight of the cantilever arm falsework was about 200,000 lb. exclusive of permanent track stringers utilized and the box girders, the heaviest members, weighed



Traveler Falsework Suspended from Cantilever Arm, Looking up.

about 25,000 lb. each. All members were handled by tackles swung from the completed portion of the cantilever arm or from the traveler itself and after the erection was well advanced the rear panel falsework could be removed and replaced in front ready for the traveler to be moved forward on it in a short time.

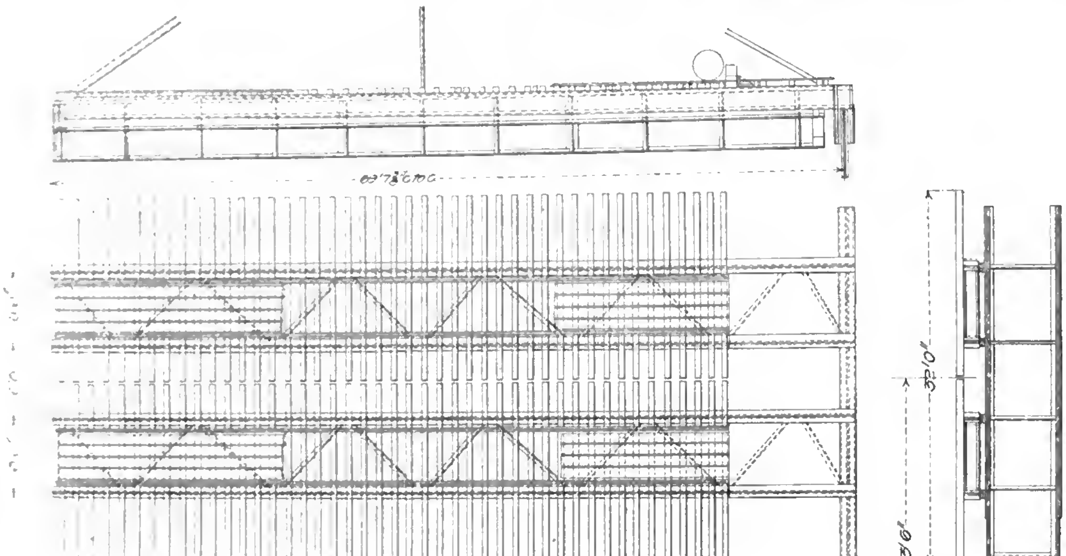
The suspended box girders were 106 ft. long, 6 ft. deep and 42 in. wide over all. Each girder had two 72x½-in. webs, 28 in. apart made in three shop-spliced sections, eight 6x6x9-16-in. full length flange angles and on each flange four 14x½-in. cover plates varying in length from 29 to about 87 ft. The webs were connected by five transverse vertical shop riveted diaphragms and both top and bottom flanges were connected by side plates and lattice bars as indicated in the general drawings.

Three sets of connections were temporarily bolted to the top flanges to provide for the attachment of the hoisting tackles by which the girders were handled. Each set consisted of a pair of short 12-in. channels with their vertical webs riveted together and bored to receive a 6-in. horizontal pin with its axis parallel to that of the bridge. The lower flanges were secured to the top flanges of the beam by 14 turned bolts through each and the connection resembles a simple shoe to receive the end bearing of a small truss. In the planes of the cantilever trusses and of the vertical posts in the falsework bents the plate girder webs were stiffened by vertical reinforcement angles and filler plates proportioned to receive the maximum vertical shear at these points.

To support the cross girder at any required panel point of the cantilever truss an eye-bar about 13 ft. long was engaged on each end of each lower chord pin and passing down between the webs of the girder, engaged a parallel pin through three vertical diaphragms, parallel to the bridge axis, which connected the web of a special bearing girder fitted to the bottom flange of the main girder at its intersection with each plane of the cantilever trusses. Each bearing girder was about 7 ft. long and 4 ft. deep with two webs 28 in. apart connected by six diaphragms 1¼ in. thick. The center of each web was reinforced by two 12-in. channels and two 12x½-in. vertical plates. In order to insure the proper position of the bearing girder under the transverse girder, a plate was riveted across the flanges of the former and engaged a slot in the flanges of the latter.

Riveted triangular filler blocks were seated on the top flanges of the main girders under the panel points of the lower chords and were wedged up to close bearing against the bottom flanges of the latter by means of tapered shim plates between them and the girders. These fillers were made with two ⅜-in. web plates about 4½ ft. apart parallel to the bridge axis and have single 6x6x½-in. flange angles on the outsides of their webs on the horizontal and inclined edges. The webs were connected by two ⅜-in. vertical transverse diaphragm plates and both upper and lower flange angles had open holes for turned bolts connecting them to the bottom flange of the lower chord and the top flange of the girders. The inclined top flange angles were slightly bent to enable them to conform exactly to both adjacent sections of the lower chord. In erection the bearing girders were permanently bolted to the main girder and the eye-bar suspenders were permanently connected to the former, the filler pieces being changed every time the transverse girders were moved, to correspond with the varying inclinations of the bottom chord.

Handling 106-Foot Bottom Girder to Support Suspended Falsework.



Cantilever Truss and Working Platform of Main Traveler,

The transverse trestle bent for each traveler track consisted of two vertical posts 12 ft. apart transverse to the bridge axis, braced with zigzag angles. The inside post carried a much heavier load than the outside post and had a rectangular cross section made with two built channels latticed. The outside post had an I-shaped cross section made with a web plate and four angles. Horizontal connection angles were riveted across tie plates on the opposite flanges at the feet of the columns and received four 1⅝-in. vertical bolts about 2 ft. long with upset ends which passed through pockets and had lower nuts bearing on corresponding angles riveted to the web of the transverse girder thus firmly securing the column to it. The base plate of the inside column was bolted to the top flange of the girder with 24 short vertical bolts. Each pair of columns was handled as a separate unit by tackles suspended from the overhang of the traveler and was changed for a shorter one to correspond with the increased elevation of the transverse girder every time the latter was moved.

Each column bent carried three lines of 4-ft. 10½-in. plate girder stringers, two of which were bolted close together with pairs of separators between their webs and were centered on the outside columns. The third girder was centered on the outside column and was connected to the other two by end and intermediate vertical transverse frames and bottom flange zig-zag angles rigidly uniting the three girders so that they formed a single unit shifted from rear to front as the erection progressed by tackles suspended from the traveler. Cross ties 10 in. high, 12 in. wide and 2 in. apart in the clear were bolted with the 3 lines of rails to the top flanges of the girders and at panel points, groups of seven

10-in. I-beams were interpolated between the ties to receive the concentrated loads from the traveler tracks. The top and bottom flanges of the inside girders were connected to the vertical members of the main trusses by short horizontal braces with bolted connections and similar braces were provided at the middle points of the longest vertical columns. The stringers used for this suspended falsework were borrowed from the railroad track of the center suspended span.

In order to deliver bridge members to the tackles suspended from the overhang of the traveler during the erection of the cantilever arm, a working cantilever platform corresponding to the overhang was extended from the foot of the traveler at roadway level. A light riveted triangular longitudinal truss 69½ ft. long and 38 ft. deep with a horizontal bottom chord was bolted through its end vertical post to each outside forward column of the traveler, 79 ft. apart transversely on centers. The lower chords of these trusses were stiffened laterally by inclined horizontal outriggers braced to form with the lower chords virtually horizontal triangular trusses 12 ft. deep at the inner ends. The outer ends of the cantilever trusses are connected by a transverse plate girder 6 ft. deep with its top flange bearing across the bottom flanges of the lower chords of the cantilever trusses. The girder was suspended from the lower chord at each end by four vertical angles engaging the webs of the chords, which were made with built channels having their flange angles turned in and latticed, and riveted at their lower ends to gusset plate projecting from the webs of the girder parallel with the bridge axis.

This girder carried the outer ends of four lines of plate girder stringers 5 ft. deep and 69½ ft. long, which at the inner ends were directly connected to the permanent floor beam. These girders had drop ends seated on the top flange of the forward transverse girder and were spaced 3 ft. 3 in. and 9 ft. 9 in. both sides of the center line of the traveler to correspond with a spacing of the two material tracks which they supported. The stringers for each track were braced together in the usual manner with vertical transverse sway-brace frames and zigzag flange angles. Each track had 6x8-in. ties 16 ft. long and 16 in. apart on centers, covered between the rails with a solid floor of 4-in. longitudinal spruce planks. It was at first intended to provide 2 additional stringers midway between the outside track stringers and the cantilever trusses to support solid floors about 16 ft. wide each side of the tracks, but these were finally omitted. Rail stops solidly riveted to the stringers and braced to the end of the platform were provided for each track to prevent the possibility of material cars being pushed over the end. The pairs of stringers, with the ties, rails and bracing for each track were independent units easily connected and disconnected from the cantilever overhang and were removed and set inside the traveler tower every time the latter was moved in order to give clearance for lowering the transverse falsework girders and permanent floor members through the framework of the cantilever overhang.

Each track on the overhang was long enough to receive one freight car and the forward truck of a second, a total of 6 axle loads, which when both tracks were simultaneously loaded were limited to the dead load of car plus 12,500 lb. each, equivalent to 50,000 live load on the car. When only one track was loaded a live load of 116,000 lb. per car, equal to a live load of 29,000 lb. on each axle was allowed. These loads produced total live load reactions of 65,000 lb. at each end of the forward transverse girder where the dead load reactions are 52,560 lb. Care was taken to remove the cars from the overhang as soon as their loads were lifted from them.

The Cooling Plant for Walter Baker & Co., Ltd., Dorchester, Mass.

In The Engineering Record of April 20, 1907, the new central power plant of Walter Baker & Co., Ltd., of Dorchester, Mass., was illustrated. It is the purpose of this article to describe a new cooling plant designed by the same engineer, Mr. F. W. Dean, of Boston, for this company. This plant is interesting as embodying the most advanced ideas in refrigerating engineering, and was designed with a view not only to simplicity and ease of operation but also to high economy.

The machinery is placed in a building previously used as a power house, but vacated upon the completion of the new central power plant. This building has been remodeled by the removal of a party wall, making a machine room 66 ft. long by 44 ft. wide. A new roof with monitor gives a clear height of 21 ft. under the main roof, and 31 ft. under the monitor. A waterproof pit 7 ft. deep and irregular in shape, with an area of 1,000 sq. ft., is used for the ammonia pumps, the aqua receivers and miscellaneous piping.

At the back, adjoining and partly over the Neponset River, an addition has been erected of brick and concrete, having a roof of mill construction with monitor. The roofs of both buildings are covered with tar and gravel and copper flashing and siding.

The condenser room has a clear height of 21 ft. under the main roof and 27 ft. under the monitor. All the woodwork in the room is wire lathed and plastered while the window frames are of copper and glazed with wire glass. All iron work is protected by concrete. One-half of the condenser room is over the river, and supported on concrete piers. The floor is of concrete sloped to drain all of the condenser water to the river. The whole river side of the house is open, except for the four reinforced piers which support the roof; openings are fitted with Kinnear rolling doors 14 ft. wide by 16 ft. high.

The steam for this plant may be obtained either directly from the boiler plant of the new power house, or from the low-pressure manufacturing lines, which carry exhaust steam to the various mills.

The refrigerating machine is of the well-known Pontifex Hendricks absorption type, operated either with exhaust or reduced-pressure steam.

The present plant is designed to cool 846 gal. of calcium chloride brine of a specific gravity 1.240 from 0° Fahr. to —10° Fahr., or each of the three units installed is capable of cooling 282 gal. of brine through a ten-degree range, the warmest brine never being above 0° Fahr.

The nominal rating of each unit is 100 tons of refrigeration or the total of the three, 300 tons of refrigeration in twenty-four hours. The plant has ben designed for an ultimate capacity of 600 tons of refrigeration, and all the units, piping, and other details are laid out with this in view. It consists of brine circulating, brine cooling, ammonia generating and condensing equipments, together with the water circulating and steam condensing units.

The purpose of this installation is to furnish refrigeration throughout the various mills of the company for cooling chocolate liquors and goods, and also for cooling rooms where chocolate goods are being manipulated.

There are some 30,000 lin. ft. of 2-in. galvanized pipe installed in bunker rooms, with air circulation to the various rooms where the refrigeration is required. Extensive mains run to all parts of the buildings, while specially designed equipment is used to reduce handling and save time. This is so extensive that no attempt will be made in this article to describe anything except the mechanical plant. All ammonia piping is confined to as small an area as possible and to the machine room, all such piping being directly under the eye of the engineer.

The brine circulating plant consists of two centrifugal pumps, in duplicate, each of 1,000 gal. capacity against a 100 lb. head and direct connected to a 75-h.-p. De Laval steam turbine operated condensing.

Each pump has an 8-in. suction taken from a 12-in. main brine return line from the various factories; a standpipe 12-in. in diameter and 21 ft. high takes care of all the air in the suction line, provides for expansion in the line, and insures a nearly constant head on the pumps.

There are three 8-in. pump discharge connections into a main supply header to the brine coolers, space being reserved for another pump of the same capacity. The brine from the pump is discharged into a 12-in. main distributing header, which has 6-in. branches to each cooler. An 8-in. by-pass is also provided for shunting a part of the brine around the coolers when desired. The brine coolers are of the Hendricks enclosed type, with spiral brine coils contained by a cast iron shell 45 in. in diameter and 15 ft. long, each weighing some 24,000 lb.

There are three Venturi meters, one on the supply to each cooler. These are provided with manometer tubes, so that the quantity of brine passing to each cooler may be easily noted. Thermometers are placed on the supply to and the return from each cooler, so that the temperature of the brine to and from each is obtained. Having given the temperature difference and the quantity of brine circulated to each, the amount of refrigeration, both total and that which each cooler is doing, in tons per twenty-four hours may be exactly computed.

The return from the cooler, which is also the supply to the factory, is 12 in. in diameter, and is connected into the main returns, both directly and through a brine tank. This tank is 4 ft. 6-in. in diameter and 14 ft. long, with a man-hole at the top for supplying calcium in bulk, when the charge needs to be increased or strengthened. It also serves as a reservoir for brine.

Adjacent to each cooler is its anhydrous receiver with the ammonia expansion line connection. These receivers are 18 in. in diameter and 10 ft. high, and contain cooling coils. Both cooler and receivers are provided with gauge glasses with automatic self-closing gauge cocks of the Hiller type. The insulation on both consists of Nonpareil sheet cork with hardwood lagging.

The generators, each consisting of a cast-iron shell 45 in. in diameter and 14 ft. long, have 2-in. diameter steam coils of the return-bend pattern, immersed in the aqua ammonia charge, and terminating in a 5-in. main steam supply header. The condensation from these coils is carried to a 3-in. main drip header, these headers being trapped and discharged to 7½ x 4½ x 6-in. Warren receiver pumps through a 3-in. pipe. These receiver pumps are in duplicate.

The main to the generator steam headers is 5 in. in diameter in each case, and is connected both into an 8-in. low-pressure main, and into an 8-in. high-pressure main through a 5-in. reducing valve. All reducing valves are by-passed and provided with valves, so that they may be repaired while the plant is running. A safety valve is also placed on the low side of this reducing valve in order to safeguard against excessive pressure. All the generator drips are pumped back to the boilers. The use of a separator on the main steam supply to the generator insures dry steam.

The refrigerating machines are designed to run on 5 lb. pressure during part of the year and on 20 lb. or thereabouts the remainder of the time.

The rectifier, absorber and condenser are of the atmospheric type and are contained in the condenser room on the river side of the plant. These consist of a series of vertical coils arranged side by side; the top coil is the condenser; the bottom coil the absorber, while between each 100-ton unit the rectifier is carried on pipe supports above and to one side of the condenser coil. This allows the warm water from the rectifier coils to go to waste without passing over either the condenser or absorber coils. Water distributing troughs are suspended over each vertical coil.

The rectifiers consist of 3-in. extra heavy galvanized pipe made into counterbored steel return bends, galvanized and fitted with gland and packing in addition to the pipe thread. These coils are 24-in. on center, ten pipes high and 26 ft. long.

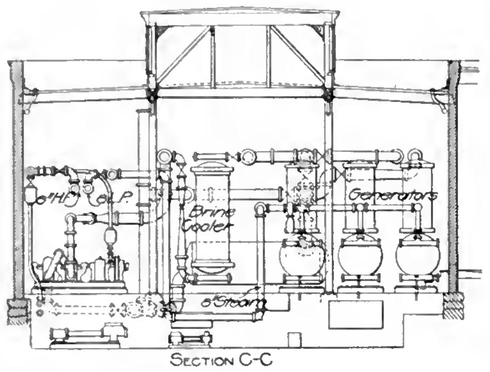
The condenser consists of 2-in. extra heavy wrought iron pipe, galvanized on the outside and made into counterbored cast steel return bends, galvanized with gland and packing. Each condenser has ten coils twenty pipes high, 26 ft. long, and the condensing surface is aproximately 2,500 sq. ft.

The absorber is of the same general design as the condenser, with gas distributing pipes entering the return bends. Each absorber has ten coils of 3-in. extra heavy galvanized, wrought iron pipe 18 pipes high and 26 ft. long.

generators are covered with 2 in. of 85 per cent. magnesia and ½ in. of plastic magnesia, the whole lagged with hardwood sheathing.

The water circulating units consist of two vertical duplex Warren steam pumps, each 7½ x 7 x 12 in. for the steam condensers, and two centrifugal pumps made by the De Laval Steam Turbine Co., each of 800 gal. capacity against 30 lb. pressure for the ammonia condensers.

The turbine pumps are direct-connected to a 20-h.-p. De Laval steam turbine operated condensing. The water for condensing purposes is



Section through Machinery Room.

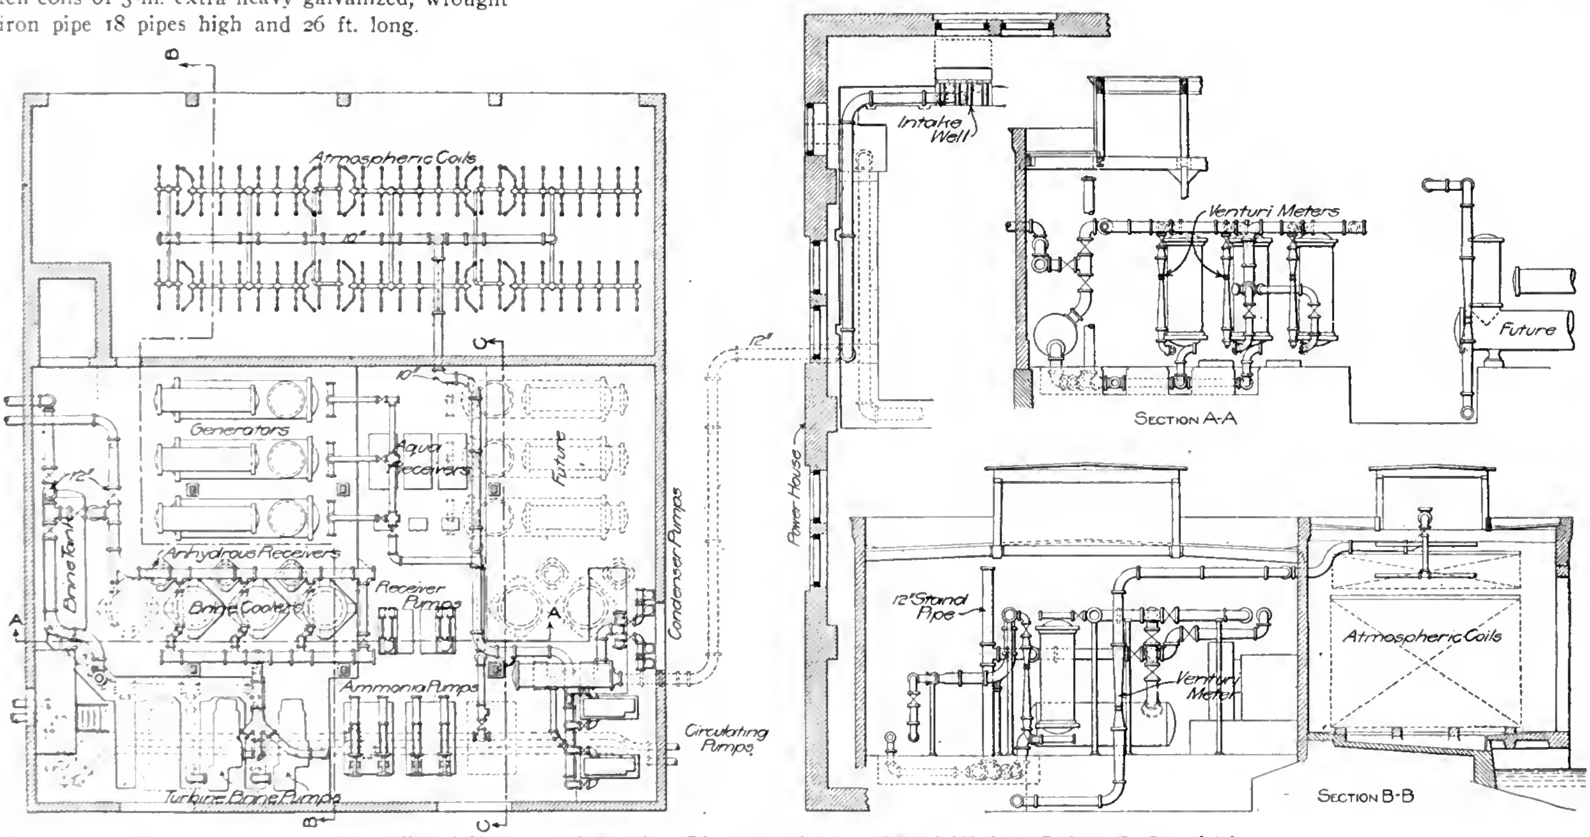
line, and to the steam supply of the generators. This applies equally to all steam pumps.

The Bulkley condensers are located on the outside wall of the machine room with space for an additional one when required. All the piping is designed with provision for future extension. The steam riser to each condenser is 7 in. in diameter, the water supply 3 in. in diameter, and an overflow 3½ in. in diameter, with a drop of 36 ft. to a main overflow drain which discharges into the river.

The discharge from the vertical pump is 5 in. running into an 8-in. common water main to the steam condensers. A strainer with by-pass connection is placed in this line which enlarges into a 15-in. drum having 3-in. outlets.

There are three gauge boards of grey polished marble, one is mounted with a Howard clock, two vacuum gauges for the steam condensers, one steam and one steam recording gauge for the supply steam. Another is provided with a brine suction, a brine discharge gauge and a recording gauge for the brine discharge. The third board is fitted with six ammonia gauges, one for each absorber, and one for each generator. There are also three steam gauges, one for each generator.

The large quantity of exhaust and low pressure steam available in the warm weather determined the choice of equipment. In the winter time



Details of New Refrigerating Plant at the Works of Walter Baker & Co., Ltd.

The condensing water to the atmospheric coils is through a 10-in. main, which supplies a multitude of headers with 1¼-in. branches leading to the water-distributing troughs over the coils.

The brine cooler, the generator and anhydrous receiver are provided with special Ashton automatic ammonia relief valves with removable metal seats. The brine tank, brine mains and all piping which frost or are liable to sweat are insulated.

Except in the subway, which is constructed for about 200 ft. under a street, the brine mains are insulated with 3 in. of hair felt and canvas jacket, painted. In the subway they are insulated with 3 in. of Nonpareil cork painted with rubber cement, and the pipes are supported with special hangers outside of the insulation. The brine coolers, the anhydrous receiver, and the brine tank are insulated with 4 in. of Nonpareil cork and sheathed with hardwood lagging. The

drawn from the Neponset River through a suction well, provided with screens and located in the basement of the large power house. A 12-in. cast iron main suction line leads from the well to a suction chamber 30 in. in diameter by 10 ft. long. All the water pumps take water from this chamber.

The atmospheric absorbers are each drained to a receiver 36 in. in diameter by 6 ft. long, and provided with gauge glass, and self-closing cocks. From the bottom of each aqua receiver suction lines are carried to the ammonia pumps. There are four such pumps, each of the Blake direct acting type, 12x6x16 in., one for each refrigerating unit and one in reserve.

The steam is condensed by two 7-in. Bulkley condensers, one for the turbine water pumps and one for the brine pumps. Not only may these pumps be run condensing, but are also cross-connected into an 8-in. low-pressure manufacturing

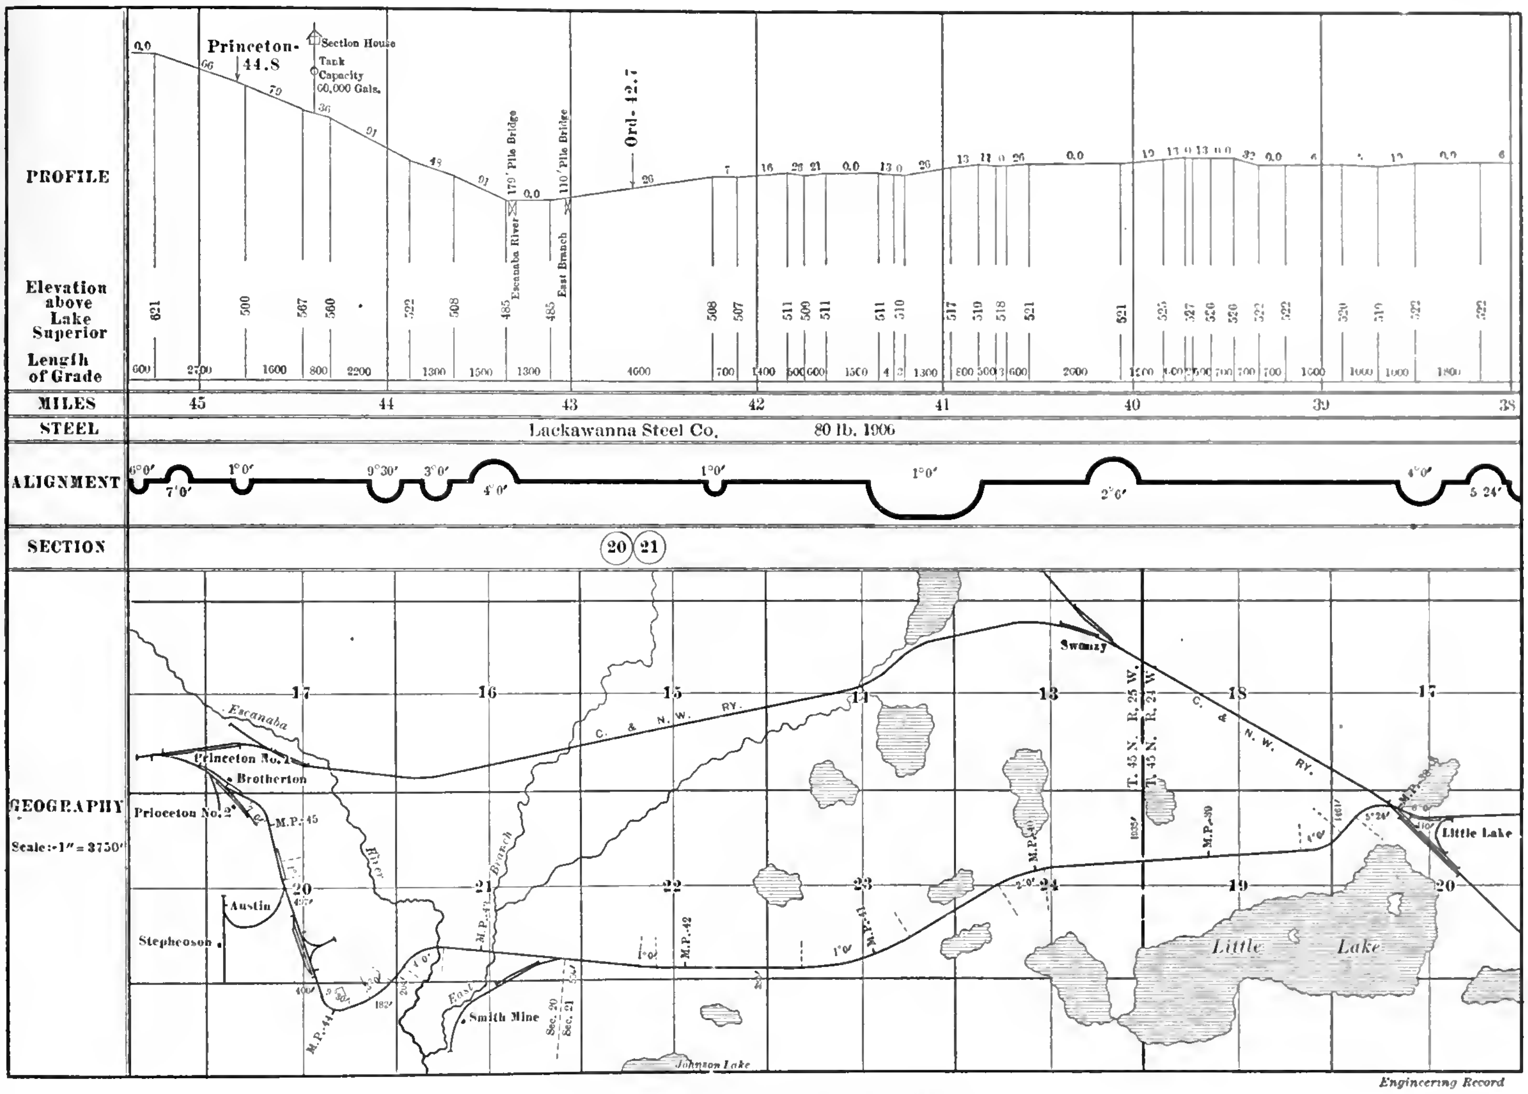
when the refrigerating machine is not in commission to any extent, large amounts of low-pressure steam are required for heating the mills. In the late spring, in the summer season and early fall, when the refrigerating machines are most used, the heating requirements are small and consequently the supply of low-pressure steam is ample for the needs of refrigeration. With the selection of economical pumping units operated condensing, the amount of live steam consumed should be small. The plant has been operated long enough to substantiate this hypothesis, and has demonstrated that although it is a comparatively large plant a minimum of attention is required.

A 1,200-VOLT DIRECT CURRENT on an overhead trolley electric railway was inaugurated recently by the Indianapolis & Louisville Traction Co. on its line between Scottsburg and Seymour, Ind.

A Convenient Profile Chart and Map.

A chart showing the geography, profile and various other information concerning railroad location and grades has been adopted by Mr. R. C. Young, chief engineer of the Lake Superior & Ishpeming Ry., the Munising Ry., and the Marquette & Southeastern Ry. A section of this chart covering about 9 miles of a new branch of the Munising Ry. is reproduced herewith. The method of indicating the geography of the line, which is shown at the bottom of the chart, involves no special features. Just above the map, the number of the section is given and above that the alignment of the track. The weight and the manufacturer of the rails and the year the latter were laid are noted in the next line. Above that is the profile proper on which are shown the length of each grade, the elevation of different points above Lake Superior and the rate of grade in feet per mile. The location of stations, section houses, water tanks and bridges is also given accurately. This chart is made in convenient lengths on tracing cloth, so any number of blue-print copies of it may be made. It has been found of considerable value to the operating department as well as for a record of the different features of the line for the engineering department.

In this connection the method of numbering bridges which is used by these companies is worthy of notice. The accounts of the various railroads and their branches are, for convenience, distinguished in the auditing department by different letters, which are also shown on the station list on the reverse of all working time tables. These same letters are used by the engineering department in numbering bridges, the number given each bridge being the distance in miles and hundredths of a mile from the base from which measurements are made. For example, the accounts of the branch shown in the accompanying chart are carried under the letter B and a bridge on that branch 5.33 miles from its starting point would be number B5-33. With this system a bridge can always be located at once and in case a new bridge is required or an old one abandoned, the continuity of the numbering of the other bridges is not changed.



A Convenient Profile Chart and Map.

Inspection of Asphalt Pavement in the Borough of Manhattan, New York City.

A system of inspection of asphalt pavement recently introduced in the Bureau of Highways of the Borough of Manhattan, New York City, has proved so satisfactory during the few months it has been in effect that it is believed all classes of pavement in the borough will be ultimately put under the same system.

The borough, the total area of which is about 21.9 square miles, is divided into six sections of nearly equal area, each in charge of a chief inspector. Each section is subdivided into two to five divisions, each in charge of a sub-inspector. The sub-inspectors patrol the asphalt paved streets in their respective districts and make daily reports of their condition to a special office of the Bureau of Highways. The reports are in tabular form and indicate the location of every hole, its dimensions and yardage, and how made. From these reports similar lists are made out and forwarded to every contractor from whom repair work is required, showing the location of all holes in pavements of his construction that are still under contract, together with an order that same should be repaired within five days after the receipt of the notice.

The repair work is in charge of an assistant engineer, to whom the chief inspectors report in person daily. They notify him of the number of repair gangs required in their respective sections on the day following and he arranges with the contractors to supply the men.

The chief engineer of the Bureau of Highways is supplied daily with a report showing the number of repair gangs at work and the location of each. For convenience this report is indicated graphically on a wall map of the borough with pins with various colored heads, a color being reserved for each contractor.

In the special office are large-scale wall maps on which are indicated in water colors the stretches of asphalt pavement under contract, a color being reserved for each contractor as before and pins being used to mark the general location of the defects reported. When the defects are remedied the pins are removed or, if they are not repaired, a pin of a different color is substituted, so that by a glance at the map a general idea of the condition of the pavements can be obtained.

The office is able in this way to keep closely in touch with the work of the contractors and notify them promptly when repairs are necessary. Sections 1, 2 and 3 comprise the area below 59th St., and in these sections the system is in full operation. The other three sections are being organized as rapidly as possible.

The new system was devised by Mr. Henry S. Thompson, Commissioner of Public Works of the Borough of Manhattan. Mr. George W. Tillson is chief engineer of the Bureau of Highways and Mr. D. B. Goodsell, assistant engineer, is in charge of the general repairs.

Test of the Reinforced Concrete Viaduct of the Richmond & Chesapeake Bay Ry.

The test of the Richmond & Chesapeake Bay Ry. Co.'s reinforced concrete viaduct at Richmond, Va., a description of which structure was given in this journal on Mar. 2, 1907, will, no doubt, be of interest to users of concrete. The viaduct was designed for a train of cars each weighing 150,000 lb., with a factor of safety of four. The cars are 54-ft. long, with trucks 33-ft. apart center to center, and the wheels of the trucks on 7-ft. centers.

The specifications called for a test of twice the designed load, but as it was found practically impossible to carry out the exact prescribed test, the chief engineer devised a test load that would give practically as severe strains and a thorough test as to the strength of the structure. The accompanying sketch shows the weight and the approximate wheel spacing of the test load as agreed upon by the designer and the railway company. The gondolas were loaded with rails, spikes and bolts to their capacity, while the tender of the engine was piled with coal and the tank filled with water.

Results of Test of Viaduct of the Richmond & Chesapeake Bay Railway Co.

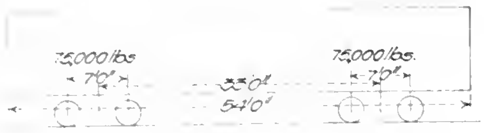
	72-73	1/8"	1/8"	26' 0"	1/2496	1/2496
Marshall St.	82-83	5/32"	5/32"	67.4'	1/5176	1/5176

All of the concrete in the structure had had at least five months in which to harden and under a close inspection previous to the test, not a flaw or crack could be found which would in any way weaken the bridge. The front of the engine was attached to the cars and backed on to the structure, the tender therefore being the first to go on the bridge. The test train was first run over the bridge three times at a slow rate of speed and then accurate measurements were made for the deflection of a number of spans. The first span tested was the 49-ft. span over Sledd St. One end of these girders slide on a concrete abutment making a joint for expansion, while the other ends are built continuous with the adjoining girders. These Sledd St. girders are 54 in. deep and 20 in. wide, with a solid 3½-in. floor joining them. This span showed a ratio of deflection to total length of span of 1:2688.

The deflection of this span was measured in three different ways: First, by setting a sliding rod directly under the middle of the girders and reading by the vernier of the rod the exact deflections: second, by taking a sight with an engineer's level at the rod held on the girder unloaded, and then again with the load in the position to give the greatest bending; third, by measuring with a steel tape the exact deflection from a fine mark on the girder to a solidly driven point on the ground. The three methods gave exactly the same results, and therefore it was decided in testing other spans to use only that method of ascertaining the deflections which would be most convenient.



Car for Which Viaduct Was Designed.

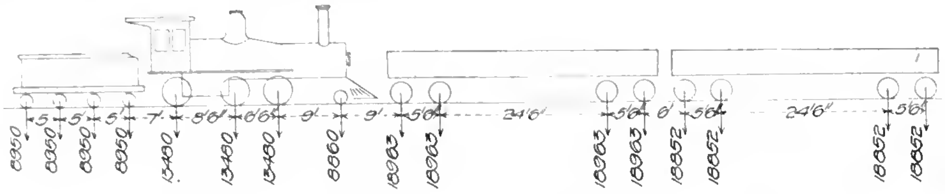


Diagram of Test Train for Reinforced Concrete Viaduct.

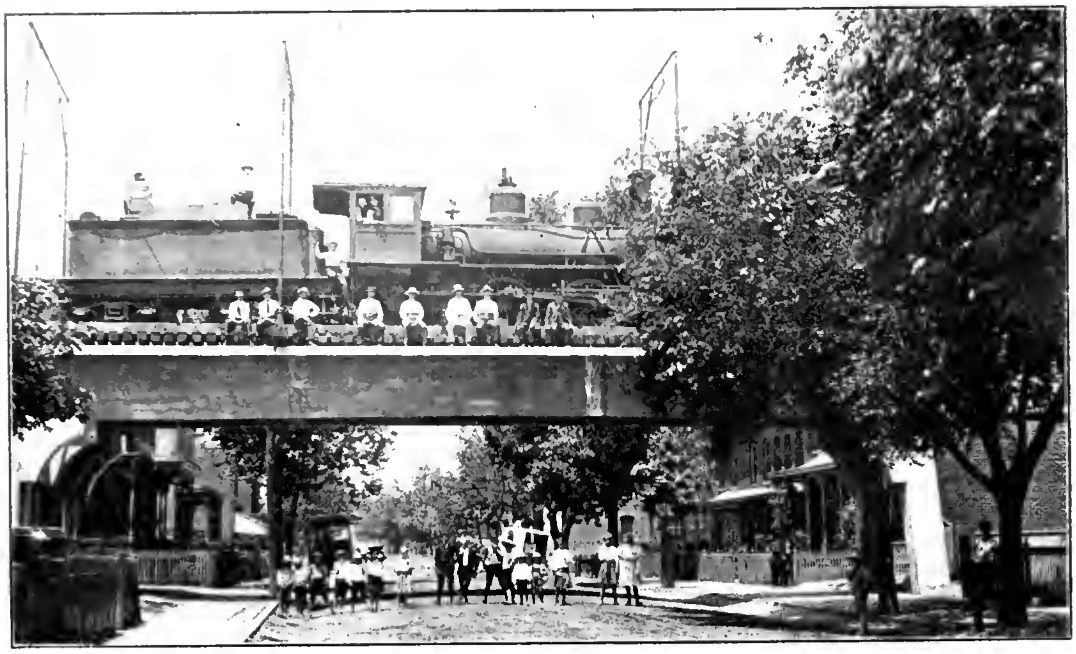
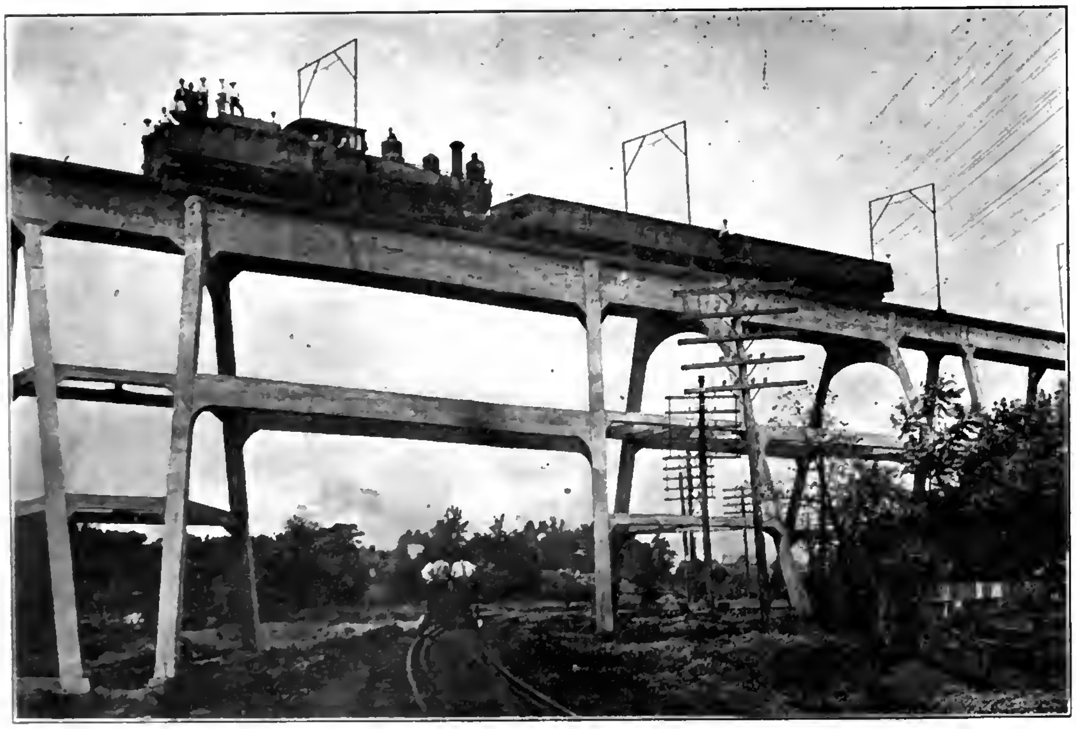


Test Train over Marshall Street, Span 67.4 Feet.



Test Train over Crossing of Seaboard Air Line Railway.

The next spans tested were a number of 23½-ft. spans adjoining the Sledd St. span, and where, on account of the viaduct being low, it was very easy to get exact results. The girders on each side of the bridge gave exactly the same results for deflection until the curve was reached, where, on account of the super-elevation of the outer rail, the center of gravity was moved toward the western girders and, as was to be expected, they showed a trifle more deflection than the eastern ones.

Fourteen of these spans were tested and showed a ratio of deflection to total span of from 1:1808 to 1:3357. Deflections for all of these girders were so near alike it was decided that it was only necessary to test typical spans in the remainder of the bridge, as it was practically impossible to get exact results where the bridge was 50, 60 or 70-ft. high, and where there was no solid place to set a level instrument.

A typical 26-ft. span showed a ratio of deflection to span of 1:2496.

A typical 33-ft. span showed a ratio of deflection to span of 1:4224. The Marshall St. span of 67.4 ft. center to center was next tested, and the ratio of deflection to the total span was 1:5176. The Clay St. crossing with the same span of 67.4 ft. as Marshall St. resulted in the east girder deflecting 3/32 in., making a ratio of 1:8628, while the west girder deflected twice as much, with a ratio of 1:4314.

As authorities give as the permissible ratio of deflection to span 1:750, and as all of the deflections measured were so small, it was considered unnecessary to continue measuring addi-

tional spans, so it was decided to test the effect upon the bridge of the train moving at a high rate of speed, and also coming to a sudden stop by the application of the air brake. The bridge showed remarkably little vibration under this heavy load moving at a high rate of speed, and repeated tests of sudden stops made no jar in the bridge that could be noticed at all.

The test train was run over the entire bridge seven times and gave a fair test of the perfect strength and stability of the structure. The girders were perfectly elastic, returning to their original position immediately when the test load was removed. At all the spans where there were expansion joints, the deflection was greater owing to the non-continuous girders. It might be interesting to note that on very hot days the expansion is very noticeable. Although no actual measurements of the expansion have been made so far, it is safe to say that on certain days it has expanded ½ in. in 200 ft.

Since the above test of the viaduct was made the heavy suburban cars, estimated to weigh 120,000 lb. loaded, have been running back and forth continuously at a rate of speed of about 25 miles per hour. A car was suddenly stopped by the emergency brake while running at the rate of about 15 miles, but no undue vibration could be felt although the car stopped within a distance of 3 or 4 ft.

Although no deflections were taken, a rather severe test was made some days later, which was not contemplated beforehand. In order that the construction trains of the railway company might pass it was necessary to send two of the electric cars, an engine and six ballast cars loaded with ballast and also a smaller engine and a line construction car all on the bridge at one time. The vibration was no greater with this long moving load than it is with one car. After the test was over the viaduct was again closely examined. No cracks of any description appeared and the structure seemed perfect.

The Railway Statistics of the United States compiled by the Interstate Commerce Commission for the year ending June 30, 1906, have just been made public. They show that the total single-track mileage in the United States was 224,363 miles or about 6,262 miles more than at the end of the previous year. The commission received operating data from 222,340 miles. The rolling stock reported consisted of 51,672 locomotives, of which 29,848 were in freight service, 12,249 in passenger service and the remainder used for switching; 42,262 passenger cars, 1,837,914 freight cars and 78,736 cars in company service. These figures do not include cars owned by private corporations. The average number of passenger-miles per passenger locomotive was 2,055,309 and the number of ton-miles per freight locomotive was 7,232,563. There were 1,521,355 people on the pay-rolls of the railroads, equivalent to 684 employees per hundred miles of line. Of this number 59,855 were enginemen, 62,678 were firemen, 43,936 were conductors and 119,087 were other trainmen. The employees in general administrative work numbered 57,054; for maintenance of way and structures, 495,879; for maintenance of equipment, 315,952; and for conducting transportation, 649,820. The par value of the outstanding railway capital was $14,570,-421,478, equivalent to $67,936 per mile. Of this amount 33.46 per cent. paid no dividends. The amount of dividends declared during the year was equivalent to 6.03 per cent. on dividend-paying stock. The average revenue per passenger-mile was 2.002 cents, and the average revenue per ton-mile was 0.748 cent. The total number of casualities during the year was 108,324, of which 10,618 were fatal. During 1906, one passenger was killed for every 2,227,041 carried and one was injured for every 74,276 carried.

Book Notes.

An excellent little trade list known as the "Directory of Portland Cement Manufacturers of the United States," has been compiled and published at $1.00, by Mr. C. Earle E. Bottomley, Land Title Building, Philadelphia. The compiler's position as secretary of the Association of American Portland Cement Manufacturers gives him the best of opportunities for obtaining accurate information regarding existing and projected companies. The statements in this directory have been corrected to Aug. 1 of the current year, and have been approved by the companies mentioned except in a very few cases. The information is arranged in the same order under the head of each company, and the notes relating to the companies are arranged alphabetically, the first company being the Aetna, and the last the York. The notes give the location of the principal office and that of the works, a list of the officers and the heads of departments, the capitalization, and the capacity of the mills.

For a good many years Mr. John K. Allen has been doing good work for sanitation through the columns of "Domestic Engineering," a trade journal which was started shortly after The Engineering Record, and has been maintained ever since as an exponent of good design and workmanship in everything relating to the heating, plumbing and lighting of buildings. During this period the sanitary fittings of a house have completely changed in their character, and what was the luxury of a few a quarter of a century ago is now the necessity of all. This is shown in a number of places in Mr. Allen's "Sanitation in the Modern Home," a small volume full of sound advice concerning the selection and drainage of a building site, the general interior arrangement from a sanitary viewpoint, the proper construction of cellar floors and walls, plumbing in the different rooms, warming by steam and hot water, furnace heating, ventilation and temperature control, lighting and other subjects. The information is well arranged and presented in such a form that anybody interested in healthy and comfortable houses can readily grasp it. (Chicago, Domestic Engineering.)

A description of works executed between 1897 and 1905 by the Mediterranean Ry. Co. has recently been issued in two sumptuously published quarto volumes profusely illustrated bearing the title "Relazione sugli Studi e Lavori Eseguiti dal 1897 al 1905." The text volume is divided into several parts, while the large atlas contains many admirable drawings and engravings. The book is mainly interesting for its account of the railroad connecting the Simplon Tunnel line with the Italian railway system. This connecting line has a number of unusual features: much of it lies through an Alpine country where the construction was extremely difficult and in places it was necessary to use helical tunnels such as were first introduced for overcoming grades on the St. Gothard R. R. The first part of the volume describes the railroads built by the company as contractor, and the second part is a collection of papers concerning their technical features, including extensive earthworks, masonry structures, iron bridges, tunnels and buildings. The last part of the book is a collection of monographs on some of the more interesting technical subjects. These include several tunnels in rock and in soft earth, the specifications for bridges prescribed by the Italian Government and other specifications for the same class of structures suggested by the company, and the geology of the region in which the work was done. The volumes form one of the most elaborate publications of an engineering nature ever issued and will be found full of valuable information concerning the construction of tunnels and railway work. (Milan, Società Italiana per le Strade Ferrate del Mediterraneo.)

Investigations of the mechanical properties of wood by the United States Forest Service are being conducted by several timber-testing stations in cooperation with the University of California, Purdue University, the University of Oregon, the University of Washington and the Yale Forest School. The general aim of these tests is to supply useful information for engineers and architects as well as to determine the value for specific purposes of quick-growing woods thus promoting the practice of conservative forest management and determining proper substitutes for material which is more valuable for uses other than those for which it is now employed. At the present time the programme of the investigation calls for tests to determine the properties of structural timber made on pieces of commercial size and grade: tests to determine the effect of the rate of application of the test loads and the effect of moisture, and tests to ascertain the influence on the properties of timber, of preservatives, methods of seasoning and fire retardants. The determination of the effect of moisture was assigned to the technical laboratory of the Yale Forest School under the general direction of Professor J. W. Toumey. The work was done by Mr. H. D. Tieman, and his report has recently been issued by the forest service under the title of "Effect of Moisture upon the Strength and Stiffness of Wood." Mr. Tiemann has determined factors by the use of which the results of tests of wood having various degrees of moisture may be reduced to a common basis in the case of certain species and certain kinds of tests. He has established the percentages of moisture at which the cell walls are saturated in the case of these species, and has determined the true nature of the law representing the effect of any further reduction of moisture on the strength of timber. His studies explain the reasons for the various facts and his subsidiary studies on case-hardening, on prolonged soaking, and on soaking followed by drying have direct application to the utilization of timber. The results apply to hardwood in small forms, such as are used in carriage building, and to softwood timber in some forms, such as crossarms for telegraph poles, where thorough and uniform drying and consequent large increase in strength may be obtained. An abridged form of the paper has also been published by the Forest Service under the title of "Strength of Wood as Influenced by Moisture," which contains the valuable reduction tables of the complete monograph.

So much depends upon proper illumination by artificial means that it is rather surprising no book on the practical features of the subject was published before Messrs. J. R. Cravath and V. R. Lansingh wrote "Practical Illumination," a work equally valuable to the technical and the non-technical reader. It is generally recognized that a large proportion of the light furnished by artificial means is wasted, while oculists are agreed that a considerable part of the deterioration of eyesight now so prevalent is due to the improper use of artificial lights. Accordingly the authors confine their discussion to the best use of light after it is produced rather than the apparatus for producing it. Most of the tests described were made in the Electrical Testing Laboratories of New York, and were thus uniform in method and character: no tests made by manufacturers have been used. Interior illumination alone has been considered, and a great many illustrations are given to show bad and good arrangements of lamps for a given purpose. The first three chapters outline the laws of light and its measurement and explain the methods of calculating the amount of illumination, thus preparing the reader to un-

derstand the methods of rating different sources of illumination adopted by the authors. Three chapters follow on individual electric, gas and acetylene burners, and their reflectors, shades and globes. The amount and dispersion of light from a naked source of illumination and their modification by reflectors and shades is a subject that few people have considered as carefully as they should, or otherwise the inefficient "decorative" shades so often seen where art alone is considered would have no sale. The number of people whose eyesight is hurt every night by attempts to reproduce the visually-destructive dinner-table candles of our forefathers must be enormous, and many have inveighed more than once against the outrages committed in the name of illumination in reading rooms and libraries. The use of clusters of incandescent lamps is becoming quite prevalent for some purposes, and a chapter is devoted to a discussion of methods of obtaining the best results from such groups. Chapters are also given on the characteristics of Nernst, electric arc, gas arc and vapor lamps, and the diagrams of the distribution of light from them give full information to those who are considering their use but are uncertain concerning the illumination they will give. Two important chapters explain the methods of making practical tests of lamps by means of demonstration rooms, and summarize the authors' views regarding the comparative uses of different illuminants. The remainder of the book describes the selection, arrangement and improvement of artificial lights for many classes of indoor service. It is illustrated by engravings showing the lighting arrangements, good and bad, in many different rooms, and will appeal directly to all who have been puzzled about the best way to light individual rooms as well as entire buildings. (New York, McGraw Publishing Co., $3.00.)

Letters to the Editor.

THE UNION PACIFIC LOCATION.

SIR: In an editorial article entitled "The Function of Light Railways," in The Engineering Record for August 31, 1907, occurs the following statement: "Railroads have grown over the country in a sprawling, irregular fashion ever since the zig-zag war dance of the Union Pacific over its land allotments." It surprises and grieves me that such thoughtless language should be permitted to appear in a leading article of a paper conducted with the dignity and fairness which we are accustomed to find in The Engineering Record.

One infers from the quotation above cited that the editorial writer believed that the Union Pacific Railroad as originally built was located on a tortuous route, so as to make it as long as possible and thus increase its land grant, which was so many sections of land per mile of main line. Such loose talk has appeared from time to time in the speeches of cheap politicians, with an axe to grind. But it is unkind for a reputable engineering paper to publish such a gratuitous reflection on the character of the engineers who located and built the Union Pacific.

When that line was built the country through which it ran was a wilderness populated only by savage Indians. There was no traffic except as the railroad created it. It was a common saying for years after the road was opened that the receipts from the occasional trains were not enough to pay for the fuel and wheel grease used. It would have been the greatest folly to make expenditures at that time necessary to build a twentieth century trunk line. And yet what was the character of the line the Union Pacific did build in the sixties? This question is practically answered by investigating the work done during the past ten years in efforts to improve grades, alignment and distance. With practically unlimited funds to draw upon, after thorough surveys and careful examination by skilled engineers, with able contractors, a railroad in operation to deliver men and materials at any desired point, the railroad people, after years of effort and millions of expenditure, succeeded in cutting down the total length of the Union Pacific from 1033 miles to 1003 miles, less than three per cent.! Does that look like a "zig-zag war dance over land allotments?"

The original location of the Union Pacific Railroad, with which I never had anything to do, not even an acquaintance with the engineers who made it, was a piece of remarkably good engineering judgment from beginning to end, and will be so esteemed by all thoughtful engineers who may be able to investigate the facts. The Union Pacific was not built in "sprawling, irregular fashion," although financial necessity has often compelled railroads in other parts of the country, which were built in the days of small things, to adopt that sort of a location.

Respectfully, T. A.

THE QUEBEC BRIDGE COLLAPSE.

SIR:—I beg to submit a theory of the Quebec bridge disaster that accounts for every phase of the disaster so far as the facts have been made public. The theory thus far given the greatest prominence is entirely inconsistent with the facts for the following reasons. (This theory is that a bottom chord member, A9L, on the left truss in the anchor arm failed and brought down the structure.) In the first place it is unbelievable that a member of the size of the one under suspicion, with the intensity of strain it sustained, could have failed under a steady load. In the second place, initial failure of a bottom-chord member on the left truss would have thrown the whole structure to the left and not to the right as it actually fell. In the third place, initial failure in the bottom chord of the anchor arm would have thrown an enormous thrust at the foot of the tower and pushed it toward shore instead of allowing the greater part of the tower to fall riverward. In the fourth place, if the failure were the result of the continuation of the weakness observed in bottom chord member A9L, we should look for that member to fail by bowing, since it was a partial bow that was observed. In the general collapse, however, this member took an S shape.

My theory is that the traveler, which was about twice as high as the truss where it was standing, was either pulled over by accident or fell over due to insufficient cross-bracing, and that this fall to the right threw the whole top chord system to that side, crushing the vertical posts and thus causing cumulative failure of the entire superstructure. The pulling over of the erection gantry or traveler may have been done by the workmen in bracing the traveler for the night. It is customary to take the falls from one side of a traveler and attach the block to some part of the other side of the structure, then vice versa, forming X-bracing. The pulling on one such diagonal line could easily start the traveler to fall. The truss posts could not resist the fall.

The reasons I have for believing that the whole cause of failure was due to the traveler are as follows:

(1) The traveler was being dismantled, and, though 300 tons of its weight had been removed, 800 tons remained. If only 500 tons of this was in the top structure, there would be a force of about five tons at the top chord of truss for every foot that the side bents were out of plumb.

(2) The traveler had little or no lateral bracing. If it was braced, it must have been with wire ropes, which in any event, by reason of their extensibility would allow large stretch and large swaying.

(3) The vertical posts, excepting the main tower post, had little stiffness laterally to resist such a force as this traveler would produce. The single lacing was in planes normal to the truss, making the posts exceptionally weak in that direction.

(4) A blow from the traveler, such as its falling to one side would produce, would cause just such a failure as the one that occurred. It would deflect the top chord, with the sway-bracing, to one side, and the weakest part, namely, the part of the posts beside the roadway opening, would bend. This would allow the entire upper system to come down.

(5) This theory would agree with what little has been published as to the observation of men at the bridge. They say no swaying of the structure was observed. This would be expected on account of the stiffness of the lateral system at floor level. They say that the floor of the anchor arm sunk and they had to run up hill. This would be the case if the upper structure should come down: the lower chord as an arch would not stand the weight of the floor. If the lower chord failed first on one side and in one member, there would be swaying of the floor because of the unsymmetrical failure.

(6) The S shape assumed by A9L, the lower chord member that is supposed by some engineers to have been the cause of failure, fits exactly in this theory. Your account states that this S was in both members A9. The lateral thrust to the right would be communicated down the first main diagonal and the first main post in the anchor arm, at the foot of which one end of A9L was located; and this end of A9L would be pushed to the right in forming the S, just as it was found to be. This lateral push was even enough to overcome the observed bow of which so much is made and reverse half of it.

(7) The failure must have been something that affected both trusses alike otherwise the almost vertical drop is inexplicable. This would be the case with a lateral force exerted against the top chord; for as soon as the vertical posts, which were under heavy stress, would bend to one side enough to fail, everything else would give way almost at once, and every part of each truss would be affected just alike. The sway bracing between posts above the overhead struts and below the floor would hold the posts vertical in these portions until the force of the fall would crush the posts.

There is nothing mysterious about the above theory to account for the failure, and it does not carry with it the suspicion that all other large structures in which there are heavy compression members may be on the point of failure. The failure is simply brought into the class with about all other great erection failures, and is due to an omission to provide sufficient unyielding sway bracing.

Yours very truly,
EDWARD GODFREY.

Pittsburg, Sept. 14.

THE PEAT-BRIQUETTING PLANT of the Commercial Artificial Fuel Co., near Lambertville, Mich., has a capacity of 60 tons daily, the product containing 16.7 per cent. moisture, 55.3 volatile matter, 20.5 fixed carbon and 7.5 ash. Its heating value is stated to be about 10,600 B. t. u. per pound. The peat is obtained from a 10-ft. bog by a dipper dredge and taken in scows to the plant. Here it is first passed through a cutter, in which it is thoroughly disintegrated, and then through a kneading machine. It is next compressed and discharged through a die as 4x4-in. bars, which are cut by knives into briquettes 12 in. long. The latter are then dried like soft brick in sheds.

THE ENGINEERING RECORD

PUBLISHED WEEKLY BY THE

McGraw Publishing Company

James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.

MAIN OFFICES:

239 WEST 39TH STREET, NEW YORK.

BRANCH OFFICES:

CHICAGO: Old Colony Building.
PHILADELPHIA: Real Estate Trust Building.
CLEVELAND: Schofield Building.
SAN FRANCISCO: Atlas Building.

LONDON OFFICE: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico............$3.00 a year
Canada ....$4.50 a year
Foreign subscription.......................$6.00 a year
25 shillings. 25 marks. 31 francs.

Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of THE ENGINEERING RECORD on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

REMITTANCES.—Remittances should be made by check, New York draft, or money order, in favor of THE ENGINEERING RECORD.

CHANGES OF ADDRESS.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

BACK COPIES.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.

DATE ON WRAPPER indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

CLUB RATE.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. The rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 14,250 copies are printed. Total circulation for 1907 to date, 556,500 copies, an average of 14,526 copies per week.

TABLE OF LEADING ARTICLES.

The Public Roads of the United States.

About ten years ago there was considerable controversy concerning the approximate length, cost of construction and maintenance charges of public roads in this country. Some figures were given out by government officials regarding the advantages to farmers of public roads of fairly good construction, and these figures were attacked as extremely inaccurate, and also for the illogical use made of them. The tilt between Prof. I. O. Baker of the University of Illinois and the late Roy Stone will be recalled with considerable interest by those who followed this controversy. Probably the figures were far from accurate, but they had a certain measure of value as attempts in the direction of securing information on which to base some decidedly important studies. It goes without saying that the federal government is best equipped to gather information of this nature, and Mr. L. W. Page, director of the Office of Public Roads of the Department of Agriculture recognized this fact some time ago and arranged for another and better investigation, covering the mileage, revenues and expenses of public roads in 1904 throughout the country. By his enthusiasm in public road affairs he was able to interest officials and private individuals to help him in this work, and the result, just made public, is an interesting compilation of data far more reliable than any previously gathered in this country.

The collection of the statistics has been a troublesome task, not only on account of the great diversity which exists in the methods of carrying on road improvements in different parts of the country, but also because it was necessary in some cases to write from fifteen to twenty letters to a single township in order to secure all the information needed to make the investigation complete. In some states there are as many as 1,500 of these townships which must be taken into account. In states where road taxes are assessed and collected by county officials, the task was comparatively easy, but that it was an onerous undertaking is shown by the fact that about 60,000 communications had to be sent out before the investigation was complete. The systems of road taxation and the methods of collecting and sending road funds differed so radically in various states and even in parts of the same state that it was necessary to prepare a great variety of blank forms before all the data could be obtained. After they were secured the accuracy of all doubtful figures was verified so far as practicable. Some reports were returned to those making them for checking or correction, and in some states the heads of the highway and geological departments rendered valuable aid in revising the figures. It is possible, however, that errors crept in, for the mileage of roads on the boundary lines of townships and counties may have been reported twice in some cases and not at all in others. The roads in many counties and townships have never been surveyed and estimates had to be made of their length in such cases. In some places no permanent records have apparently been kept of the collection and expenditure of road funds and in other places the records are in a confused condition. In a few instances the officials refused to supply the information unless paid by the Agriculture Department, and as the Department had no funds for the purpose, it became necessary to secure the information through unofficial sources. Taking the figures as a whole, however, it is believed that they are fairly correct and will form a valuable basis for comparison and future work.

The report uses the term "improved road" as signifying a highway graded, drained and surfaced with a material or combination of materials or treated with the application of some preparation resulting in a reasonably smooth, firm and durable surface. The figures show that in 1904 there were 2,161,570 miles of public road in the United States of which amount 7.14 per cent. had been improved as above defined. Of these improved roads 108,233 miles were surfaced with gravel, 38,622 miles with stone, and 6,810 miles with special materials like shells, sand-clay, oil and brick. Taking the country as a whole, there is 0.73 miles of road per square mile of territory, or 1 mile of road to every 35 inhabitants and 1 mile of improved road to every 492 inhabitants. These figures do not include roads in the Indian Territory, Alaska, and the island possessions or the mileage of roads in incorporated cities and villages.

The District of Columbia stands first with 3.18 miles of road per square mile of area, and Connecticut is next with 2.0 miles. Rhode Island has 2.24 miles, Pennsylvania 2.21 miles and Arizona has but 0.05 mile. The District of Columbia has 1,459 people per mile of road, Rhode Island 181 people, Massachusetts 164, New Jersey 127 and Connecticut 64. Nevada has but 3 persons per mile of public road, North Dakota 5, South Dakota 7, Wyoming 8, Idaho and Oklahoma 9 each and Montana 10. These figures relate to public roads of every sort. When the improved roads alone are considered, Indiana is found to have the largest mileage, 23,877 miles. Ohio has 23,460 miles, Wisconsin 10,633 miles, Kentucky 9,486, California 8,803, Illinois, Massachusetts and Michigan over 7,000 miles each, Minnesota over 6,000 miles, and New York over 5,000 miles. In about two-thirds of the states gravel has been the principal surfacing material used in improving the roads. Massachusetts has 45.89 per cent. of the roads improved in some manner, Rhode Island has 43.26 per cent., Indiana 34.94 per cent., Ohio 33.78 per cent., California 18.87 per cent., Connecticut 16.75 per cent., Wisconsin 16.72 per cent., Kentucky 16.60 per cent., New Jersey 16.32 per cent. It is interesting to observe how closely the higher percentages of improved roads agrees with the higher figures of population per mile of road. Unquestionably this fact is the kernel of the growing regard with which railroad corporations are holding highway improvements. Improved highways are becoming the best feeders for railways, and the heads of great railway systems are now seriously directing their efforts toward securing the betterment of common roads.

The feature of the investigation which is most important, however, is not that relating to the extent of the improvements, but rather to the amount of the expenditures for highway work in different parts of the country and the returns obtained from these sums. The investigation shows that during 1904 the public roads were responsible for an expenditure from property and poll taxes, bond issues and state-aid funds, together with the value of labor expended under the statute-labor laws, of nearly $80,000,000. Of this amount nearly $54,000,000 was obtained from property and poll taxes payable in cash, nearly $20,000,000 was the value of the labor taxes, and the remainder came from bond issues and state-aid funds. The expenditure amounted to $37.07 per mile of public road, or $1.05 per capita. These figures include the cost of such bridges as were necessary in connection with road improvements. Although the sum is small when it is divided on the basis of the total mileage of public highways, it is about eight-thirteenths of the expenditures for public schools in the country during 1903-1904, and about ten-thirteenths as much as was spent for river and harbor improvements.

The voluminous statistics which the Office of Public Roads has just made public shows conclusively that the best results will be obtained in those states where all road taxes are paid in cash, in order that the work may be placed in the hands of persons who have a practical knowledge of the subject and whose duty it is to devote their whole time and attention to highway improvement. New York and Pennsylvania have encouraged this practice by giving over to all counties where the practice of working out road taxes has been abolished in favor of cash payment, a certain percentage of the amount of the taxes so collected. Taking the country as a whole, the figures show that if the percentage of improved roads is a fair standard for judg-

ing the condition of a district, the best results have been obtained in those states which have abolished statute labor and where the road taxes are paid chiefly in cash. The amount of property taxation for road purposes varies widely, and one of the best features of the investigation referred to is the compilation of information concerning what is done in this respect throughout the country. If the investigation produced no other result than this comprehensive statement of taxation for road purposes, it would have been fully justified. It is impracticable to summarize it here and the reader is referred to the full report for it. The document is an important contribution to our knowledge of roads, and the Office of Public Roads is to be congratulated on the success of its investigation, from which a good many people did not expect any such useful and instructive results.

Operating Records in New Power Plants.

In the construction of a new power plant for important service the installation of the machinery usually takes so much attention from the operating staff that there is little opportunity for the keeping of records in great detail. Everyone realizes that it is useless to expect good economy in fuel consumption and labor cost per kilowatt-hour before the plant is half loaded, and for this reason the question of log sheets and load curves is generally one of the last things to be put on a regular working basis. In some plants practically no records are kept until the station is opened for commercial service.

The wisdom of not attempting too great refinement in early records is indisputable, but it is clearly a mistake to go to the other extreme and keep practically no station log whatever. For example, in the case of a power plant approaching completion in connection with the electrification of a steam railroad, steam is sure to be demanded from the boilers long before commercial trains begin to run; engines or turbines must be turned over and gradually speeded up to full usefulness; and some of the generating units will be finished in installation before others and will be needed for the operation of trial trains on experimental track sections, or for supplying current for construction purposes. In an industrial plant designed to supply power to a motor-driven factory installation certain departments will be first equipped, tested and commercially supplied, current being required more or less irregularly each day or two until the changeover is to a considerable extent completed. If no records of fuel consumption by days, general load variations and partial or complete shifts of attendance are kept, the company may know the grand total cost of getting the plant ready for service, but it will not know anything about the behavior of the installation on the cost side in relation to the exigencies of irregular though practically continuous service.

The main points of operation should be noted day by day during the construction period quite as much as in the routine days to follow. It ought to be possible to keep a close record of the coal burned each day, the total station output each day, the water consumption and the hours of attendants put in on operating work as distinguished from inspection of contractors' doings. It is a nice question in electrical auditing to determine just what part of a plant's running expenses during the installation period should be charged to construction, and what part to the operation of the service, as in the case of supplying trial trains with electric power. Separate meters are valuable in this connection, even if their use is temporary.

It is often claimed by the owners of new plants that the load curves imposed upon the station by the inauguration of a partial service are not representative, and therefore are of little interest. Few plants can show a daily load curve from the first hour in which they supplied current for actual use down to the present, but it is a fact that the study of some of these freakish diagrams in cases where they have been taken has proved to be of the greatest value from an engineering standpoint. It is distinctly the conception of the layman that matters must be well established in an installation before the results of operation will be instructive. Of course, deductions from incomplete data are a positive hindrance to good work, but if all the essential conditions are known, their analysis is bound to be suggestive, no matter how wide may be the departure of the data from the ordered regularity attained in routine service. The chief engineer may not have time to plot load curves himself during the construction period, but if the essential readings are taken and recorded, the deductions can be made at leisure. It is better to find out that a given machine needs modifications to secure economy before commercial service begins than afterwards. Just how much attention should be given by the operating staff of a station to construction and installation pure and simple is a question; practice in the past has neglected operating problems in the early stages in favor of assembly and erection oversight, but in the future it is probable that more consideration will be paid to the broader questions of plant economy. If the company's organization permits, its regular engineering staff rather than the operating men in the station itself should be charged with the duty of seeing that specifications and guarantees are met by contractors.

No general rules can be laid down as to the form of records best adapted to the needs of a plant in the early stages of its work, but a little foresight in each case will enable the essentials to be properly recorded. If a standard size of daily, weekly or monthly log can be determined at the outset much will be gained even though the forms of charts and tabulations may necessarily be varied and extended later. The great point is to have the records filed consistently with one another, leaving ample space for future contingencies. The deductions may be irregular or postponed, but if the facts are at hand, the company will never regret securing them during the days when everything in the plant from the coal-handling machinery to the high-tension lightning arresters was in a state of upheaval. Fuel consumption, labor, water and supplies will show extravagant figures per unit of output with the abominable load factors which irregular outputs in the construction period throw upon the plant, but they point the way toward a more efficient service as the duty of the station broadens out into routine service. It would be an instructive thing to plot the curve of coal consumption per kilowatt-hour from the early weeks of a new plant's service down to the months of regular operation on commercial loads, taking the fuel as the ordinate and time as the abscissa. Yet, as suggested above, few plants have the data upon which such a curve could be built. Such will not always be the case, for the time is coming when engineers will study the abnormal conditions of early service with the same interest that they give to the records of plants which have been turned over to the owners for the rest of their commercial lives. A special reason for keeping such records is their probable usefulness when something goes wrong during operation. It is well known that those who become acquainted with the behavior of a plant while it is being tuned up are generally able to locate promptly the cause of any troubles that subsequently arise.

The Maintenance of Small Works for Treating Sewage and Water.

The rapid increase in the number of small works for the treatment of water and sewage is noticeable, and it is therefore timely to sound a note of caution regarding the results to be expected from such plants. Practically all of them depend for their efficiency upon the properly controlled action of bacteria, and this action is affected by a large number of different conditions, some of which we are fairly well acquainted with while others present an almost untouched field of research. Most of the larger plants for purifying water and treating sewage are operated in a fairly efficient manner, and some of them receive excellent attention. This is not true, however, of the smaller plants, and as the total investment in them is probably much larger than that in the works built for great cities, the importance of a better appreciation of the responsibility for their efficient management is evident. For some reason it is comparatively easy to secure an appropriation for the construction of such works for small cities, but extremely difficult to have the plants managed properly after they are built. In fact, there are so many sewage disposal works in the Central States which are now practically useless on account of mismanagement that it is somewhat surprising more plants are being constructed all the time. It would seem as though the poor results from these mismanaged plants would stop the progress of sewage disposal. This would have happened, probably, were it not that public health authorities generally have power to compel small cities and towns to put in sewage disposal works, although unfortunately they have not been given authority to compel the owners of such plants to operate them in an efficient manner. It is strange that a town should be willing to spend a considerable sum in proportion to its resources for a sewage disposal or water purification plant, and then by its failure to put the works in charge of a competent man should practically destroy the value of such an investment. Yet this condition can be observed in so many places that it is a manifest fact which sanitary engineers must recognize. They are being held responsible in a considerable measure for the failure of a good many of these ill-managed plants to run as they should, and it therefore behooves them to take steps which will prevent such undesirable criticisms of their work.

There is a great difference in the character of the sewage and in the nature of the water supplies of different places, and for this reason hard and fast rules applicable to all communities have to be of such a general nature that they are useless except as somewhat superficial suggestions. Moreover, just what details will be most satisfactory in the management of sewage disposal and water purification works in any city may be open to some doubt. The most an engineer can do in designing such plants is to provide a system of works having enough flexibility so that by careful observation of the early stages of operation, the best procedure can be ascertained. When it is ascertained, the maintenance of the operations according to this method is comparatively easy. Where the character of a water supply fluctuates considerably from month to month and in those places where the sewage is liable to change in character for one reason or another, there is particular need of a careful study of the operation of the plants during the first few years they are in service. Accordingly there are good grounds for the belief that designing engineers will do well to urge their clients in some cases to make contracts with them to supervise the operation of sewage disposal and water purification plants for a sufficient period after their

completion to insure a full determination of the problems that will arise and the methods of meeting them. This supervision is not necessarily an expensive matter; it may cost considerably less than the losses incurred through faulty management of the works. It does not necessitate the constant presence of one of the consulting engineers at the works, nor does it require a highly trained chemist or biologist to be in constant attendance. In most cases the same class of men who have mismanaged the plants in so many small places, owing to their ignorance, could have been trained to look after the works properly if they had been under the supervision of the designers of the works from the outset of the operation.

The remedy for the present unfortunate situation lies largely with the designing engineers. If they take the position in arguing with their clients that the works built from their plans form a delicate piece of apparatus, which must be managed with a much higher degree of attention than a machine tool or an engine, in order to produce the best results, it is but reasonable to expect that the supervision of such works will be entrusted to their designers during a sufficient time to insure the proper training of the attendants and the proper procedures in treating the water or sewage under the different conditions that arise during the year. So much criticism is being made concerning the inefficiency of works of this nature, that engineers making a specialty of such plants ought to protect themselves by urging their clients to place the works under their supervision for operation during a short time at least.

A Possible Result of Electric Train Operation.

Elsewhere in this issue there is a description of some of the engineering features of the difficult mountain section of the Western Pacific Railway. It will be noticed in the article explaining it that there is an exceptional opportunity along the line to develop a large amount of water power; in fact, a power company has been formed for the purpose and it is currently understood to be working in harmony with the railway company. In the same way there are excellent opportunities for power development on the mountain line of the Chicago, Milwaukee & St. Paul extension to the Pacific Coast and also near the other northern trans-continental routes. It is generally believed that advantage will shortly be taken of these exceptional opportunities for developing water power to operate mountain sections of some of the roads electrically. The arrangements for electric traction were outlined in this journal on August 17, and it is unnecessary to review them at length again. The great advantage offered by the introduction of the electric locomotive is believed to be the increase of tonnage capacity of single track and the general reduction in cost per ton-mile resulting from handling heavy trains at higher speed with a certainty of operation not practicable with the steam locomotive. By properly proportioning the electric locomotive and the power station and line, it is practicable to operate trains at any speed up grade that is consistent with the alignment of the track. In other words, the same schedule can be maintained upgrade and downgrade, and the movement of trains on heavy-grade sections can thus be greatly facilitated.

There is another feature, however, of electric operation which will probably be found an important one, although it is opposite in a sense to that just stated. At the present time there is a marked demand for a more rapid movement of mixed freight. One of the serious criticisms against certain Western railroads is that even when high rates are paid for moving freight, the latter is handled only when the railroad gets ready and not with reasonable regard to the necessities of the shipper. In other words freight of every sort, except the most perishable classes, is held until a train load is secured satisfactory to the operating officials. Naturally enough on those roads which have been laid out with a view to handling business in this way, the attempts of the shippers to secure prompt deliveries by sending out lighter trains at more frequent intervals are not met with any marked degree of enthusiasm. There can be no question, however, that this matter of delay is responsible for a considerable part of the present general belief among business people and farmers that a reform can be made in some branches of railway operation without hurting the stockholders of the road and to the great advantage of the shipper.

Just how far the use of electricity will enable such a change in operation to be made is something of a problem, for it involves a good many other things than the use of electric locomotives. For instance, sidings have to be provided in suitable places for frequent short trains as well as for long heavy ones, and these sidings should not be at the same places for both kinds of operation. The amount of time a train spends on sidings when traffic is at all heavy is often so large as to be a material factor in the total time of transit of freight. It seems fairly possible, however, that electric operation on mountain grades for heavy trains, by supplying the means for equally economical operation of more frequent lighter trains, will lead to experiments with the latter. This is contrary to accepted methods of economical railway operation with steam locomotives, but if electric operation permits the defects of those methods to be avoided without appreciable sacrifice of economy, public opinion will eventually compel their adoption.

Notes and Comment.

THE BELMONT TUNNEL connecting Long Island City and Manhattan was traversed on Tuesday morning by an electric car carrying about forty officers of the road and the city and guests identified with New York traction matters. Later in the day, at a luncheon at the Hotel Belmont, a silver model of the car was presented to Mr. St. John Clark, chief engineer of the work, whose energetic direction of the tunneling operations is largely the cause of the fact that the first regular passenger car entering Manhattan by way of a subaqueous tunnel ran over this route. The work has been fully described in The Engineering Record of March 3, 1906, and June 8, 1907. It consists for the most part of two parallel single-track tunnels 28 ft. apart on centers and is about 1,700 ft. long. Three sections have been used, according to the material traversed. In rock the concrete lining has a clear width of 12½ ft. and a clear height of 13 ft., and is of horseshoe shape. In earth, the tubes have a segmental iron lining with a clear diameter of 15½ ft., and in Long Island about 1,800 ft. of double-track rectangular reinforced concrete tunnel has been built. Some of the shield work has been very difficult and dangerous. Where the sand was very soft, the shields were pushed ahead without excavating at all until the sand became too dense for any further movement and had to be removed in the usual way. Where it was soft, it was the custom to remove the slope under the hood of the shield as rapidly as possible and support the face by a bulkhead of horizontal boards braced against the shield, the diaphragm being backed with hay where the sand was fine enough to penetrate the cracks. Mr. Robert Shailer, chief engineer for the Degnon Contracting Co., which built the tunnel, was in personal charge of this work, and the manner in which he conducted it has been warmly commended by specialists in such construction. Mention should also be made of the expedient to prevent distortion of the iron lining by temporary unbalanced pressures. Each alternate ring, as soon as set, was provided with a 1¼-in. horizontal tie with sleevenut adjustment; this was pinned to the flanges of the ring at the springing line, and screwed to a moderate initial tension, holding the lining in shape until the earth settled firmly about it or grout could be injected behind it. Less has been said about this work than any other of the subaqueous tunnels entering the city, and most of the attention it has received has been due to controversy concerning the franchise under which operations have been conducted. When the terminal facilities are completed it will open up a rapid transit route into the heart of Manhattan which should play an important part in the development of the Borough of Queens, a section of the city which has been developing slowly on account of the absence of adequate communication with Manhattan. The location of this borough is such that the completion of the Belmont tunnel, the Blackwell's Island bridge and the Pennsylvania tunnels seem likely to bring it into a far more important rank in the divisions of the city than it has heretofore held.

THE BREAK IN COPPER PRICES is one of the most interesting recent commercial incidents to engineers, for it brings down to a reasonable basis of cost a very important metal for many industries. While the manifold extensive uses of it in electricity have increased surprisingly in the last decade, the production has also increased, and it has seemed very strange for some years that the price of the metal should remain so high. The explanations advanced, asserting enormous demand and barely sufficient production, hardly seemed consistent with known facts concerning metallurgical operations while it was felt that market manipulation was an important factor in the conditions. It is now known that these surmises were correct. There is an enormous stock of unsold copper on hand which has at last caused a sensational drop in prices, and the high prices for the metal have resulted in the production of alloys which may be substituted for it with a saving in cost for equal efficiency. The composite cable of steel and aluminum wire recently introduced for transmission lines is an example, and the substitution of aluminum for copper in various parts of electrical apparatus is going forward steadily. Nevertheless copper must always have an important place in the industrial world, and for this reason a study of the conditions leading to the present situation is advisable as likely to suggest a way to avoid another abnormal upward soaring of prices under the manipulation of masters of high finance.

THE INTERNATIONAL PHOTOMETRIC COMMISSION which met at Zurich this summer has settled some things regarding primary standards of light now in use. There are three of these, the hefner, the pentane standard and the carcel. The last is deficient in uniformity and reproducibility, and is not as good as the others; its importance is due rather to its considerable use than to its excellence. The hefner is open to criticism on account of its small power and inconvenient color, and the 10-c.-p. pentane standard is relatively complicated and subject to variations with atmospheric fluctuations. Moreover, in spite of the skill shown in experiments to compare the luminosity of the various standards there is an outstanding discrepancy of 5 per cent. in the results to be accounted for in some way. The discussion by the Commission shows that the investigation leading to a satisfactory primary standard of light will be a long one, since not only has the thing itself to be found, but the inertia of long usage must be overcome.

ENGINEERING FEATURES OF THE WESTERN PACIFIC RAILWAY.

By George P. Low.

When the Central Pacific R. R. was built, the aim was to secure railway communication between Ogden and the Pacific Coast by the easiest and most feasible route, to obtain which heavy subsidies were granted by the national government. The problem then was one of construction, viewed in the light of which its builders accomplished a marvelous piece of engineering work. To-day the problem to be solved in building a transcontinental railroad pertains to operation rather than to construction. The distinction is marked; where the Central Pacific spanned the distance from Ogden to San Francisco by the most readily-constructed route, the Western Pacific, in practically paralleling it, as shown in the map, virtually ignored any and all difficulties of construction where operative efficiency could be increased by so doing. In consequence, the Western Pacific engineers are to-day hewing a grade out of the granites of the Sierra Nevada Mountains that in many respects constitutes the most remarkable piece of heavy railway construction in existence.

The Western Pacific Railway Grade through Oroville and Five Miles East of That City.

The Western Pacific line will be longer than that of the Central Pacific by 143 miles, but its maximum grade after having been compensated for curvature will not exceed an actual 1 per cent., while that of the Central Pacific is 2.6 per cent (not 2.2 per cent. as claimed), with many miles of 10 deg. curves which bring the maximum gradient up to virtually 3 per cent. On the Western Pacific the maximum curvature is 8 deg. The Central Pacific crosses the Siera Nevadas at an elevation of 7,019 ft. above sea level, which necessitates the expensive maintenance of some 40 miles of snowsheds. The Western Pacific crosses these mountains at an elevation almost exactly 2,000 ft. lower and no snowsheds are necessary; during last winter, which was unusually severe, the maximum depth of snow on the line of the Western Pacific was 4 ft., while on the Central Pacific it was in excess of 40 ft.

It is anomalous that a piece of engineering work which is as heavy and as remarkable as is the trans-Sierran line of the Western Pacific should be so scantily possessed with features of engineering interest—indeed, the line presents greater opportunities for depicting natural scenery than for describing engineering achievement. The work is heavy in that practically throughout the mountains the grade is cut into the sides of rock-walled river and creek canyons, and it is remarkable, not only in that it crosses the Sierras at a comparatively low altitude, but in the manner in which it gets added distance and a lighter grade than would have been possible by adopting the more direct route presented in the canyon of the Middle Fork of the Feather River. The Sierra Division, covering 163 miles between Deep Hole, Nev., and Spanish Creek Crossing, Cal., contains two tunnels and a loop worthy of particular mention, and the North Fork Division, of 76 miles between Spanish Creek Crossing and Oroville, contains some special structures, but aside from these few features, standardization in all work prevails so universally that to describe one tunnel, for instance, describes all.

The most interesting portion of the line is in California from Chilkoot Tunnel, near the Nevada State line, to Oroville through a practically inaccessible region, although in the early days Beckworth Pass, which the line occupies, was well traversed. In traveling westerly, the Nevada-California State line is crossed at an elevation of 4,359 ft., whence the grade turns sharply to the south and enters Lake Valley, along which it parallels the Nevada, California & Oregon R. R. for about 17 miles, when it again takes the westerly course and, rising constantly with a maximum grade of 0.8 per cent., crosses the main divide of the Sierra Nevadas through the Chilkoot or Beckworth tunnel at an elevation of 5,018.76 ft. above sea level, the elevation of the trail over Beckworth Pass proper being about 5,250 ft. A slightly descending grade (0.4 per cent.) takes the line some 20 miles before reaching the town of Beckwith, and the head of the maximum grade of 1 per cent. extending practically all the way to Oroville, which is at an elevation of 199 ft.

The Middle Fork of the Feather River is reached within half a mile of the town of Beckwith, three crossings being made during the ensuing 12 miles. For 30 miles the grade follows the Middle Fork in a general northwesterly trend until reaching Spring Garden Tunnel, where it leaves the river at a point 15 ft. above extreme high water mark and cuts northwesterly through a divide which brings the line out on a small tributary of the North Fork of the Feather River. Though 80 miles of land lying within the State of California has been traversed thus far, the country, with its sage brush and cacti and arid wastes of sand, is characteristic of Nevada rather than of the Golden State, but on emerging from Spring Garden Tunnel, the westbound traveler will enter into a scene of paradise, so strongly contrasted are the Eastern and Western slopes of the Sierras.

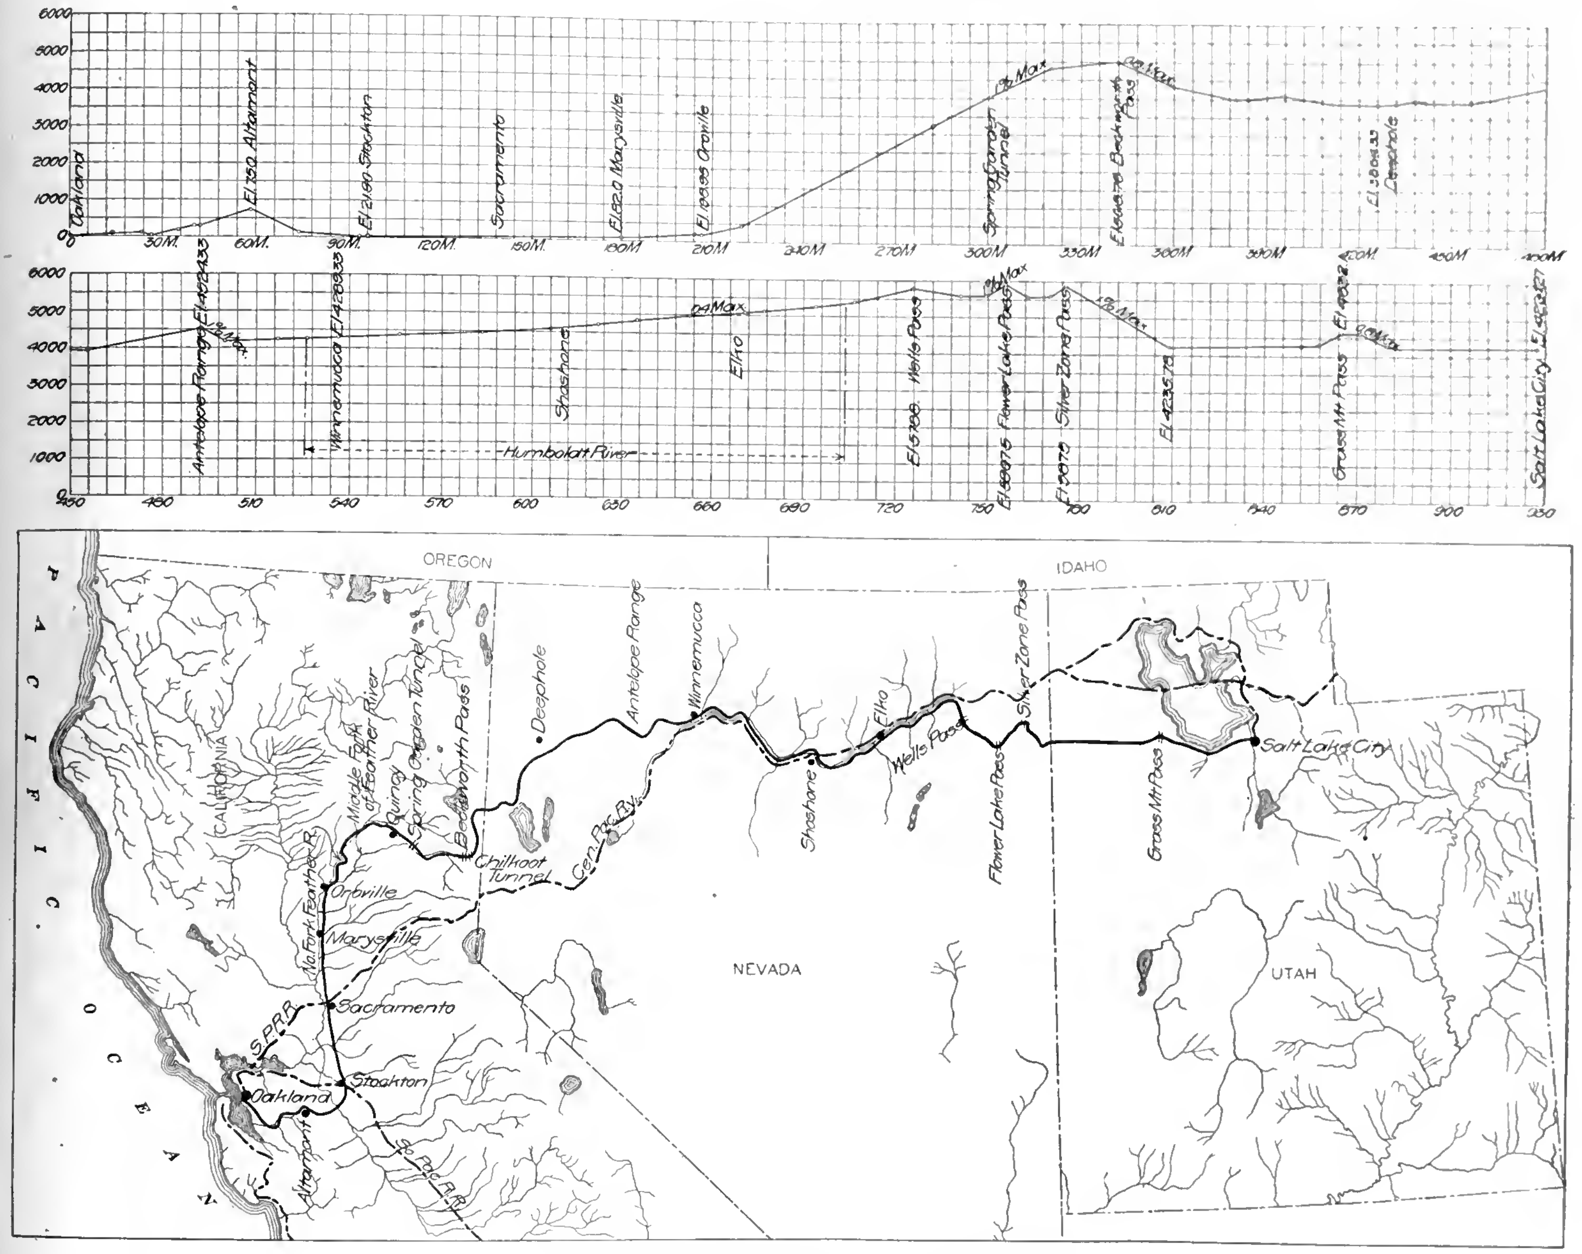
It would have shortened the distance from Spring Garden Tunnel to Oroville by approximately 45 miles to have continued down the canyon of the Middle Fork to Oroville instead of leaving it for the North Fork of the Feather, but by so doing the grade would have dropped from 4,000 ft., making an inadmissible gradient of considerably more than 1½ per cent. Besides the slopes of the route selected, though extremely difficult, are more practicable to build over than those of the Middle Fork. Within a mile after leaving the lower portal of Spring Garden Tunnel, the grade enters Williams Loop, which has a difference in elevation of 33 ft. between the two tracks where they cross. The loop has a maximum diameter of 1,600 ft., crosses Spring Garden Creek twice and Pine Creek once, its maximum curvature is 8 deg., and its minimum 5 deg., and its length is about 5,600 ft. Seven miles below the loop, the grade leave Spring Garden Creek for Spanish Creek, which it follows until reaching, first, the East Branch of the North Fork and then the North Fork of the Feather River, when its general trend becomes southwesterly in a course that is maintained along the canyon of the North Fork until reaching the junction of the North and Middle Forks which occurs at a point about 7½ miles from Oroville. Thence the canyon of the main river is followed until Oroville is reached.

Before determining upon the final location of the grade, a careful reconnaissance was made of the river canyons to be traversed, during which the extreme high water line was accurately determined, for of all destructive agencies to which engineering works in the Sierra Nevadas are exposed, water is recognized as the one whose action is the most sudden and violent, and which, if not anticipated and fortified against, is almost invariably attended with the gravest consequences. Seldom does the constructing engineer meet with altogether unexpected problems of more serious import than those which arise from the torrents of these most erratic streams which perennially discredit the predictions of "oldest inhabitant" wiseacres by out-doing all previous performances. During this reconnaissance the extreme high water mark—that of 1881—was clearly delineated along the canyon sides. At the junction of the North and Middle Forks, for instance, it was at an elevation of 275 ft. above sea level. Early in March last, a flood of unusual severity occurred during which the water exceeded by a few feet the record established by the flood of 1881. It was then believed that the country would be immune from excessive flood for years to come, but the storm in the mountains was renewed with redoubled vigor and on March 18, the level of

the river at the junction of the North and Middle Forks reached an altitude of 293 ft., or approximately 18 ft. above the high water of 1881, while the crest of the river at Pier 2 of the Western Pacific bridge across the Middle Fork reached 297 ft. above sea level.

A few incidents will illustrate the deceptiveness of these Sierran streams. The Great Western Power Co. has begun the construction of a series of hydro-electric and steam power generating plants in Central California which are to operate high-tension, long-distance power transmission lines that will commercially parallel the waters of the river were awash the floor of the tent, which shortly went downward with the flood.

Eight miles below, at Oroville, the streets were flooded from 5 to 6 ft., buildings were floated from their foundations and wrecked, the bridge across the Feather River to Thermalito was washed away, and one of the largest gold dredges of the Oroville district was torn from its moorings and utterly demolished. For the first time in its history, Oroville has become convinced that it must be protected by levees. Were it not for the fact that other cities in Central California cated the necessity of so building the roadbed that its various structures should be of the most stable character. As a result of the experience, nearly all wooden trestles have been abandoned in favor of earth fills, concrete masonry and steel structures. Aside from last winter's lessons, however, the fact remains that with the exception of a few landslides, the removal of which would not have caused an hour's interruption in the operation of the finished line, absolutely no damage was done to those portions of the Western Pacific roadbed which were completed, for it was fully realized at the outset that every precaution



Map and Profile of the Western Pacific Railway.

existing systems of the California Gas & Electric Corporation. The principal hydro-electric generating plant of this company is to be located at the Big Bend of the North Fork of the Feather River, 27 miles above Oroville. Buildings were erected last winter by the Great Western Power Co. to house the forces which were to have been engaged in the construction of the power plant during the present summer, but the flood of March last washed away the buildings and compelled the abandonment of all plans made for the location of the plant at that particular site.

An assistant engineer of the Western Pacific Ry. had his headquarters at the junction of the North and Middle Forks of the Feather River. The office building was at the top of a hill, and a tent wherein lived the engineer and his wife was not far away. Perfect security in its location was felt after the first flood of March had receded, but on March 18, most unexpectedly the are leveed, the cosequences of the flood elsewhere would have been equally as disastrous as at Oroville. At Marysville, for instance, the wagon bridge across the Yuba River was washed away, and the new steel bridge of the Southern Pacific Co. near by was practically under water. The track of the Northern Electric Co., operating a third rail electric system between Oroville, Chico and Marysville, was inundated for several miles, and the grade of the Southern Pacific Co. was washed out in some places and the damage wrought to its trestles, culverts and roadbed was so extensive that its monetary loss thereby probably reached $1,500,000.

These matters have been gone into thus fully in order to point out the fact that the occurrence of the unprecedented floods of last March was not only confirmatory of the sound engineering judgment of the locators of the Western Pacific Ry., but was providential as well in that it indi- must be taken to protect the roadbed against the action of water and to carry the water away from it. In fact, the late floods proved that the waterways and culverts were too large rather than too small.

In no case were the engineers misled by apparently dry gullies, as their lengths and drainage areas were fully investigated and ample waterways were provided for them before construction was begun. When, during the progress of the work, severe storms occurred, the assistant and resident engineers went over the work, observing closely the quantity and action of the storm waters with the view of determining more definitely the sufficiency of the openings contemplated or the advisability of reducing the size determined upon. Ample surface ditches were provided to carry off the storm water to the culverts and openings and to keep the water from saturating the slopes of cuts or undermining the

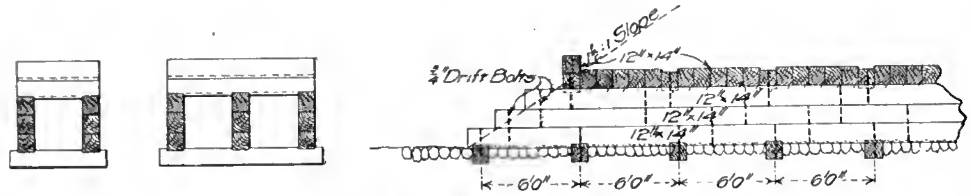
foot of embankments, causing them to slide. Where a ravine was found to descend abruptly to the roadbed, a catch basin was excavated to hold in every case at least 5 cu. yd. of debris in order to prevent the culvert from becoming choked. All culverts were built so that they would discharge water under any head that could possibly arise without injury to themselves or the embankment. Whenever practicable they were laid out at right angles to the center line and set low enough to drain the borrow pits. All culverts were built in solid ground wherever possible, but where it was found impossible to secure such foundation, the bottom was planked to prevent leakage and crowned slightly in the center to allow for settlement. Care was exercised in every case in filling around culverts not to tip or shove them out of place, inclined braces, both inside and outside the culvert, being used to prevent this. Blind drains, being regarded as objectionable, were always avoided unless the amount of water to be disposed of was known to be very small.

There are 44 tunnels in the line of the Western Pacific between Oakland and Deep Hole, Nev., of which three are in the Altamont hills east of Oakland, thirty are in the North Fork Division, and eleven are in the Sierra Division. The Chilkoot Tunnel, which is 6,000 ft. long and as stated pierces Beckworth Pass, is on a tangent with no engineering features of interest regarding location. It is of interest, however, in that it is east of the heavy snow fall region of the Sierra Nevadas. Usually the Pass is bare of snow; seldom does more than 1 ft. of snow fall upon it, and the heaviest snowfall ever known occurred in March last when it covered the ground to a depth of 2 ft. Spring Garden Tunnel, 7,400 ft. in length, is the longest tunnel in the line, but its interest centers in the advantage it gives of added distance and a lighter grade, as previously explained. The total length of tunnels in the North Fork Division aggregates 12,438 ft., the longest tunnel being 1,220 ft. and the shortest, 150 ft.

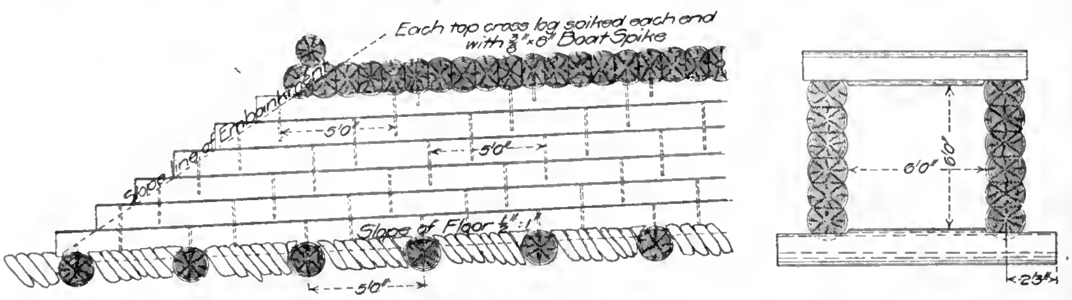
All tunnels in the Sierra Nevadas are being taken out for single-track construction, their normal cross section being not less than 16 ft. wide nor more than 17 ft. wide between vertical side walls, 22½ ft. high above sub-grade, and 1 ft. below sub-grade. The standard 16-ft. section tunnel is being built on tangents and curves of 3 deg. or less, and on curves of over 3 deg., the 17-ft. section is used. It has been found as a general rule that in excavating the approach, the cost of tunnel and of cut about balance when a depth of 50 ft. on the center line of cut has been reached, hence if solid material is encountered, the heading is placed approximately on this center line, but if the excavated material is loose and difficult to hold, the heading is started as soon as sufficient depth to secure a good face has been reached, as in so doing the weight of the heading timbers is reduced to minimum. The curves of the arches of these tunnels are a semicircle whose springing lines are 14 ft. and 14 ft. 6 in. above sub-grade in the 16-ft. and 17-ft. tunnels respectively. The normal cross-section for single-track tunnels contains an area of 368.4 sq. ft., equaling 13.65 cu. yd. per lineal foot of tunnel.

Tunnel 4, which pierces Cape Horn, on the Feather River about 2½ miles east of Oroville, may be accepted as typical of all tunnels on the North Fork and Sierra Divisions. It is a standard 17-ft. tunnel, 806 ft. long and built on a curvature of 8 deg. Work on the easterly and westerly approaches was begun in November, 1905, and in January, 1906, respectively, and the excavation of the heading was completed in October, 1906, while that of the bench was finished in January last. During the first one or two months, considerable progress was made in excavating the approaches, which were of loose rock and conglomerate, then solid rock was encountered and as hand drilling only was used, the progress was slow until February, 1906, when compressed air became available at the east portal. The advance was more rapid thereafter until in May a stratum of exceedingly hard rock was encountered so that during May and July but approximately 15 ft. headway was made. Then the material became easier to work and in November the maximum cut of 95 ft. was made in the bench. A similar condition existed from the west end where compressed air was introduced in March. The heading was finished in October and the bench in January last, the tunnel being completed a few weeks later.

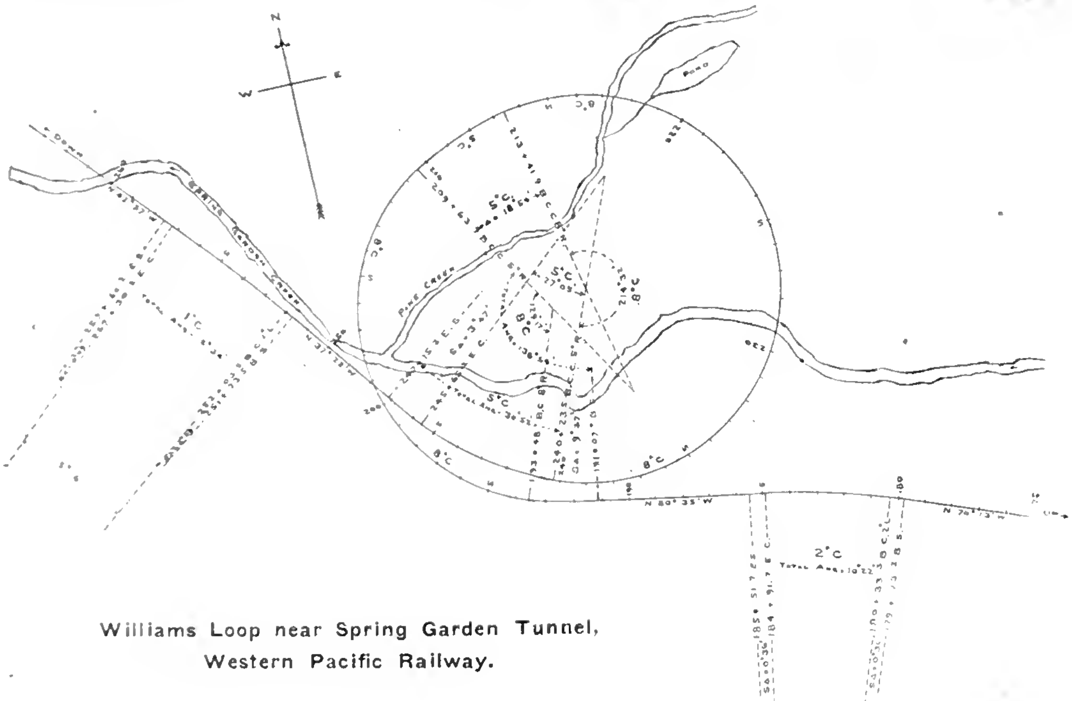
The portals and lining are of Oregon pine, their main timbers being 12 x 12 in. in size. At each portal, eight upright posts, lagged together with 6x12x12-in. blocks, bolted and toe-nailed, rest on 24-ft. sills and are stiffened by two outer and two inner main braces each 12 x 12 in. and 22 and 26 ft. long respectively, the posts being capped by 22-ft. timbers which are lagged with 4x12-in. planking continuing throughout the tunnel. The bents are 12 x 12 in. in size, set on 3-ft. centers with 4x12-in. plank lagging. In framing timbers the joints at the tops of segments were made to flare a little so that when pressure came on them, they were brought to a close fit throughout the flare. Particular attention is given to see that the dry packing used is tamped in solidly, an inspector being employed to look after this work.



Standard Timber Culvert.



Standard Log Culvert.



Williams Loop near Spring Garden Tunnel, Western Pacific Railway.

Roadbed sections are in three forms, earth filling for single track, and ballast, broken stone or cinder filling for double and single track respectively. From Oroville through to Stockton the track will be ballasted mainly with the gravel tailings of the gold dredgers in and about Oroville, and considerable of the track of the North Fork Division is to be similarly ballasted. Earth filling is to be used very sparingly, if at all, through the mountains, but when used it is to be made highest in the center where, for one foot on each side of the center line, it will be 3 in. deep over the top of cross ties, thence sloping off each way to the bottom ends of the ties. The ends of all ties are to be left just clear of the ground, and the roadbed outside and beyond the ends of the ties is to have a uniform slope descending away from them.

Retaining walls of either dry rubble or concrete or masonry are used in preference to log cribs wherever rock that breaks out in slabs can be secured. Their foundations are always sunk to a solid footing, the face batter varying accordingly to the type and height of the wall. The limiting heights of dry rubble and concrete or masonry walls are 20 and 30 ft. respectively. The stones used in building rubble walls vary in size and material with the character of the excavation, quarries or borrow pits whence they are obtained, but no stone used on the face of the wall is less than 8 in. in thickness nor less than 18 in. in its least horizontal dimension. Headers are at least 3 ft. long, unless the wall is 3 ft. in thick-

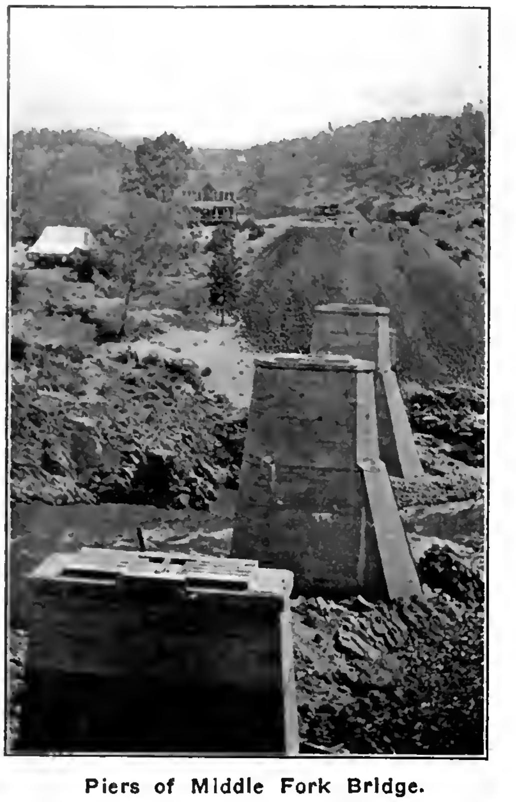
Standard Types of Masonry and Concrete Retaining Walls.

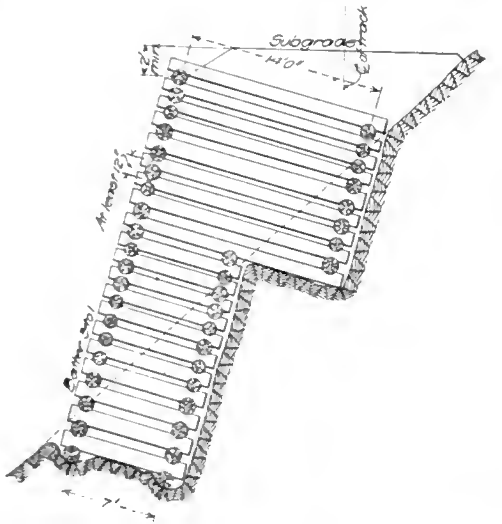
ness, in which event they extend entirely through the wall, at least one header being placed for every three stretchers. On steep slopes, steps are cut in the natural slope to prevent the embankment from sliding, regardless of the type of wall used. Walls built near the line of the roadway and having a height in excess of 10 ft. are invariably of third-class masonry or concrete. Ample drainage is provided through weep holes that are 6 in. square and placed 6 ft. apart as nearly in line as is possible with the natural slope, particularly if it be of stone. These walls rest on a base which is excavated to an inward slope of 1:12, and the center of this base is keyed in to the footing.

Where a suitable quantity of stone can not be obtained near by for building retaining walls, log cribs are being built to hold the foot of embankments, provided their maximum height does not exceed 30 ft. Such cribs are built log-house fashion, of round logs with bark removed. The face and rear longitudinal logs average at least 14 in. in thickness at the butts, and are laid with butts and tops alternating, so that each course, which averages at least 12 in., will build up nearly horizontal. Both tie logs and wall logs are notched at least 2 in. deep, so that a firm bearing will obtain. Tie logs are generally laid 8 in. apart, and the structure is bolted together, log by

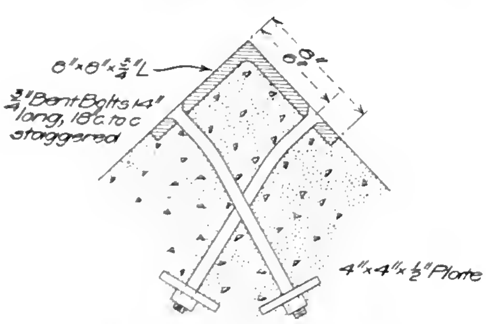


Piers of Middle Fork Bridge.

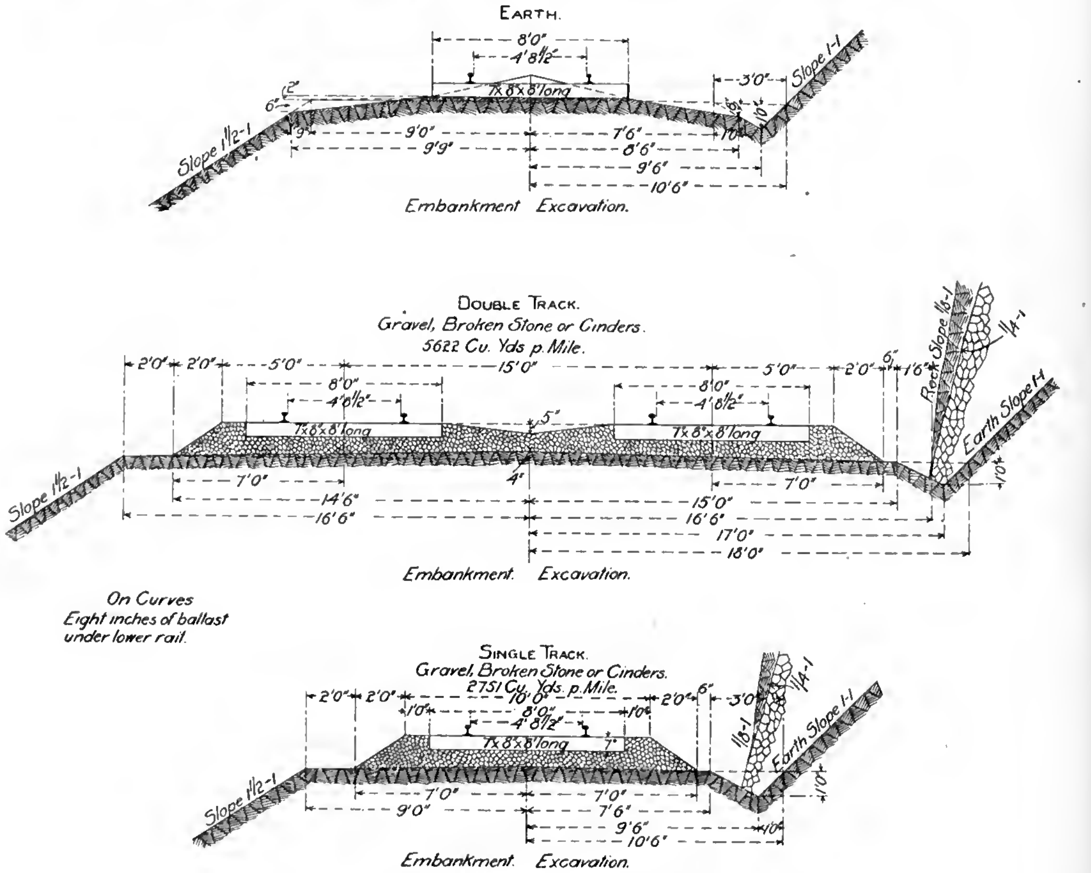
The bridges of the North Fork Division are to be nine in number, two across the North Fork of the Feather River, one across the Middle Fork, and the remainder being across various creeks. All of these bridges of consequence are to be of steel, and vary in length from a 60-ft. plate girder bridge to a 480-ft. plate girder and riveted deck span bridge at Spanish Creek. Bridge 18 which spans the Middle Fork at its junction with the North Fork is a typical struc- and will support two 125-ft. riveted deck spans and three 64-ft. deck plate girders, giving the bridge a total length of 442 ft. At this point the Middle Fork courses over a bed of solid rock which affords thoroughly stable footings for the four piers and two abutments. The tops of Piers 2 and 3 are on a level, barring the slight rise in grade which exists, while the elevation of the top of Pier 4 is some 13 ft. below, and the elevations of the abutments are approximately 20 ft. above, the mean height of the tops of the main piers. The piers and abutments were built during an extreme low water period which made cofferdamming unnecessary. The structures are of concrete, 2,230 bbl. of Atlas cement being used, its economic efficiency being found to be 1.07 bbl. of cement per cubic yard of finished structure. The mixture used was in the proportion of 1:2½:5, with considerable large rock incorpor-



Standard Log Crib.



Angle Iron for Pier Nose.



Standard Roadbed Sections.

log, with ⅜x18-in. drift bolts. The batter of the face varies with the slope of the ground, but generally it is 1:4, and the width of the log crib similarly varies with the slope, the endeavor being to make the width of its base as great as possible up to one-half its height. The sub-grade is at a minimum of 2 ft. above the line of the uppermost face log.

In drainage openings of a size not requiring arch, timber or log culverts, or where suitable material is not at hand for stone box culverts, concrete pipe culvert openings are being used in diameters varying from 12 to 48 in. These pipes are made of washed gravel or quarry-run crushed rock, no axis of which is greater than 1½ in., mixed wet with cement in the proportion of 1:4 and thoroughly tamped in forms. The pipe lengths are jointed with neat cement after having been laid on lines and firmly bedded. All pipes have a uniform length of 30 in. and a uniform depth of 3 in. at each end, their remaining dimensions varying as follows:

Inside Diam., in.	Thickness of Main Shell, in.	Thickness of Shell at Tips, in.	Base of Taper, in.	Width of Shoulder, in.	Cost of Complete Form.	Pattern.
12	2	¾	1¼	...	.....	Bell
12	3	1	½	1½	$13.75	Straight
18	3	1	½	1½	.....	"
24	4	1½	½	2	15.75	"
36	6	2½	½	3	22.75	"
48	8	3½	½	4	.....	"

In places on the Sacramento Division where culvert openings are used through levees on which the roadway runs, or where, in maintaining the grade, the embankment tends to restrain flood waters to their natural channels, the culvert pipes are provided with swinging check valves.

ated in the concrete of each structure, great care being taken to clean thoroughly and wet each stone before being placed. They are laid not closer than 18 in. from any surface, nor less than 24 in. from bottoms, and are placed at least 12 in. apart so as to give sufficient room for tamping.

These piers were subjected to a supreme test during the unprecedented flood of March 18, when, as already stated, the torrential waters of the Middle Fork reached a mean of 18 in. above previously recorded extreme high water as discernible by the wash in the canyon sides. At the point where these piers cross the river, the stream showed a crest of about 4 ft. at Pier 2, reaching within a foot of its top. Some 600 ft. above, a wagon road crossed the chasm of the river by means of a combination steel and timber bridge

having a 140-ft. span, which was lifted off its abutments and carried down stream transverse to the axis of the river. The center of the runaway bridge struck Pier 2 with terrific violence. For a moment the bridge quavered before breaking at its center, and, being held by the pier, as its ends swung together the bridge was lifted over the top of the pier by the backwater created, and then carried on down stream. Despite the fact that the forms had not been off the pier thirty days, it was absolutely uninjured save for a scratch on its nose.

The engineering organization of the Western Pacific Ry. Co. was explained in this journal on Aug. 3 of this year. The work is under the direction of Mr. Virgil G. Bogue, first vice-president and chief engineer. Mr. H. M. McCartney is the principal assistant engineer, with offices at San Francisco, and the division engineers are Messrs. C. Harlowe at Cobre, Nev., J. Q. Jamieson at Clio, Cal.; L. H. Jones, at San Francisco; Emery Oliver at Oroville; J. T. Williams at Oakland, and T. J. Wyche at Salt Lake City.

Calf Killer Bridge, Nashville, Chattanooga & St. Louis Ry.

The section of the Sparta branch of the Nashville, Chattanooga & St. Louis Ry. from Sparta to Bon Air was built in 1887, the crossing of the Calf Killer River being part of the work. At the south edge of Sparta the river makes a bend of 160 deg. inside of 700 ft., and the bridge was built in this bend on a tangent at right angles to the flow. The grade of the bridge was 1 per cent., ascending toward Bon Air. About 500 ft. south of the bridge the grade changed to 3 per cent, and, with the exception of four short benches, continued ascending at that grade to Bon Air. This put the Calf Killer Bridge at the base of eight miles of steep grade.

The masonry for the bridge consisted of two end piers, one middle pier and a stem wall at each end. The first pier (the north pier) was founded on concrete at a depth of 4 ft. below the surface of the natural ground; the second pier was founded on solid rock in the bed of the river at a depth of 48 ft. below base of rail, and the third pier (the south pier) was founded on solid rock at a depth of 45 ft. below base of rail. The distance from base of rail to bridge seat was 25 ft. 1⅛ in. The masonry for these two spans was made to take Phœnix-column deck trusses of Warren type, removed from the Tennessee River Bridge at Bridgeport, Ala. Their length, center to center of end pins, was 153 ft. 4 in., and width, truss to truss centers, 12 ft. There were five panels to the truss, of length 30 ft. 8 in. This bridge had been in service about fifteen years previous to its re-erection at Calf Killer in 1888.

The principal reasons for putting up a new bridge may be briefly stated thus: The old bridge was too light for present-day traffic; its location at the foot of the long, steep grade made it more dangerous than usual for trains of lost control coming down the mountain; the top chords of the trusses being of cast iron, made their strength an uncertain factor, and the style of columns and bases were such that a serious defect might be present and pass undetected. For the renewal of the entire deck of this old bridge 2-ply 8x16-in x 32-ft. wooden chords on the top chords of trusses on each side for the full length of the bridge and 8x14-in. x 14½-ft. ties were required. The deck of the new bridge requires only the 8x9-in. x 10-ft. ties.

A number of plans were suggested for rebuilding the bridge. One was to fill one-half of the north span and put a girder on the other half and replace the south span with a stronger span from Bridgeport; estimated cost, $23,000. Another was to renew the two spans on the same masonry; estimated cost, $21,000. Another scheme was to use one 30-ft. girder and two 60-ft. girders supported on towers in place of the north span and replace the south span with a stronger span; estimated cost, $17,000. Another scheme was to build two new piers and top out the old ones, using four spans of 75-ft. deck plate girders; estimated cost, $11,850. This latter plan was adopted.

A survey was then made to get the physical data of the crossing necessary to make plans for the new masonry and to get the exact position of the old bridge on the masonry, especially noting its position at points likely to interfere with the construction of the new masonry. This was done with a view to carrying up the new masonry without erecting false work before the time to put in the new girders and without delaying traffic.

The procedure in the construction of the masonry as adopted was: (*a*) Build up piers 1 and 5, encasing the end vertical posts and end braces, removing the latter when the old structure is taken down; (*b*) finish complete piers 2 and 4, leaving slots, through which the old chord bars can be withdrawn; (*c*) erect on both sides of pier 3 falsework towers sufficiently strong to support the ends of the new girders, after which the old spans will be taken down and the new superstructure put in place, when the old center pier (No. 3), without obstructions, will be built up. By this design the old masonry was to be built up to the finish for 7-ft. deck plate girders, using vertical faces and not exceeding the size of the old piers. The length of this top section on the old masonry was to be 14 ft. on each of the piers, and the design of the entirely new piers is in size and shape similar to the old mid-pier, with its new top section. This gives the set a uniformity of design and effect.

The first work to be done on the construction of the masonry was to put in a cofferdam for pier 4, the only one coming in the bed of the river, to be built entirely new. The cofferdam was started when water in the river was about 6 ft deep.

As piers 2 and 4 came midway of the center panel of the old trusses and the top of the new masonry being 8 ft. 1 in. from base of rail, they were built complete, without being obstructed by the middle diagonals of the old bridge, except to box around the bars of the lower chords, filling in the slots with concrete after the old bridge had been removed. A temporary pile bent was previously driven at each end of the bridge to permit of the removal of the end vertical posts of the old trusses, so that the top sections of the end piers could be built up complete, except for having to incase the bases of the end braces, which small open sections remaining could soon be built out even with the finished faces. These slots and open sections were not large enough to lessen the strength of the masonry perceptibly for carrying the bridge and trains. When all the piers but the middle one were ready for the new bridge, falsework towers were put up on each side of the middle pier and the new girders put in place, their ends at the middle pier resting on these towers just about 2 in. above the top elevation to be given the pier.

The plate girders are 75 ft. center to center of bearings, 77 ft. 6 in. out to out of girders, and spaced 8 ft. centers. The web plate is 84 in. deep by 7-16 in. thick. There are two flange angles 6x6x¾ in. for full length of girders on top and bottom. The top has four cover plates, each 14x⅜ in.; lengths, 7 ft., 34 ft., 49 ft., and one the full length of girder. The bottom cover plates are of the same size and number as the top ones, except that the longest one is only 54 ft. instead of the full length of girders. The rivet pitch used is 3 in., with alternate spacing.

Before placing the girders falsework bents were put up between the old trusses through one span to the height of the new masonry. Pony bents were erected on top of these to carry the track. The wooden chords on the top chords of the old trusses were shifted to these pony bents for stringers. The ties were replaced with shorter ones, allowing space between their ends and the old trusses to lower the girders to the main bents and new masonry. Before the girders were lowered the lateral rods and braces of the top of the old trusses had to be removed. The girders were handled from trucks on the bridge to place by a gallows from a traveler bearing upon the top chords of the old trusses. By these arrangements trains were carried on falsework for each span about three weeks, one span being put in before the other was put on falsework. If the stability of the old spans, with top lateral rods and braces removed, had not been so greatly impaired and the time required to shift and handle the long and large bridge ties had not been so long, these girders could have been put in without trains having to run on false work, except for the tower bents at the center pier and the bents at both ends of the bridge in place of the vertical posts removed. When these girders were in place and the old spans removed the middle pier was built up complete without obstructions. Then after the concrete was sufficiently set the tower bents carrying the ends of the girders were removed and the girders let to their final position on the pier.

The arrangements for handling the concrete material and for making and placing the concrete is worthy of description. The sand and aggregate, consisting of blast-furnace slag from South Pittsburg, Tenn., were unloaded from cars to platforms on a level with the top of rail about 100 ft. south from the south end of the bridge. The concrete mixer, a cubical form of 1-6 cu. yd. capacity, run by a gasolene engine, was located on a platform built up about 50 ft. south from the south end pier. A tank near the mixer to supply the water was elevated enough to get the desired head and was kept filled by a pump run by another gasolene engine located down on the river bank. The cement house was close by, a little to one side, between the mixer platform and slag pile. Wheelbarrows were used to deliver the slag and sand to the mixer. The mixer was so placed that it would dump onto the platform, and the concrete was then shoveled into the specially designed narrow-gauge car, which used one rail of the main track and an extra rail on the outside for its running track. A turnout for clearing passing trains was provided for at both ends of the bridge. The grade of the track over the bridge was descending from the mixer 1.05 per cent., so that with a little start the concrete car would roll alone down to points on the bridge; and only in returning empty to the mixer did the car have to be pushed by hand, although this was never for a distance of more than 400 ft. Over the piers on the bridge in the center of the concrete car's track, openings were sawed out to let the concrete pass to the forms below. To get the concrete into the forms with very little disturbance and fall there were used zigzag chutes, with arms about 10 ft. in length, which sections were removed as the level of the concrete in the forms came up close to the end. This chute was a convenience because its end alternated from one side to the other as the arms were removed in coming up. A swinging section could have been provided for the end to swing the concrete to the desired spot in the form; but the extra time required to swing it about, to detach from one section and attach it to the next, would have been much more than that required to shovel the concrete to points in the form not directly under the end of the chute.

The foundation work for this bridge was built

up by the railway's masonry gangs. The bridge company furnishing the girders put them in. The work was commenced about June 20, 1905, and the bridge was finished complete about Dec. 1 of the same year.

The cost of the masonry is shown in an accompanying table. There were 460 cu. yd. of concrete the cost per yard for the entire work being $6.49.

Cost of Foundations and Piers.

		Cost per cu. yd.
Unloading material	$ 88.15	$0.19
Labor on forms and bins	435.50	0.95
Lumber	472.00	1.03
Cofferdam—excavation, lumber and labor	293.20	....
Mixing and placing concrete	428.00	2.79
Cement, slag and sand	854.90	
Taking down forms and cleaning up	211.40	0.46
Engineering and supervision	200.00	0.43
Total	$2,983.15	

The new steel cost $10,082.80 erected, and deducting the scrap value of the old spans, $1,800, leaves the net cost for the steel as $8,282.80. This added to the cost of the masonry makes a total of $11,265.95, which is $584.05 below the preliminary estimate, made when the reconstruction of the bridge was first determined upon.

The weight in pounds of the metal of the two old spans was 186,860. The maximum safe engine load in tons of the old bridge was 84. The weight of the four new spans is 268,451 lb. The maximum safe engine load of the new bridge is two 141-ton engines coupled, followed by a uniform load of 4,500 lb. per foot, with allowance for impact as specified by the American Railway Engineering and Maintenance of Way Association. The cost of the new steel bridge erected per pound was 3¼ cents. This does not include the cost of the new deck, as this was charged to the renewal account. The steel work could not be duplicated for the above cost, for an error was made in the calculation of the weight of the bridge by the company making the bid. It is estimated that about $1,500 should have been added to the bid for the steel work to make the total cost come up to the cost of similar structures.

The work was described by Mr. J. G. Huff in a paper before the Engineering Association of the South, from which the data for these notes were taken.

Explosions of Coal Dust have caused so much trouble in cement mills that managers of such works will probably be interested to learn of experiments which Prof. Phillips Bedson described at the recent meeting of the British Association. His first experiment was made by fitting glass tubes 1½ in. in diameter into opposite sides of a 9-in. cubical tin box provided with a hole in the top and in the bottom so that a gas flame could burn within it. The dust was prepared for the experiments by passing it through a sieve with 100 meshes to the inch, and was then placed in one of the glass tubes and blown into the box by air pressure. It was found that some kinds of dust would inflame under this condition, flour and powdered aluminum flashing up violently, but coal dust acted in an uneven manner. In order that the experiments might give more definite results, Professor Bedson used a larger box and increased the charge of dust to two grams or more, which was ignited electrically while suspended in the box. Various modifications of the apparatus were made to enable him to vary the experiments. It was found that ordinary coal dust was not directly inflammable, the most inflammable coals seeming to be those which contained considerable volatile gas. The amount of moisture had little apparent influence so long as the dust was not absolutely wet. The main thing shown by the experiments was that it is necessary to make extended investigations before any definite general knowledge of the nature of these explosions can be obtained.

Examination of Water Purification Plant at Owensboro, Ky.

By Philip Burgess, Assoc. M. Am. S. C. E.
Special Assistant Engineer, Ohio State Board of Health.

In the issue of The Engineering Record for Aug. 31, 1907, is found an interesting description of the intake of the Water Works Company of Owensboro, Ky. As the writer had just completed an examination of this plant on Aug. 28, 1907, with particular reference to results obtained, it is thought that a report of this examination may be interesting as a conclusion to the above mentioned description. The Ohio State Board of Health has been so frequently called upon for advice relative to the installation of so-called natural filtration plants, particularly on the Ohio River, that it has been considered desirable to obtain all the information available regarding existing plants of this type. The plant at Owensboro, Ky., had been cited as an example of a successful infiltration plant, and this examination was undertaken to study its principal features and to determine the degree of purification obtained.

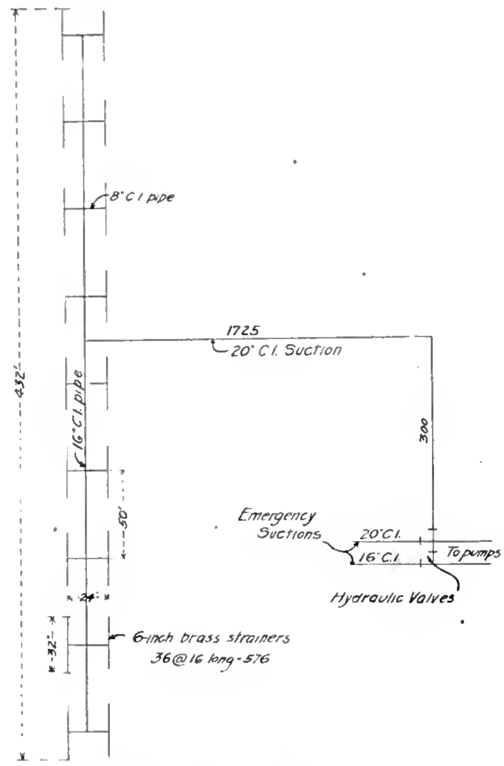


Diagram of Owensboro Intake.

Since May, 1906, the writer has been engaged by the Ohio State Board of Health in making examinations of the various water purification plants in Ohio, and the examination of the Owensboro plant was conducted in a similar manner to that in which these other tests have been made. Boxes containing the necessary laboratory media and supplies, especially built for this purpose, were shipped by express to the pumping station and such chemical and bacterial determinations as practicable made there, while samples of the water were shipped by express to the laboratory of the State Board of Health at Columbus for such determinations as it was not practicable to make in the field. Mr. Asa Williams, the chief engineer of the Owensboro Water Works Co., assisted the writer in making the examination of the plant and also furnished the data and descriptions embodied in this report.

Owensboro is a city of about 20,000 inhabitants, situated on the Ohio River about 115 miles below Louisville. Until recent years the water supply had been obtained directly from the river without purification and was unsatisfactory from all points of view, being very turbid at times and always subject to considerable pollution. About four years ago pressure was brought by the city officials on the Owensboro Water Co. to purify the supply. The water company was desirous, if possible, of installing some system in which the purification would not be dependent on the ordinary methods employed but one in which the necessary care and expense that are involved in the usual filter plants would be eliminated. After considerable consultation the present system was installed by which the purification is effected by the infiltration of water through the gravel bottom of the river and its collection into a system of horizontal brass strainers.

Several tests of the quantity and quality of the water obtainable were made before any construction was undertaken. Owensboro is fortunate in having a sand and gravel bar directly opposite the pumping station on the shore of an island, and it is from this bar that the present supply is obtained. In order to learn the quality of the water available, a small pipe was first driven into the gravel and water pumped from this by means of a hand-pump. In this way it was found that the supply was of satisfactory quality, but it was not possible to estimate the quantity obtainable. In a subsequent test a 2-ft. tile pipe was sunk into the bar to a depth of 8 ft., and the water which percolated into this well was pumped by a steam pump. It was noted that the water stood 58 in. deep in this well until the pumping was increased to a quantity greater than 50 gal. per minute. With a greater quantity than this, the level of water in the well was reduced, and finally at 90 gal. per minute, sand and water together were drawn up through the well. From these figures it was estimated that 50 gal. per minute was the maximum capacity of the well, corresponding to 16 gal. per square foot per minute. Water was pumped from this test well continuously for several hours and found to be of satisfactory quality, being clear and free from iron. At a depth of 14 ft. in the gravel, Mr. Williams stated that a water was obtained which soon turned red on being exposed to air and light and was evidently a ground water containing considerable iron.

The essential features of the plant as installed are a system of slotted brass pipes or strainers embedded in the bottom of the river at from 4 to 5 ft. in depth in the gravel bar, these strainers being directly connected by a system of collecting and suction pipes to the pumps by which the water entering the system is pumped into the mains without storage in a distributing reservoir. The river water thus percolates through the bed of the river into the collecting pipes, leaving the impurities behind on the sand and is not again exposed to the light until drawn from some part of the distributing system.

The strainers are what are known as the No. 8 Cook well-point strainers and are 16 ft. long, 36 in number, giving a total length of 576 ft. The openings in these strainers were cut with a tool 0.008 in. thick, at right angles to the axes. Mr. Williams stated that probably a somewhat larger opening would have been more suitable for the kind of material in which the strainers are laid.

As at the time of the examination the water in the river was about 10 ft. deep over the bar in which the intake is laid, it was impossible to examine the filtering material, which is said to consist of clean sand and fine gravel and is so located in the stream that there is little, if any, deposit of mud on the surface. The intake is at about the low water mark of the river, and the material over it is thus constantly submerged.

The accompanying diagram shows the layout of the strainers with the cast-iron collecting and suction pipes. It will be seen that the water enters the strainers, then blows through an 8-in. cast-iron pipe into a 16-in. pipe, and thence into the main 20-in. cast-iron suction leading to the pumps. The total length of the strainers, as stated, is 576 ft. and they probably drain an area of approximately 4,500 sq. ft. Assuming the capacity

of the sand bed to be 16 gal. per square foot per minute (as determined by previous tests), the maximum quantity of water available by the strainers is 72,000 gal. per minute, or 10,000,000 gal. per day, assuming the entire area equally efficient. At the time of the examination, water was being pumped at the rate of 1,200 gal. per minute, or about 1,500,000 gal. per day, showing that the estimated capacity of the intake provides for a very considerable future increase of consumption. The strainers are patented and were purchased at a total cost of $2,000.

On the diagram it will be noted that 16-in. and 20-in. emergency intakes are provided, which are intended to be used in case something happens to the strainers. As has been noted, there is no storage or distribution reservoir, and in case the strainers become clogged or for any reason do not give sufficient water, it is intended to back flush them by pumping direct, using one of the emergency intakes. The plant has been in use since July 1, 1906, and it has never been found necessary to back flush.

One interesting feature developed in operating the plant is that the suction lift seems to be independent of the stage of water in the river but varies only with the quantity of water pumped. Even with very high stages of the river, the ordinary vacuum of 3 in. is maintained when the pump makes 30 r. p. m.; but when increased to 34 r. p. m. the vacuum is 4 in. This is true also at low stages of the river, and it would seem that there is but little loss of head in the filtering process itself, the actual movement of water into the strainers being very slow, but that the loss of head developed while pumping is due to friction in the suction pipe. This is a very interesting fact, as it would be expected that ultimately the capacity of such systems would be limited by the amount of water that could be drawn through the sand, a quantity which depends finally on the suction lift at the pumps. It was stated that the suction at the pumps had not increased since the beginning of operations, and the fact that it has never been necessary to back flush and clean the sand would show that there is but little decrease in the capacity of the strainers.

After the plant was first started in operation it was found that the filtered water was occasionally turbid, and an inspection showed that proper attention had not been given by the contractor to leveling the sand and gravel after back filling over the strainers, so that there were numerous places where the filtering material was not of sufficient depth to give proper purification. In December, 1906, more filtering material was added and the river bed leveled off, since which time the plant has been in successful operation giving a very satisfactory water up to the present time.

The plant was operating under normal conditions at the time of the examination, the river being fairly turbid and rising, due to a rain of the previous night. Only four samples were collected: One from the river, one from a tap at the pump, and two from a tap at the force main.

The following table shows the analyses made and the results obtained in parts per million:

	River Water.	Tap from Pump.	Tap from Force Main 1	Tap from Force Main 2
Turbidity	170	2 ±	2 ±	2
Color	22	15	15	15
Carbon dioxide	2	14	12	..
Alkalinity	75	95	95	95
Incrustants	29	18	32	25
Total hardness	104	113	127	120
Iron	1.6	0.7	0.2	0.3
Chlorine	13.0	12.2	9.5	9.5
Bacteria per c.c.	26,500	29	29	21
Colon in 1 c.c.	Yes	No	No	No
Colon in 100 c.c.	Yes	No	No	No

The bacterial plates were made in the field, as were also the chemical determinations of turbidity, alkalinity, color, and carbon dioxide. The remaining analyses were made in the laboratory.

The above analyses show a remarkable purification of the river water, the bacteria being practically all removed by the filtration. The slight increase in total hardness and of carbon dioxide indicates a small percentage of ground water, but it will be noted that the filtered water contains even less iron and chlorine than the water in the river. There were a large number of bacteria in the raw water, and also the presence of considerable pollution is indicated by the coli results. No coli, however, were found in the filtered water.

It will be noted that there is not a very great removal of color, the reduction being but seven parts per million.

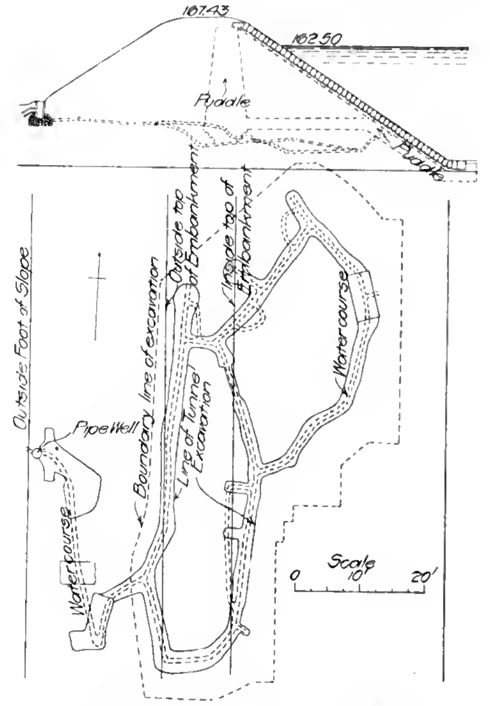
The samples of filtered water were seen to contain small particles of suspended matter, and a subsequent microscopical examination in the laboratory revealed the fact that there was present a considerable quantity of growth similar to Crenothrix. No trouble has yet been experienced with odors or tastes in the supply, but it is quite probable that in the future considerable trouble may develop due to the luxuriant growth of this plant, causing a subsequent closing of part of the strainers and a diminution of the capacity of the intake. Owing to the lack of storage of filtered water, it is necessary to run the pumps continuously, and it will be very difficult to treat the intake for the removal of any such growth.

In conclusion it should be said that the present intake of the Owensboro Water Co.'s plant has for about one year been furnishing a clear, satisfactory water obtained by the filtration of water from the river with no greater expense of maintenance than would be incurred by the pumping of untreated river water. At the time of the examination the supply was found to have a remarkably low bacterial content and to be in every way satisfactory as a municipal supply. The probability of future trouble by the clogging of the strainer system by growths very difficult of removal is apparent, a condition which might render the present supply very unsatisfactory.

A CORRECTION should be made in one of the values of the coefficient of discharge in the table on page 354 of this issue, being part of the article on "Experiments with Submerged Tubes 4 Feet Square." Under a head, h, of 0.20 ft. and form of entrance and outlet of type a, the coefficient for length of tube of 2.50 ft. should be .694 instead of .684 as printed.

Repairing a Leak at Hope Reservoir, Providence.

Mention was made last year of the fact that a leak which has existed for over 25 years in the embankment of Hope reservoir at Providence, R. I., had been giving the city engineering department quite a puzzle before its course was finally traced. This reservoir is a service basin surrounded by dwellings. The leak appeared originally at the foot of one of the slopes, where a pipe well was constructed to intercept the seepage and direct it into a street sewer. Measurements of the discharge were kept for many years, and during the last few years the amount had increased somewhat, although not enough to cause alarm. Examinations had been made a number of times and considerable time and money had been expended, without finding any clew as to the location of the point on the inside of the bank where the water escaped. In May of last year the reservoir was drawn off for the purpose of cleaning it, and advantage was taken of this opportunity to investigate and repair the leak. The work is described in the 1906 report of Mr. Otis F. Clapp, city engineer, from which the following notes are taken:



Seepage Channels, Hope Reservoir.

It was thought that the best way to trace the course of the water would be to follow the stream back into the bank. When the water had been drawn down so that there was a head of about 1 ft. on the discharge, digging was commenced. Almost immediately a water channel was found, measuring from 2 to 4 in. high and from 4 to 8 in. in width, and nearly level. This was followed some 54 ft. in open trench and then tunnelling was commenced. When a point was reached about under the outer top edge of the embankment the channel divided and ran in nearly opposite directions. In the belief that time could be saved by so doing, a lot of colored water was forced back into the reservoir by way of each of these two routes, but the color appeared at the same point on the surface of the water in the reservoir.

The reservoir was then emptied and cleaned and the tunneling was continued by way of both branches. The stone slope wall was taken down where the colored water had appeared and a hole was found several inches in diameter, which went back into the bank for several feet, where it branched and ran in opposite directions. The tunneling was prosecuted until the lines met, every effort being made to discover any side openings that might lead away, but only a few were found and those followed to the end. The material of the embankment was found to be hard and in the best of condition, only a few soft places were found, and those, all near the water course, were completely removed. The tunnel averaged about 4 ft. high and 2½ ft. wide, just large enough for a man to work in. This tunnel was surveyed and platted, and a sketch of it is reproduced here. The tunnel measured 251 lin. ft., with 54 ft. of open cut. There were discovered 359 lin. ft. of water course in embankment.

It was not thought safe to refill the tunnel, and so that portion of the bank lying over the tunnel excavation was taken out and the embankment rebuilt. The water channel was found to have been about on the surface of the original soil, or where the artificial work in building the embankment was begun. In repairing, the precaution was taken to go down lower in the line of the core wall, finding rock from 2 to 5 ft below where the embankment had been started before, and filling in with cement concrete. The excavation was then refilled with great care, some three carloads of clay being added to the soil taken out before replacing.

The work of repairing took about 3½ months to perform, and no sign of any leak has since

appeared at this point Mr. Samuel M. Gray, who was resident engineer at the time the reservoir was built, was consulted in relation to the repairs. A smaller leak or spring, co-existent with the other leak, is still discharging near the corner of the reservoir and will be examined later.

Strengthening an Old Lattice Girder Bridge.

By George Jacob Davis, Jr.

The city of Grand Rapids, Mich., is divided into two parts by the Grand River, which is spanned by a number of bridges, two of which were originally timber lattice girders. The lattice girder bridge at Bridge St. was replaced by a steel pony-truss bridge to accommodate street cars and these trusses were, in 1904, replaced by a reinforced concrete arch bridge. The lattice bridge at Leonard St., built in 1879, still stands and carries a very heavy traffic. A few notes on the method used by the designer in computing the stresses in the bridge and on its failure and strengthening may be of interest.

The bridge consists of eight spans of 104 ft. each, built of white pine. The trusses, as shown in the illustration, are sextuple system Warren trusses, fastened together at each intersection with treenails. There were, originally, no vertical posts except three in each truss at each end of the bridge, the trusses being continuous over the intermediate piers.

From the original computations it appears that the dead load was taken as 1,000 lb., and the live load as 1,848 lb. per running foot of bridge, on two trusses. Taking the distance between centers of gravity of chords as 13.3 ft. and the span as $104-5=99$ ft. (piers are about 5 ft. wide on top), and considering the girders as simple beams, gave the computer a stress of about 131,300 lb. on each chord, of which 78,800 lb. would be carried by the outer boom and 52,500 lb. by the inner boom. Calling the girders continuous would reduce the maximum strain to about 40,000 lb. or 800 lb per square inch, only 48 sq. in. being considered available at joints in the booms. In taking care of the shear the computer assumed all the diagonal strains to be carried by one system and delivered to the abutment by one strut giving a load of about 70,488 lb. per truss on the abutment or 70,488 sec. $\theta = 93{,}987$ lb. as the approximate strain on the diagonal, which was too great, but by dividing by six (the number of diagonals cut by a vertical section) gave roughly 15,500 lb. to be carried by one diagonal.

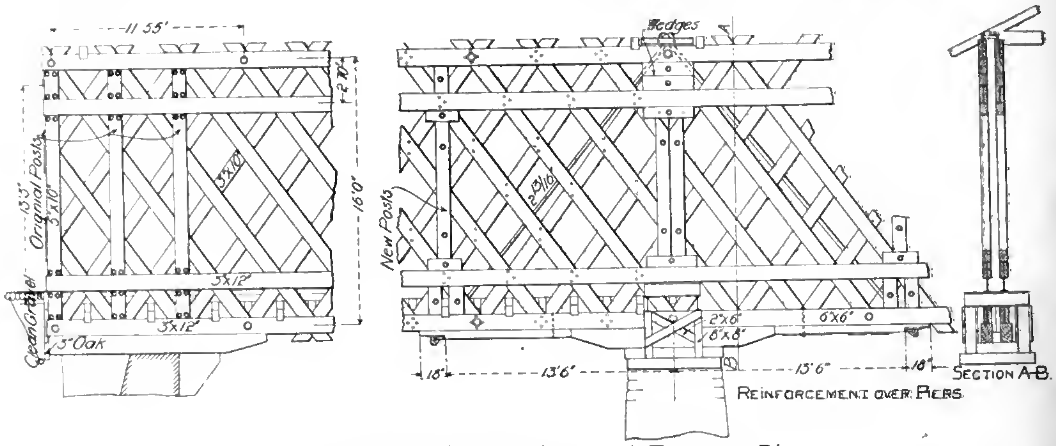
Assuming the 3x10-in. white pine diagonals to have an ultimate strength of 95,190 lb. and considering them to act as long columns, 3 ft. long, they were found to have a factor of safety of about six when the truss was considered as a simple beam. This factor of safety is still further increased by virtue of the fact of the truss acting as a continuous girder, but it is diminished by virtue of the fact that the diagonals are not rigidly supported at 3 ft. intervals, it being possible for several of them to tend to bend in the same direction, thus increasing the effective length of the columns. This action has, in fact, taken place. In some cases several of the diagonals have bowed, perhaps 1½ in., while in others, they are bent into an S form.

The chords each consist of two booms of four 3x12-in. timbers, each 30.8 ft. long. To determine the length required it was assumed that each timber would carry a stress of 27,000 lb., giving 1,500 lb. per square inch on the net area of 18 sq. in. which remain after deducting for the three 2-in. pins which were intended to be used. It will be noted above that the designer decided that only about 40,000 lb. would come on the two halves of the boom or 20,000 lb. to be transmitted past a joint by a single timber. Figuring the strength of the pins in single shear as 500 lb. per square inch, or 1,500 lb. per pin, gave a safe stress of 4,500 lb. per set of three pins. Hence to carry the 27,000 lb. past a joint six sets of pins were required. The sets are $11.55 \div 3 = 3.85$ ft. apart. This would require a plank 2x6x3.85, or 46.2 ft. long, plus something for end shearing. To reduce the length, clusters of four 1¾-in. pins were put in instead of three 2 in., the area of pins also being increased thereby from 9.42 to 9.6 sq. in. These pins also connect the lowest boom to the diagonals and they are here considered to be acting in double shear.

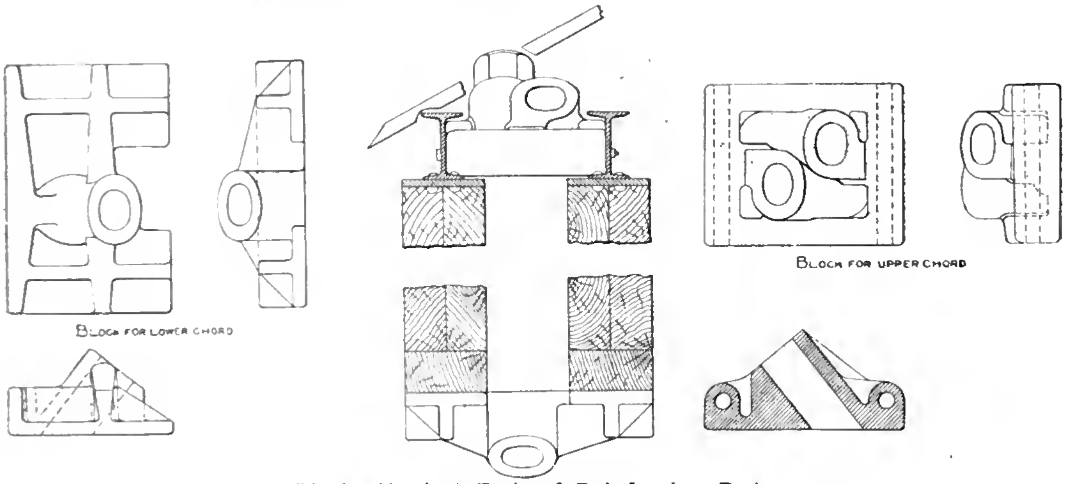
No clue is given in the old notes as to how the number and size of pins required to connect the diagonals to one another was determined.

A roof which covers the bridge has perfectly preserved the timbers except the ends of the floorbeams, which extend out to support the sidewalks and are thereby subjected to periodical wettings by rain.

The trusses have proved to be amply strong to resist the bending stresses. In the middle of the spans where the bending moment is greatest, there is no distortion noticeable in either diagonals or booms, the pins apparently have not sheared and the original camber still exists. Over the piers, however, the trusses have failed by shearing, allowing the bridge as a whole to settle approximately 0.2 ft. The floor, being supported by the lowest boom, which could not settle over the piers, shows ugly humps at these points. The failure occurred partly by the diagonals buckling between chords, as indicated above, and partly by the crushing and twisting of the lowest boom and probably a shearing of the pins connecting it to the diagonals or a distortion of the lower end of the diagonals. Of the 0.2 ft. by which the upper chord has approached the pier only about 0.02 ft. on an average was produced by the buckling of the diagonals, the remaining 0.18 ft. being the result of the other failures. The 8x14-in. bolsters and lowest boom are bent into an arc. The upper chord seems to retain very closely its original shape and the distortion in the lower chord extends only about 10 ft. each side of the piers.



End of Lattice Girder Bridge and Truss at Pier.



Blocks Used at Ends of Reinforcing Rods.

In reinforcing the bridge no attempt was made to bring the trusses back into shape, but only to relieve them of some of the stress and to prevent any further failure at these points. Jacks were put under the upper chord and screwed up, thereby stretching the chords apart slightly, and columns were then slipped in between the chords with very tight fitting joints. I-beams were next inserted under the upper booms of the lower chord and wedged up tight. Then the 2 13/16-in. round bars were placed and tightened until the new parts took a firm bearing and the bridge showed a slight rise on each side of the pier. The humps in the floor were removed by dressing down the stringers when the new flooring was laid.

Rankine states that lattice-work girders were first introduced by Mr. Ithiel Towne. They are not economical of material, being of the same strength in all parts regardless of the variation of the stresses. They were, however, easily and cheaply built, but have fallen into disuse on account of the growing scarcity of timber. Lattice trusses of iron and steel are still used somewhat in Europe. From the experience with this bridge it would seem that the introduction of posts over the piers when the bridge was built, in that way distributing the stresses from the pier reactions more uniformly among the various systems of diagonals, would have prevented the failure. The bridge is now apparently good for many more years of service.

The bridge was designed and built by Mr. Wm. Seekel, who was then city engineer of Grand Rapids. The recent reinforcement was done under the direction of the present city engineer, Mr. L. W. Anderson, the author being in charge of the work.

The Large Traveler used in erecting the Blackwell's Island bridge across the East River at New York, was injured by lightning on Sept. 23.

The Erection of the South Cantilever Arm of the Quebec Bridge.

The design, fabrication and erection of the Quebec bridge have been fully explained in previous issues of this journal, and those who wish to become familiar with the structure are referred to the list of articles which closes with this description of some details of the erection of the south cantilever arm, not previously published.

The erection of the cantilever arm was commenced with the forward bent of the traveler in the plane of the main vertical posts. The forward 69½-ft. cantilever trusses were secured to the foot of the traveler and their extremities were connected by the transverse girder 81 ft. long, which weighed 25,000 lb., and was handled from the overhang of the traveler by two pairs of wire rope tackles converging to a swivelled attachment at the center point. The top of the traveler was temporarily braced to the top of the permanent superstructure in order to avoid special anchorage at this point and the first panel of the cantilever arm was erected in 37 operations made with the traveler in the same position, which was the fifteenth counting from the commencement of the erection of the south anchor arm.

The erection superintendent was furnished with a blue-print showing the sequence and detail of all these operations and illustrated with dimension sketches giving the lengths and widths of all their principal members and showing where and how the tackles were attached to them. A number of diagrams were also given to show the positions of the different tackles suspended from the traveler and their capacities and the reference letters by which they are designated in the description, R and L, always meaning right and left hand.

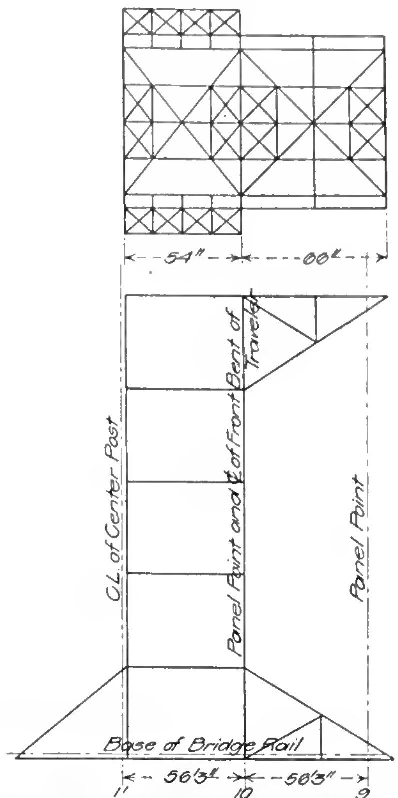


Diagram of Traveler.

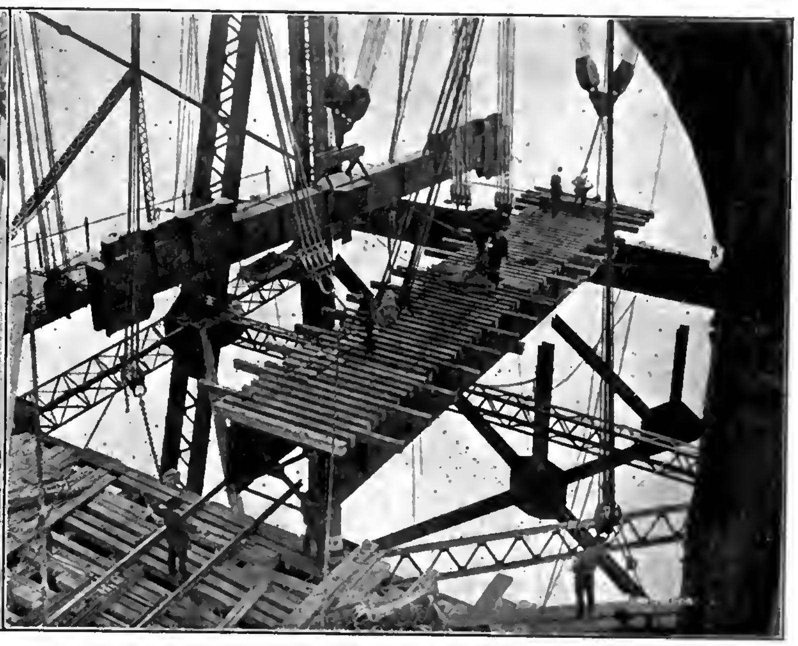
Erecting First Panel of Cantilever Lower Chord.



Handling Track in Cantilever Platform of Traveler.

Preparatory to the first operation a pair of stringers and its track, making a unit 69½ ft. long weighing 60,000 lb., was delivered on cars in the tower of the traveler and hoisted by one 22-ton tackle EC and two 17-ton tackles MC, both attached to it at the center of gravity. Tackle EC was slacked off to fleet the girders forward under tackles MC which fleeted it transversely into position. The duplicate pair of track stringers on the opposite side of the bridge axis were similarly put in place and the first panel, No. 10, of bottom chord for each truss was delivered on 2 cars. Each piece was 70 ft. 7 in. long, weighed 195,000 lb. and was supported, 19 ft. from the forward end, on a bolster in the middle of a flat car 40 ft. 2 in. long over all. The rear end of the chord was supported on a bolster just in the rear of the forward truck of the rear car and was held back by a horizontal preventer tackle made with a 1½-in. rope rove through 14-in. blocks to exert a maximum pull of 15,000 lb. Pivoted attachments described in a previous article were secured to both ends of the chord projecting above its top flanges to receive two wire rope tackles HR and HL at the rear and two wire ropes tackles AR and AL in front by which it was unloaded, lowered and fleeted to position as shown in the photograph. After the lower end was splice bolted to the special V-shaped section engaging the shoe and pedestal, tackles H were released and the upper end was sustained by tackles A.

The first section LSB5, of each diagonal, R and L 63 ft. 9 in. long and weighing 29,000 lb., was unloaded by one tackle HR or HL attached to the center of gravity just above the center of gravity by a double 1-in. chain, snubbed to position with a double 1½-in. manila line and bolted securely at the lower end.

The lower horizontal struts SS6, R and L were each swung to position with two 1½-in. single foot lines and the connections at both ends bolted, thus completing the triangle and holding the diagonal members stable.

Temporary suspension bars were attached to the outer ends of the lower chord sections 10 R and L, releasing the tackles A, which were detached after the positions of the chords were adjusted.

The four bottom lateral members, not shown in the diagram, were erected with 1½-in. lines rove through single and double blocks and attached to their centers of gravity with ⅞-in chains.

In the sixth operation the second section MSP5 of the diagonal, 56 ft. long and weighing 22,000 lb., was unloaded and swung to place with a pair of 17-ton tackles, MR and ML attached a little above the center of gravity by a double 1-in. chain. The lower end was securely splice bolted and the tackles released.

The horizontal struts SS4, R. and L., were swung to position with single 1½-in. whip lines and securely bolted.

Transverse struts H2 and laterals N3 in the plane of struts SS4, not here shown, were swung to place with single whip lines attached at the center of gravity.

The third sections USP5, R. and L. of the diagonal, 80 ft. long and weighing 22,000 lb., were swung to position with 1 wire rope tackle FR or FL and a double 1½-in. snub line attached to double 1-in. chain a little above the center of gravity of the member. The bottom end was spliced bolted and the top end sustained in position by the tackles.

Struts SS8 R. and L. were swung to position with single whip lines and bolted at both ends.

The upper sections UT5 R. and L. of the main diagonal, 81 ft. 9 in. long and weighing 92,000 lb., each were swung to position by two pairs of wire rope tackles HR and L attached to the upper ends with a pivoted yoke and to 17-ton tackles M and MC attached to the lower end with a 1-in. chain.

Struts SS7 R. and L. and the transverse strut H3 and lateral 11 in the same horizontal plane were swung into position with single whip lines attached at their centers of gravity with 1-in. chains and bolted in position at both ends.

The lower sections LT6 R and L of the main diagonal, 81 ft. long and weighing 64,000 lb. each, were hoisted with two pairs of wire rope tackles, FR and FL, with special attachment to the member a little above the center of gravity, and temporarily held suspended by the tackles.

The upper ends UT5Z R and L of the hanger T5Z, 100 ft. long and weighing 55,000 lb. each, were hoisted by two 30-ton tackles EC at one end, attached to the lower end by a 1-in. chain and by two 55-ton tackles AR and AL with a special bent plate attachment at the upper end.

The transverse strut T1, not here shown, and the longitudinal strut SS5 R and L were hoisted with single whip lines attached with 3/4-in. chains.

The middle sections MT5Z R and L of the hangers, 54 ft. 9 in. long and weighing 21,000 lb. each, were swung by one pair of manila rope tackles X at one end and another pair of wire rope tackles HR and BL at the opposite end are all attached to it by 1-in. chains.

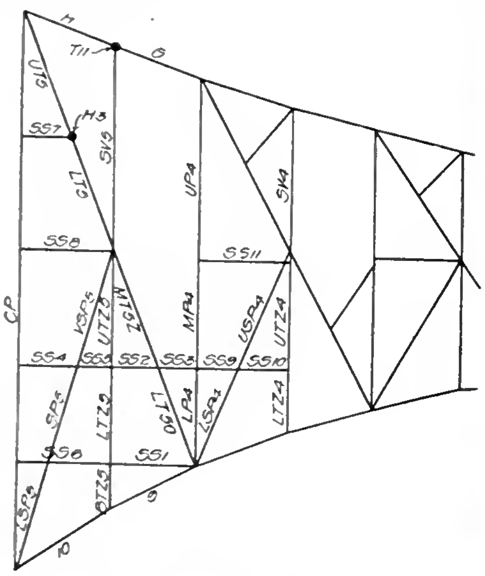
The hangers LT5Z R and L at panel point 10 were swung with single tackles attached with a 1-in. chain. All of the horizontal longitudinal struts SS, etc., were connected with temporary bolted plates permitting them to be adjusted as the panels of the truss varied during erection. The transverse struts XX, etc., were also assembled with temporarily bolted connections at one end until the main trusses came to their final adjustment.

The temporary suspension bars were removed from the river ends of the sections 10 R and L of the lower chords and the working platform on the left side of track on the cantilever of the traveler was removed. The first false-work transverse girder, 106 ft. long and weighing 108 tons, was fitted with bearing girders, chord blocks and eye-bar suspenders and swung with two wire rope tackles, HR and HL, AR and AL connected to it with a special swivelling attachment web-connected to a shoe-like device bolted to the top flanges of the girder. It was hoisted by operating the tackles HR and HL after which it was swung to one side and HL was cut loose. It was then pulled forward with tackles FR and AR and tackles HR and FR were cut loose after which tackles BL was connected to it and it was lowered to position.

Struts T6, T3, T4, T5 and T12 and diagonals T1, Too, T1 and To, all members of trussed floor beam 10, were each swung to position with two sets of manila rope tackles.

The top chord of the trussed floor beam at panel point 10, 65 ft. long and weighing 32,000 lb., was swung by a pair of 17-ton tackles MC and wire rope tackles BL and BR with a swivel connection to a horizontal beam having vertical bent plate hooks engaging the top flange of the floor beam at two points equally distant from the center. It was unloaded from the car by operating the tackle MC, drifted forward by operating tackles MDR and DL and lowered to position after the removal of the temporary track.

The two pairs of the stringers in the traveler cantilever were removed by two tackles MC and one tackle EC and were fleeted longitudinally with tackles EC and placed on cars.



Location Diagram, Cantilever Arm.

Traveler Erecting Cantilever Arm from Suspended Falsework.

Bottom laterals, diagonals N4, were lowered to position with single whip lines.

The permanent stringers were braced together in pairs at the storage yard, and one pair of railroad stringers was swung to position with two manila rope tackle EC and MC. Track was immediately laid on these stringers and cars were run out on them bringing the other stringers which were swung to position by manila tackles MC and M attached at the center of gravity.

The sub-verticals, SV5 R and L, 103 ft. 5 in. long, and each weighing 17,000 lb., were swung to position with a manila rope tackle at the lower end and two wire rope tackles WR and VL at the upper end both attached with 1-in. chains.

Lower diagonals T7, T9, T10, struts T2 and upper diagonals T8 and T9X and T10X, forming transverse bracing below sub-verticals SV5 R and L, were swung to position with single manila rope tackles.

In panels 10 of the anchor arm and cantilever arm the top chord bars were handled in three separate groups of eight each, as the space between the tops of traveler and the top chord was not quite sufficient to use the special clamps designed for the handling of the whole groups nor to fleet a group of bars over 10 ft. wide enough to clear the other twin members. In all other cases the bars were assembled in the yard and hoisted into place in one body.

The twenty-four 16-in. eye-bars in the top chord of panel H were accurately spaced and clamped together in three groups of eight bars each at the storage yard. The first outside group was swung from the cars with blocks X, MC and V and delivered to two 6-part wire rope tackle suspended from the traveler at each end of the panel with one tackle M on the overhang. The group weighing about 43,000 lb. was unloaded from the car by tackles X, MC and V suspended from the center line of the bridge and fleeted transversely into the planes of the trusses by two 6-part tackles and one 17-ton manila tackle M on each of the outside jigger beams of the traveler overhang. Tackles X, MC and V were then released and the bars were hoisted and fleeted longitudinally to position by corresponding tackles on the outside jigger beams and by the 6-part tackles at the ends of the eye-bars. The 6-part tackle at the upper end of the eye-bars was released and the bar was temporarily connected by a round timber through its pin hole. The center group of bars was swung from the cars with tackles FR and FL at the lower end and tackles X and MC at the upper end and were hoisted and fleeted to position with tackles M and a 6-part tackle suspended from the outside jigger beam. It was then drifted longitudinally to position with a 6-part tackle suspended from the outside jigger beam and a temporary pin driven as far as possible through the four holes. The third group of I-bars was swung from the cars and hoisted to position in the same way as the first group and the permanent upper pins fully driven and the temporary pin driven through the lower hole. In erection all of the bars were drifted longitudinally toward the river sufficiently to clear the main post with their upper ends and the lower ends were lifted temporarily above the top of sub-vertical post SV5. The upper ends were then drifted back longitudinally between the webs of the main post cap and the lower ends lowered to position for connection with the top of post SV5.

Top lateral diagonals L12, L13 and L14, not shown in the accompanying diagram, were swung to position with single manila tackles and the tracks and wheel stops were placed on the other stringers of the cantilever platform.

The inside vertical falsework post, 79 ft. 8 in. long and weighing 17,000 lb. each, of the first transverse bent of suspended false-work was handled by one 8-ton manila tackle X, attached with a 3/4-in. chain at the lower end and by one 10-ton manila tackle U and one 9-ton manila tackle S attached at the upper end with a 1-in. chain and after placing it into position bolted fast to the suspended transverse beam and to the truss.

The outside vertical posts of the same bent weighing 9,000 lb. each were handled by the same tackle and pulled out into position by a single tag line attached to them and rove through a snatch block on the end of an outrigger timber.

The right and left inside traveler stringers, weighing 17,000 lb. each, were swung into position with tackle M attached at the center of gravity by a 1-in. chain and fleeted into position by tackle S at the forward end and an outhaul tackle at the rear end.

The next operation was to move the traveler one panel forward until its front posts were at panel point 10 in the sixteenth position, after which the erection of the next panel of the cantilever arm was commenced with the two right and left lower chord sections, 9R and L. The number of operations for each panel was reduced to correspond with the reduction in the number of pieces. All main truss members not exceeding 140,000 lb. were erected simultaneously for both trusses, with the exception of a few

cases in which the traveler was holding up other truss members when handling these pieces.

The traveler was equipped with about 60 tackles including whip lines, all of which were operated by the eight drums and the 16 capstan heads of the four electric hoisting engines. The heaviest loads hoisted at one time were the pair of 100-ton bottom chord sections and the pair of 70-ton top chord sections simultaneously raised. All of the principal tackles were designated by numbers and signals for their operation were transmitted by the foreman to the enginemen by various gestures of the arms and head repeated a corresponding number of times. This system was so well perfected that the hoisting was done with ease and regularity and with remarkable silence, the engines running so smoothly under heavy loads that they could scarcely be heard. The work was also much facilitated by a complete telephone system connecting the superintendent's office, the traveler, the storage yard, the city of Quebec and the bridge shops at Phœnixville.

The lower cantilever working platform weighed complete about 80 tons and as already described the two pairs of stringers with their tracks were handled as separate units, each hoisted by four 8-part tackles which could remove them and place them on cars in the traveler tower in about four minutes. They were then run back to the storage yard while the permanent bridge floor was erected, after which they were returned and replaced in the traveler in its next position as already described. After the traveler had advanced to the fifth panel of the suspended traveler false-work the four vertical posts, the longitudinal girders and tracks on both sides, weighing about 40,000 lb. each, were hoisted with four 8-part tackles each in four minutes, and delivered to cars which carried them back to the storage yard until they were required for service in the next panel in advance.

The four vertical posts of the rear transverse bents were similarly hoisted, loaded on cars on the permanent bridge floor, and also sent back to the storage yard where they kept until required for use on the opposite side of the river. The suspended transverse girder was then disconnected from the lower chord pin and lowered by four 9-part tackles to a 28x100-ft. scow anchored directly below. The scow was then moved forward to a position under the fifth panel point and anchored there while the transverse beam was hoisted up and connected to the lower chord pins. Its elevation here was so near that of the track level that the vertical columns in the transverse bent were replaced by short steel blocking to receive the forward ends of the traveler track girders which were then brought back again from the storage yard and swung to position by tackles suspended from the traveler. During erection the utmost security was afforded by invariably filling every field rivet hole with a service bolt until the rivet itself was driven. Both trusses and traveler developed great rigidity and and the latter was so stable that when exposed to a wind of 55 miles per hour the upper part had an observed deflection of only 13 in.

Steel was erected in this cantilever arm with greater rapidity than it had ever before attained on cantilever erections. On Aug. 1, 1906, 410,000 lb. of steel were erected on the south cantilever arm and the maximum day's record was 340 tons when four bottom chord sections were erected for the south anchor arm. The significance of these amounts is emphasized by their comparison with the weight of an ordinary 200-ft. double track railroad bridge span which is less than the amount erected in one day on the cantilever arm with the pieces assembled in midair nearly 200 ft. above the water level.

As a matter of convenience to those who wish to study this structure, the following list of articles concerning it published in this journal is here given:

Anchorage and main piers, July 27, 1901.

Approach to anchor arm (still standing), April 11, 1903.

General methods of erection, March 4, 1905. This article illustrates the steel falsework for erecting the anchor arms and the various travelers.

The general design of the bridge—Part I, April 1; Part II, April 8, 1905. These articles outline the methods of calculation, describe the general features of the design, illustrate the anchorage and the portal bracing, and explain the chief features of the main and intermediate vertical posts, shoe and pedestal, bottom chords and eyebars.

Progress on erection of the bridge, Sept. 16, 1905. Illustrates some of the important members.

Progress on the erection of the bridge, June 23, 1906. This article contains some important illustrations giving an idea of the eye-bars and their assembly.

Suspension falsework of the cantilever arms, Sept. 21, 1907.

THE ELECTRIC TRAIN OPERATION contemplated on the Pacific Coast extension of the Chicago, Milwaukee & St. Paul Ry. will probably start near the east end of the 8,000-ft. tunnel through the Bitter Root Mountains and extend to some point west of Tekoa, Wash. Power will be furnished by developing sites along the St. Joseph River between Ferrel and North Fork, where something like 180,000 h.p. can be obtained if desired. It is understood that this power may be developed by an independent company, as in the case of the Western Pacific work, and the surplus sold at Spokane and in the Coeur d'Alene district.

The Melwood Avenue Retaining Wall, Pittsburg.

The Department of Public Works at Pittsburg, Pa., has now in course of construction on Melwood Ave., a reinforced concrete retaining wall about 220 ft. long which has a maximum height at the center of 64 ft., exclusive of the 4-ft. parapet wall. The wall spans a gulley which was formerly crossed by a timber trestle bridge. Since the street is an important thoroughfare at that end of the city, when the old timber structure decayed the problem was at once taken up of replacing it with a heavier and more permanent structure. Bids were called for on a steel viaduct and on a reinforced concrete retaining wall and resulted in the selection of the latter. The avenue runs approximately east and west and the front face of the wall forms the northern line of the street, the gulley back of it being filled in.

Briefly stated the wall consists of a reinforced concrete face and footings or floor, with reinforced counterforts at frequent intervals. The character of the grounds introduced some complications into the design of the footings and between successive counterforts hardly any two slopes of the footings are alike, the maximum being about 38 deg. parallel with the length of the wall, and about 30 deg. transversely. The footings were sloped transversely instead of being made horizontal not only to save excavation but also to save concrete. The ground consists of a layer of loose material beneath which is a bed of excellent shale on which the footings are founded.

The floor between the counterforts is 2 ft. thick, the front wall 18 in. thick through its full height and the counterforts 1 ft. thick. The concrete in the floor and the foundations consists of 1:2 ½:5 mixture and in the face wall, parapet and counterforts a 1:2:4 mixture, the sand being washed river sand, and the aggregate, gravel. The reinforced concrete portion of the wall has not been carried across the entire length of the hollow, there being a plain concrete gravity section 18 ft. long on the east end and 22 ft. long on the west end. Two vertical expansion joints have been provided at approximately the third points in the length of the wall, 74 ft. apart. These expansion joints are V-shaped and filled with three thicknesses of heavily-tarred paper.

The reinforcement consists of round rods varying in diameter from ½ to 1⅝ in., and anchored to plates imbedded in the floor and in the face of the wall by nuts and pins. These anchor plates are all ⅝ in. thick and are 8, 8½ or 11½ in. wide depending upon the height of the wall where they are used. One of these plates runs the entire length of the floor, imbedded in the latter under each counterfort and another plate is imbedded vertically in the wall in the same plane with the floor plate and the center line of the counterfort. These two plates are tied together by round rods varying in diameter from 1¼ in. at the lowest section of the wall to 1⅝ in. at the highest, their spacing and number being naturally dependent on the earth filling which they are to retain, the weight of the latter varying, of course, with the height of the section. At each end of these rods there is a forked eye and the connection is made to the plates by means of pins which after being driven are held in position by two split cotter pins. In the lowest section of the wall twelve 1-in. round rods are used, their spacing in the anchor plate imbedded in the floor being 9¼ in. on centers. From the floor anchor plates the rods spread out, the pins which connect them to the vertical anchor plates in the wall being 13 in. apart at the bottom and 41½ in. apart at the top, varying gradually between these two values. In the highest section of the wall there

are forty-two 1⅝-in. round rods imbedded in the counterfort, their connections to the floor anchor plate being 8¼ in. apart and in the wall anchor plate 10 in. at the bottom and 6 ft. 3 in. at the top, varying, as described for the lower section, between these two values. The pins used in connecting the rods to the plates vary from 1½ to 2½ in. in diameter.

The floor rods in any given sections between two adjacent counterforts are all of the same diameter, varying from nineteen 1¼-in. rods where the wall is lowest to fifty-three 1¼-in. rods where it is highest. Rods of smaller size have been used in some of the other panels and the required total section made up by using a larger number of rods. The anchor plates have three lines of holes punched in them, the upper line in the floor anchor plate being for the connection with the tie rods running through the counterfort and the other two lines for the reinforcing rods in the floors. All of the floor rods on one side of the counterfort are connected through one line of holes, the rods on the other side being connected through the other line of holes. Nuts are used on the ends of seepage water, holes have been left through the counterforts at the floor level next to the face, the total area being about 24 sq. in. Since the greatest amount of the seepage would naturally collect at the lowest point or the hollow a 15-in. tile pipe has been laid on the floor alongside of the center counterfort with Y's projecting upward every 2 ft., this pipe extending the length of the footing at this point. The water collecting between the other counterforts drains down through the openings referred to above and discharges into this 15-in. tile which has been connected below the wall to one of the city sewers. The holes through the counterforts have been made by merely inserting cores of wood which were knocked out after the concrete had set. When the wall is completed, the drainage will be further cared for by putting loose crushed stone gravel or cinders on the footings and against the back face of the wall. Two feet of this material will be placed upon the floor, 3 ft. against the back of the wall and 4 ft. over the drainage openings of the 15-in. tile pipe. When this has been placed on the footing and over the tile pipe the earth exca-

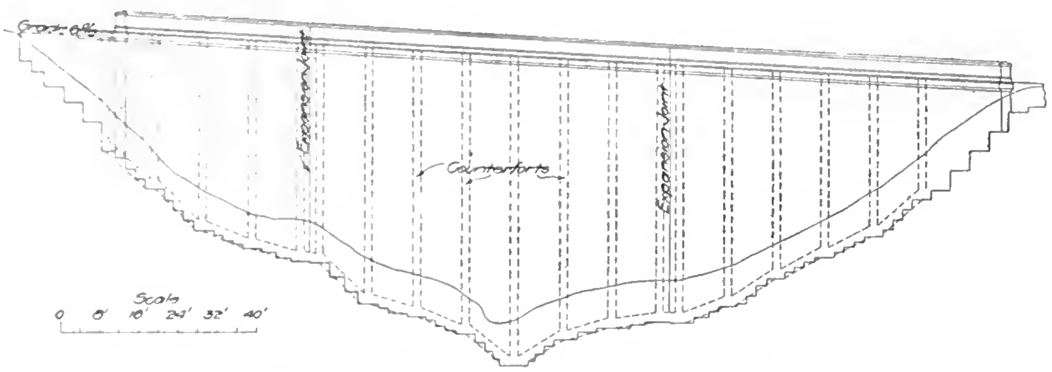
Section of Inclined Floor.



Elevation of Melwood Avenue Retaining Wall.

all of the reinforcing rods in the floor and in the wall. The length of the footings varies from 9 ft. to 29 ft. 6 in. in length, and the spacing of the reinforcing rods in them is always uniform in any given panel. All of the rods are bent downward, and though the tops of the floor anchor plates are about on a level with the floor itself the rods come within a few inches of the bottom of the concrete footings.

The reinforcing rods in the face of the wall are of the same general type as those used in the floor and are passed through the vertical anchor plates, in the planes of the counterforts, and held in place by means of nuts. Each rod spans between two adjacent counterforts. They vary in diameter from ⅞ in. at the bottom to ½ in. at the top, the spacing increasing from the bottom upward to suit the varying pressure of the earth backing. This spacing varies from 3 in. at the bottom of the highest section of the wall to 6 in. at the top of the same section. The number of reinforcing rods in the face varies from 53 in the end panels to 151 at the center.

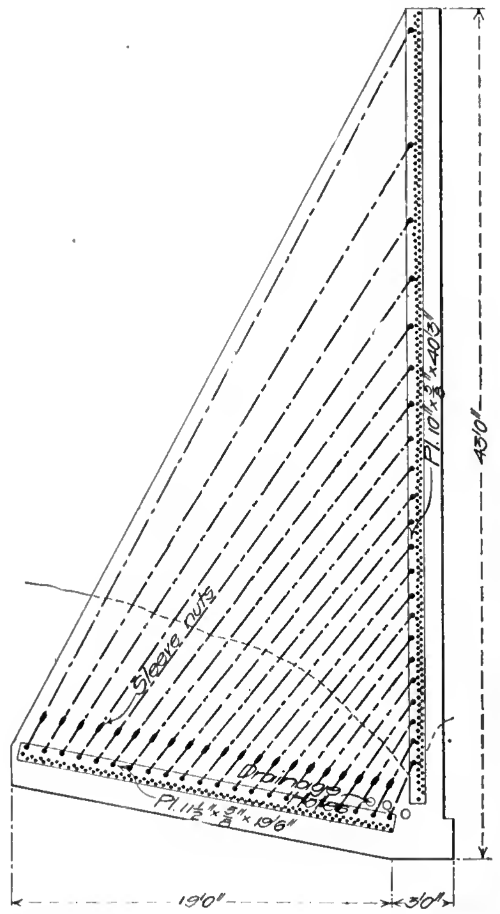
The counterforts are spaced 10 ft. apart on centers except at the two expansion joints where they are on 4 ft. centers. They are all 1 ft. wide and enclose the tie rods which connect the anchor plates in the floor and the face.

The drainage of the wall was very important because of the large run-off from the hollow across which the wall has been built. To provide for the rapid removal of the rain and vated in order to reach the solid shale foundation will be thrown over it and against the back of the wall, the entire hollow being filled up to the former street level.

The forms for the concrete work were made of 2-in. lumber dressed on one side and put together in sections. The concrete, in which Phœnix Portland cement was used, was placed in about 3-ft. courses on account of the thinness of the wall and the counterforts and the interference of the reinforcing rods. The front face of the wall was spaded and on its completion will be washed with a neat cement grout.

The materials for the concrete are all delivered at the west end of the wall and mixed on a platform at the edge of the gulley. Long-boom derricks of a combination stiff-leg and guyed type are placed in the bottom of the hollow and pick up the buckets in which the concrete is placed and handle them directly to the points where needed. These same derricks were used in making the excavation and placed the material to one side so that it can easily be picked up and used as back filling when the wall is completed.

The work is being done by the Bureau of Construction of the Department of Public Works of Pittsburg, of which Mr. Alexander B. Shepherd is Acting Director. Mr. N. S. Sprague, Assoc. M. Am. Soc. C. E., is Superintendent of the Bureau. The wall was designed by Mr. Willis Whited, Assoc. M. Am. Soc. C. E., and is being constructed under his supervision. The contractor is the Penn Bridge Co.



Reinforcement of Counterfort, Melwood Ave.

Underpinning Adjacent to the Silversmiths' Building, New York.

The Silversmith's Building, which fronts at Nos. 15, 17 and 19 Maiden Lane and at Nos. 18 and 22 John St., is a 20-story steel cage office building, with a 75x75-ft. main part reaching through from one street to the other, and two 25x75-ft. wings 12 stories and 5 stories high, respectively, one of them containing an arcade connecting the two streets. The site was previously occupied by brick buildings, with their basement floors at an average level of about 12 ft. below the highest point of the curb. As soon as these were removed an inclined plane was built with timber falsework and planking, and on it was removed the spoil provided by excavating down to a general level of 20 ft. below the curb, except under the boiler room, the floor of which was at a depth of 22 ft.

As the foundations for all but one of the adjacent old buildings were carried to a depth of more than 20 ft. below the street level, this excavation did not interfere with their stability and was made without reference to the future operations. The ground water level at the site is about 22 ft. below the curb, and the rock is covered with sand and quicksand, on which the new grillage foundations are seated at a depth of from 25 to 28 ft. below curb. As this depth was greater than that of the footings of any of the adjacent old buildings, it was necessary to provide against undermining them or causing settlement before work on the new foundations was commenced.

A 20x50 ft. plank platform at street level, supported on falsework bents set in the bottom of the excavation, was built on the south side of the lot and afforded entrance for wagons from Maiden Lane and provided for loading and unloading materials there without obstructing the narrow, crowded street. On this platform was seated a stiff-leg derrick, with a 40-ft. boom, operated by a 2-drum Lidgerwood hoisting engine, with capstan heads, which were used to swing the mast by means of an ordinary bull wheel. The cause-

way was removed, and the derrick was used for hoisting soil excavated from the pits for the foundation piers, which was shoveled into 1-yd. steel buckets and dumped in wagons driven on the working platform. Beams, girders, blocking and other supplies for the underpinning were similarly delivered to and from the excavation by the same derrick.

The two John St. wings are separated by the 5-story and basement dwelling at No. 20 John St., which is enclosed on three sides by the new building. Its exterior brick walls had footings carried down to a depth of about 17 ft. below the curb and were underpinned by new brick and concrete walls about 9 ft. deeper. The old walls were supported in the ordinary manner on needle beams made with pairs and double pairs of 12x12-in. timbers 25 ft. long, arranged two high and carried on jack screws at both ends. A line of full length timber sills and cribbing was placed across the cellar floor from end to end of the old building on the center line

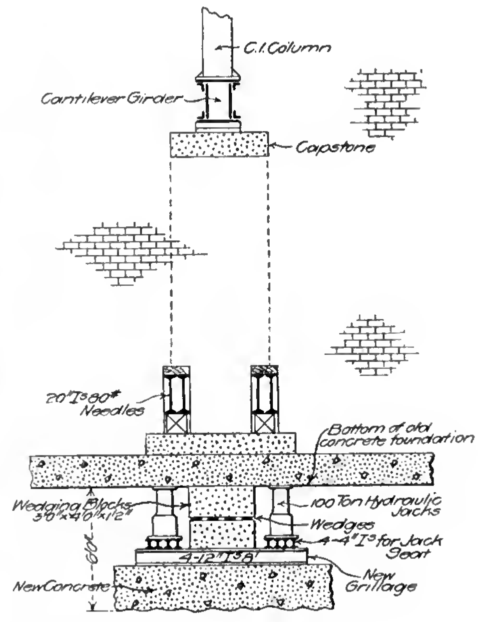
General View of Shoring.

and supported the inner ends of the row of needle beams installed for the west wall, which was the first one underpinned. The outer ends of these beams were supported on blocking, or solid timber crib work, carried down in pits below the level of the new cellar floor.

While the underpinning of this small building was in progress work was commenced on the protections of the tall buildings on both sides of the lot. The west side of the lot is bounded by a 12-story and a 15-story steel cage building, with grillage foundations for their wall columns, respectively 22 ft. 8 in. and 24 ft. 2 in. below the curb. These structures were in good condition and only required to be safeguarded against undermining through movement of the sand below the surface, due to deeper adjacent excavations. To provide against this possibility they were protected by a continuous line of United States steel sheet piles 12 ft. long, with their upper ends driven down to a level of 1 ft. above the bottom of the grillages before the new foundation excavations were commenced.

The piles were driven easily and rapidly by a 1,200-lb. hammer, with leads 28 ft. high, framed to a light portable T-shaped timber bracing like that used for driving sheet piles in the Title Guarantee & Trust Company's Building on Broadway, less than 100 ft. distant from this building and similar to the device illustrated in The Engineering Record of August 27, 1904. The hammer was made special to project beyond the face of the guide so as to work close to the plane of the wall, and with it the piles were driven 3 in. from the brickwork. The line of piles was made continuous from one street to the other, and in one case a pile soon after being started became jammed in the joint with the last driven pile and carried it down with it far below the surface of the excavation. Fortunately this occurred at a point between the two buildings, where no special external pressure was to be apprehended, and the gap thus formed in the wall was left unclosed, without any evil results. The tops of the steel sheet piles on the west side of the lot were braced by horizontal transverse 12x12-in. timbers about 10 ft. apart, abutting at one end against a ledger piece bearing across the faces of the piles and at the other end were wedged against the longitudinal sills supporting the feet of the spur piles for the side wall of the Hayes Building. The thrust of these braces against the sill was taken up by the pressure from the inclined shores and by contact of the sills against the sheeting of the crib pit for the needle beams.

On the Maiden Lane side of the lot the front wall of the sidewalk vault, being outside of the



Transferring Load to New Footing.

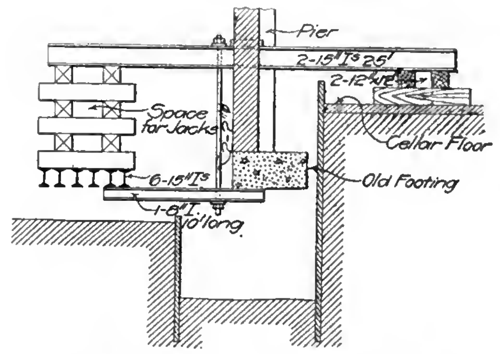
new vault line, was allowed to remain undisturbed and was secured by inclined braces against a horizontal ledger piece, while short sections of wooden sheet piles were driven below its foot to retain the earth below it when the excavation was carried to a greater depth.

On the John St. side of the lot the Cornell patent cast-iron combined curb and gutter, laid about 50 years ago, was found in a very good state of preservation and was temporarily left in service.

On the east side of the lot the John St. Building, five stories and basement in height, was supported in the usual manner on steel needle beams carried by wooden cribbing sills and timber piers, while the brick walls were carried down about 7 ft. further, or 25 ft. below the curb. On the same side of the lot the 8-story and cellar Hayes Building, at No. 21 Maiden Lane, is about 73 ft. deep and has cast-iron wall columns seated at street level on 4x4-ft and 4x5-ft. brick piers, with granite caps. The columns are enclosed in brickwork and connected by a 16-in. curtain wall extended at the base to a thickness of 4 ft. and seated on a concrete footing about 4½ ft. wide and 2 ft. thick at the height of about 22 ft. below curb level. At the beginning of operation this wall was braced with sixteen 12x12-in. inclined shores, with their upper ends gained about 12 in. into the brickwork. The lower ends were seated with wedge adjustments on a continuous line of double 12x12-in. horizontal timbers parallel to the wall and about 12 ft. from it, which was supported on a continuous grillage about 6 ft. wide of timbers. Ten of the shores were 40 ft. long and six were 25 ft. long. Three similar shores were provided to brace the exposed face of the rear wall column, to which were bolted three cast-iron lugs to receive the upper ends of the shores. The front wall of the building was braced by one 40-ft. and one 50-ft. inclined shore, with their feet outside of the sidewalk.

Opposite the 5-story building at 20 John St. pits 5 ft. wide and 8 ft. long were sheeted down about 10 ft. to a level below that of the foundation excavation, and in them were built timber crib work to support the ends of the needle beams, which carried the walls of this building and of the one at No. 24 John St. Sixteen other pits about 6 ft. square and 8 ft. deep were sheeted down to carry the crib work for other needle beams below the foundation excavation. Eight of them were located about 6 ft. apart in a row parallel with the side wall of the Hayes Building and 4 ft. in the clear away from it. These pits were sheeted with 3x10-in. tongue and groove yellow pine driven in the manner described in the recent article illustrating the work at the Murray Street Building by an Ingersoll air drill operated by steam purchased from the New York Steam Co.

At each corner of the pit the two adjacent units of sheeting were lag screwed to a 6x6x¾-in. vertical angle, which insured the alignment and water tightness of the excavation. The sheeting was braced against 4x10-in. waling pieces, and the excavation was carried down with pick and shovel as the sheeting was driven. Considerable



Suspended Support for Footing.

water was encountered, and in most of the pits it was removed by diaphragm pumps. In the deeper pits these were found inadequate, and an Edson double diaphragm pump was rigged with a walking beam and operated by a gasolene engine. Concrete footings were built in these pits and in most cases consisted of 2 ft. of 1:2½:5 hand-mixed concrete shoveled in. In some cases the water was so troublesome that it was necessary to deposit the concrete in bags, one of which was placed as fast as each shovelful of earth was removed. In each pit a 5x5-ft. pier of solid 12x12-in. yellow pine timbers was built up from the concrete footings to about the level of the top of the footing of the wall of the Hayes Building and supported a continuous line of longitudinal stringers 5 ft. in the clear from the wall, which was composed of six parallel 15-in. 60-lb. I-beams. These stringers supported the outer ends of 17 needle beams, each of them composed of 20-in. 80-lb. I-beams 25 ft long, with their inner ends resting on longitudinal double 12x12-in. continuous timbers about 5 ft. in the clear from the wall, which were laid on a continuous grillage 6 ft. wide of transverse 12-in. timbers laid on the cellar floor. Special needle beams were used at the corners of the building; all of the intermediate ones consisted of two I-beams each and were supported by one 10-ton jackscrew under each end of each I-beam, making four for each regular needle. These were set so that the I-beams had a clear span of 14 ft. between the

inner jackscrews and were calculated to have a maximum load of 50 tons each.

The cast-iron wall columns of the Hayes Building, being eccentric from their piers, are seated on cantilever girders, which have rocker bearing on cast-iron pedestals seated on capstones built into the solid brick work of the pier integral with the wall several feet above the old concrete footings. These footings were in such good condition that it required over 150 hours' work to trim a length of about 10 lin. ft. that had been partly broken away by accident. It was therefore decided, both for economy of material and more especially for the greater rapidity, to retain the old footings and build the new foundations about 6 ft. high under them. Two sets of needle beams were accordingly inserted through the old wall directly under the pedestal supporting each column and at a height just sufficient to give a working clearance over the old concrete footings.

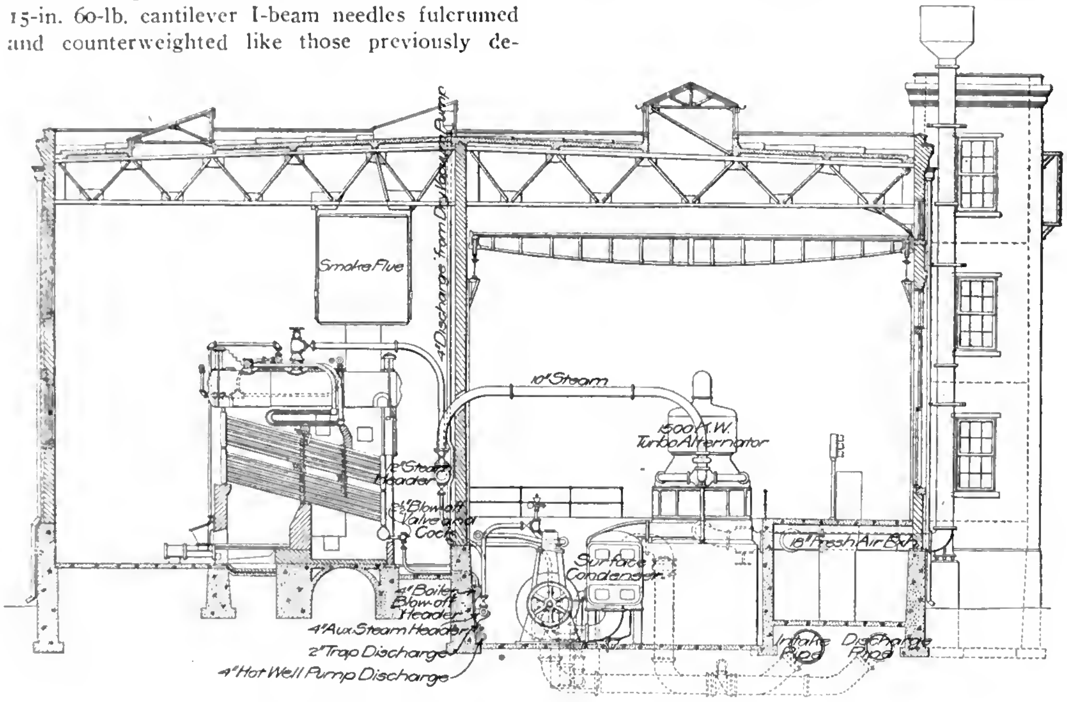
A steel bearing plate was seated across the top flanges of each pair of I-beams and gave bearing for the nuts on the upper ends of two 2-in. vertical rods about 7 ft. long. The nuts on the lower ends of these rods engaged a cross plate or saddle, forming a fulcrum for an 8-in. horizontal cantilever I-beam 10 ft. long. The long arms of the cantilever reacted upward against some of the I-beam stringers supporting the outer ends of the needle beams. The short arms took bearings about 2 ft. long on the under side of the old concrete footing, supporting it across the thickness of the wall, so that when undermined by the excavation for the new foundation the old footing looked in cross sections like a cantilever projecting about 2 ft. beyond the inner face of the wall and proved strong enough to resist the bending moment thus developed. The wall columns were about 9 ft. apart and the footing was divided in sections of corresponding length, which were alternately supported, undermined and underpinned, and were transferred to the new footings before work on the adjacent sections was commenced.

The new concrete footings were built in alternate sections 9 ft. long, excavated on the centers of the wall columns. The upper surface of the new footing was leveled off about 3½ ft. below the lower surface of the old footing, and on it on the center of each column was set a grillage of four 12-in. longitudinal I-beams 8 ft. long thoroughly bolted together with separators and concreted. In the middle of each footing was set a pair of 3x4-ft. cut granite blocks, 14 in. thick, separated by pairs of thin steel wedges. On each end of the grillage four transverse 4-in. I-beams were placed to form a seat for a 100-ton hydraulic jack reacting against the bottom of the old foundation.

As the jacks were operated the wedges were driven to maintain solid bearing between the old and new footings, with the granite blocks on the column center and thus prevented the possibility of displacement or injury to the wall from any failure of the jacks. The entire weight of wall and column was thus transferred to the new foundation, and the latter was rapidly forced to final bearing, so that no further settlement took place when the jacks were removed. By this method it is probable that excessive proportions of the loads were temporarily concentrated on each section of the footing, thus fully testing them and compressing the soil in excess of working stress and insuring against future settlement. After the jacks were removed additional pairs of wedging blocks were inserted in the positions vacated by them, and the remaining spaces between the old and new footings were closed in the usual manner.

Where the columns were placed close together no intermediate needle beams were required between their piers, but where the space was greater it was sub-divided by pairs of intermediate needle beams. The loads on the intermediate column piers were assumed at 200 tons each, but at the Maiden Lane end of the wall the pier at the corner of the building carries part of the front of the building and has an estimated load of about 300 tons. It was, therefore, carried by two regular needles, together containing four I-beams, and by one special needle, containing four more I-beams, making eight in all.

At the other end of the wall there is, adjacent to the corner pier, a 3x3-ft. pier, carrying a 24-in. iron smokestack 100 ft. high, with an estimated weight of about 6 tons. This was supported during underpinning by a single cantilever needle beam made with one 12x12-in. yellow pine timber, 25 ft. long, fulcrumed on the I-beam sills, which support the outer ends of the regular needle beams and counterweighted at the extremity of the 25-ft. long arm by a 1-yd. steel bucket filled with earth. Beyond this smokestack there is a short length of 12-in. 2-story brick wall, which during underpinning was supported by two 15-in. 60-lb. cantilever I-beam needles fulcrumed and counterweighted like those previously described. The end of this wall intersects a 20-in. cross wall, supported at the corner by an oblique cantilever needle beam made with a single 12x12-in. yellow pine timber 25 ft. long, fulcrumed on the last mentioned cantilever needle beam and anchored at the outer end by a wire cable attached to the blocking under the regular needle ebam. The jackscrews were operated to give all of the needle beams a deflection of about ¼ in. at the center and carry the full weight of the wall without causing any appreciable displacement. The old footings were then removed, the trench dug down to a depth of 1 ft. below the deepest point of the new foundations and the new footings and brickwork above them built and the weight of the old wall transferred to them in the usual manner. Careful levels were taken on a bench mark on the opposite side of the street, and repeated observations were made, which failed to show any settlement of the old walls during or after the underpinning process.



Cross-Sectional Elevation of Whitewood Station.

Nearly the full width of the Maiden Lane front of the Hayes Building is occupied by three large openings for the main entrance and wide show windows. One of these is spanned by a very flat stone arch, with the skewbacks built into the corner pier of the building very close to the underpinned side walls. To avoid the possibility of displacement of these side walls during the above described operations a pair of long inclined 12x12-in. timbers were wedged against the face of the side wall opposite the skewback of this arch, and their feet were made to engage the vault retaining wall just below sidewalk level. A similar pair of horizontal timbers were wedged against the wall at first floor level, and the two sets were united by vertical and diagonal bracing planks spiked on to them, making a sort of truss and thoroughly providing against any possibility of movement due to the thrust of the arch. As these timbers required wedging again after the work was commenced, it was assumed that they did not actually receive much stress and that their use was a precaution which might have been safely omitted.

Excavation below the cellar floor of the old building was commenced July 4, 1907, the underpinning contract was awarded July 12, and work on it was commenced the same day and carried on night and day, with two gangs of about 20 men each. On August 1 the underpinnings of the buildings at No. 20 and at 24 John St. were completed, the first pier was built in its pit on August 8, and on August 24 the underpinning of the Hayes Building was substantially finished and the work practically completed.

Clinton & Russell are the architects of the building, and the general contractor is the A. J. Robertson Co., Mr. L. H. Whitenack, superintendent in charge. The contract for underpinning was awarded to Miller, Daybill & Co. and was executed under the personal supervision of Mr. Alfred Daybill.

Patented Pavements were the subject of a recent decision of the Louisiana Supreme Court in Lacoste v. City of New Orleans, 44 S. Rep. 267. The court's syllabus of the decision is as follows: The fact that a pavement is patented is no obstacle to full and fair competition upon a municipal contract for the laying of it, when the patentee has filed with the city authorities an agreement to let the successful competitor for the contract have the free use of the patent upon payment of a fixed royalty, thereby placing all prospective competitors upon an equal footing; it appearing that the royalty thus exacted was reasonable, and did not destroy the margin of profit under the contract. It is no answer to say that the patentee can underbid his competitors for the contract. To him, as to the other bidders, the sole inducement for bidding on the contract is the margin of profit which he sees in it, and for him, as for all others, this margin of profit begins only after the royalty has been paid.

A Central Power Station in the Whitewood, S. D., Mining District.

The generating station of the Consolidated Power & Light Co. of Deadwood, S. D., has been built to supply electric current for power in the mines and mills in its vicinity, and for lighting in Deadwood, Lead and several smaller mining camps. This company was organized as a consolidation of the Belt Light & Power Co., and the Deadwood Electric Light Co. The station of the former company was at Pluma, midway between Deadwood and Lead, on Whitewood Creek and the Burlington R. R. This station was so favorably located that the decision was made to reconstruct and enlarge it according to the best practice, and to abandon the Deadwood station.

The station building as reconstructed and enlarged is 88 ft. wide and has an extreme length of 136 ft., as shown in the accompanying general plan. It is divided by a longitudinal brick wall into a boiler room, 40 ft. wide, and a generator room, 44.5 ft. wide. The original station contained two 200-kw. DeLavel turbo-generator units which were supplied with steam by three 200 h.-p. Freeman Scotch boilers. These generators and boilers have been left in their original position in the old part of the building, but have not been in service since the new equipment was installed.

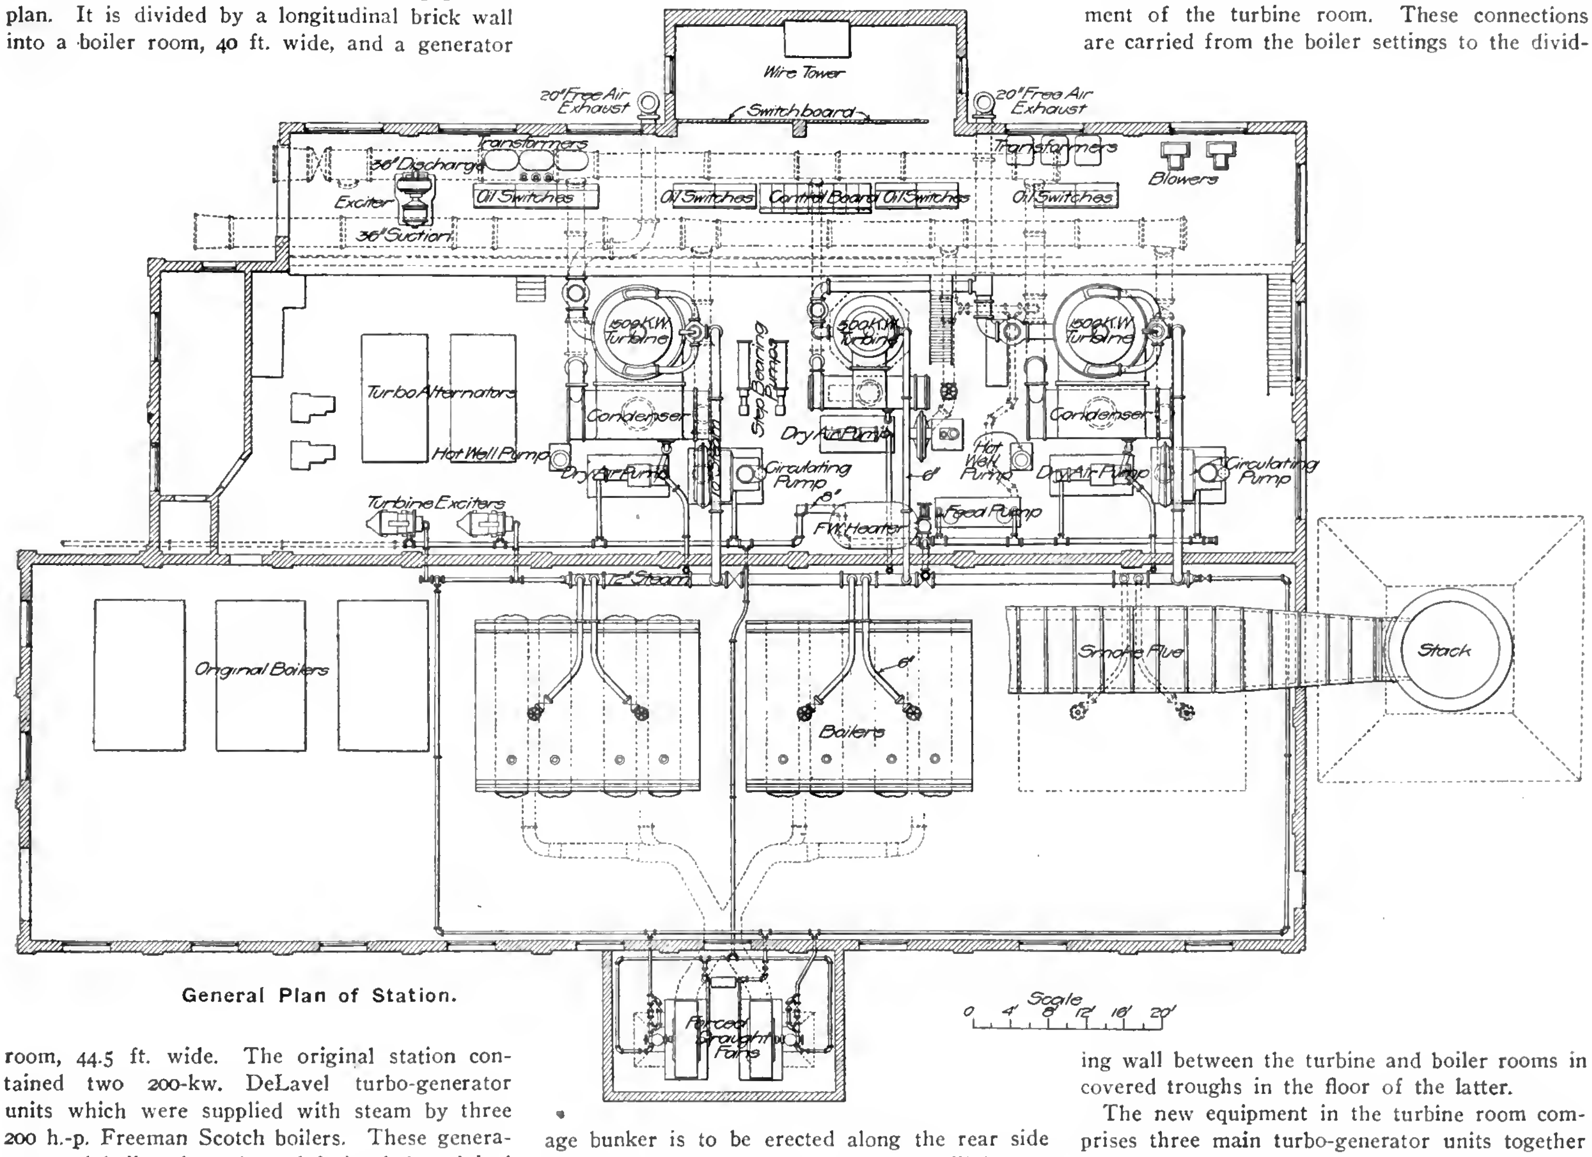
The boiler room contains four new Babcock & Wilcox boilers, arranged in two batteries, with space at the end of the row for two additional boilers. These boilers each have 3,500 sq. ft. of heating surface and are equipped with superheaters capable of raising the steam temperature 100° Fahr. above that of saturated steam. The furnace of each boiler is equipped with a Jones underfeed stoker, the forced draft used with the stokers being furnished by two American Blower Co. 120-in. blowers, either of which has sufficient capacity to supply draft to all four furnaces. These blowers and the two engines driving them are placed in a small separate room at the rear of the boiler room. The stoker rams are operated by steam in the usual manner, the automatic device controlling the supply of steam being driven by either of the blower engines. The speed of the latter is controlled by a Foster regulating valve arranged in such manner that the coal and air supply are varied automatically, so the boiler pressure is maintained constant within certain limits.

Wyoming lignite containing about 11,000 B. t. u. per pound when dry, is burned under the boilers; as this lignite is used at present, however, it contains approximately 20 per cent. of moisture. A temporary coal-handling arrangement is employed, pending the installation of a proposed coal-handling system. Coal is delivered one end of the building at present and then hauled into the boiler room and stored on the firing floor, from which it is supplied to the stokers by hand. A large structural steel storage bunker is to be erected along the rear side of the boiler room. A switch track will be extended over this bunker, in order that coal may be dumped into the latter from the cars. Chutes will lead from the bunker directly to the charging hoppers of the stokers, thus permitting the latter to be fed by gravity throughout.

Feed water is supplied to the boilers through duplicate feed lines by either of two vertical marine-type single-cylinder Dean Bros. boiler-feed pumps, either of which has sufficient capacity to furnish water to all four boilers under any operating conditions. These pumps draw from an open-exhaust Stillwell feed-water heater in the turbine room to which water is pumped from a hot-well in the basement of the generator room. Make-up water is supplied automatically by a low-service Blake pump from a circulating system for condensers in the turbine room. A float-regulated valve in the discharge of this pump actuates a Fisher governor which controls the operation of this pump. The main units in the turbine room are all operated condensing, the water of condensation passing to the hot well. The auxiliary steam-consuming units in the station are all run non-condensing, their exhaust being carried to the feed-water heater.

The boilers each have a 6-in. connection with a 12-in. steam header along the wall in the rear of their settings. These connections are each equipped at the boiler with a stop and a check valve. The header is divided in three parts, one for each pair of boilers, by stop valves. Each of these three parts is connected with a 4-in. auxiliary steam header in the basement of the turbine room, forming a ring system which enables the main units in that room to be supplied with steam under practically any conditions.

The mud drum of each boiler has two connections with a 4½-in. blow-off header in the basement of the turbine room. These connections are carried from the boiler settings to the dividing wall between the turbine and boiler rooms in covered troughs in the floor of the latter.

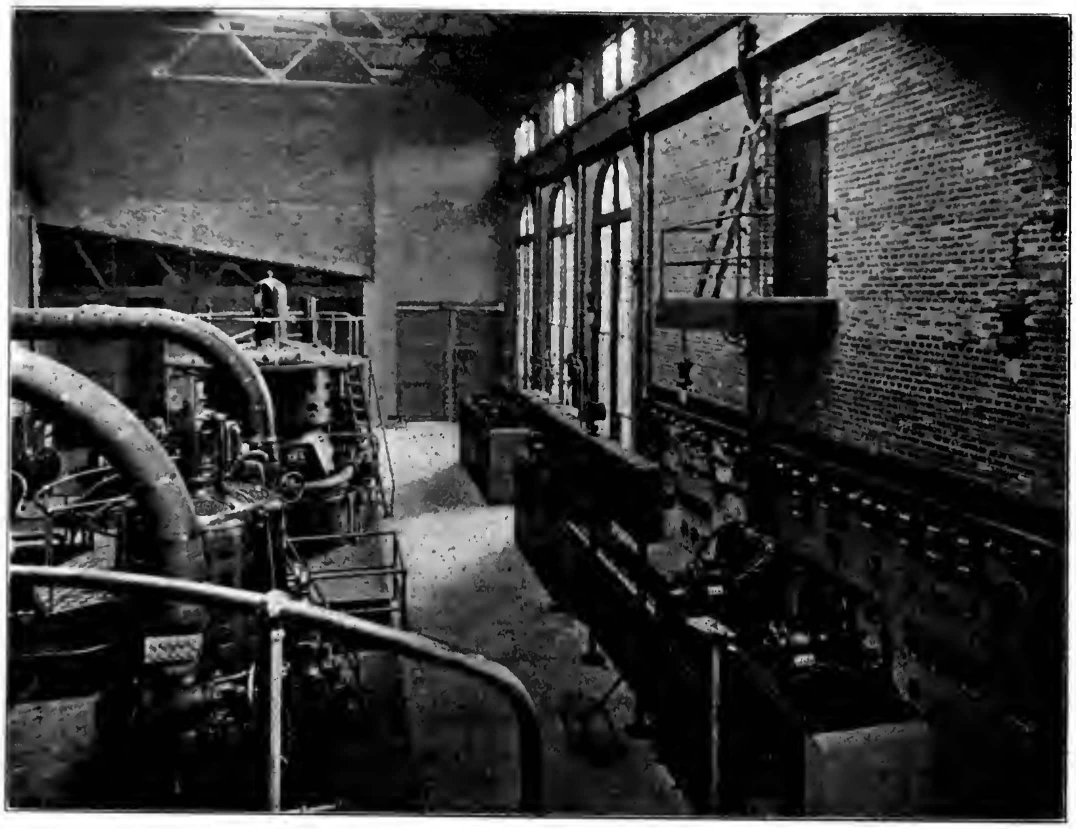


General Plan of Station.

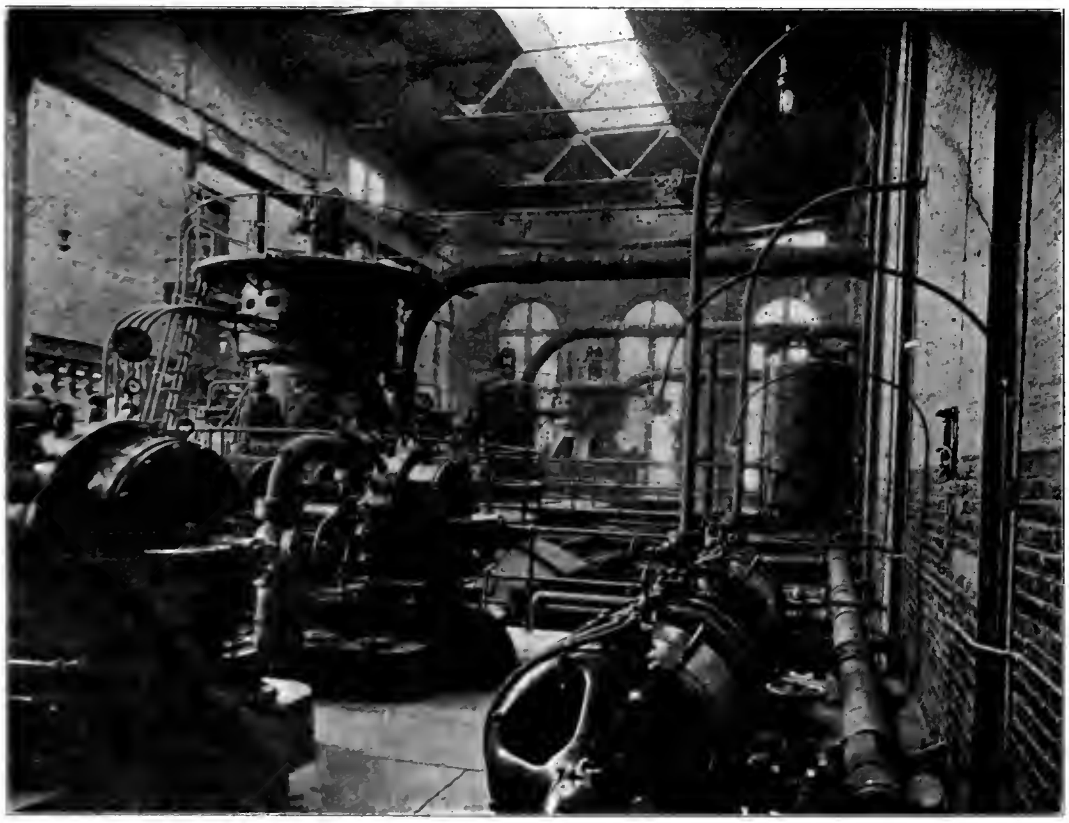
The new equipment in the turbine room comprises three main turbo-generator units together with their necessary auxiliary apparatus. One of these units is a 500-kw. 2,300-volt 60-cycle three-phase General Electric generator, direct-connected to a four-stage Curtis turbine, with water supported step bearings. The other two units each have a 1,500-kw. 11,000-volt 60-cycle three-phase General Electric generator direct-connected to a four-stage Curtis turbine; the turbines of these units also have water-supported bearings. The 500-kw. unit has a Wheeler admiralty condenser with 2,000 sq. ft. of surface, equipped with a 6x14x10-in. dry-air pump and a 10-in. steam-driven horizontal-suction centrifugal pump for circulating cooling water. The two large units also have condensers of the same type, with 6,000 sq. ft. of cooling surface, which are each served by an 8x18x12-in. dry-air pump and an 18-in. steam-driven horizontal-suction centrifugal pump for the cooling water. The exhausts of all three

units are connected to risers extending above the roof of the building where they are fitted with Wright exhaust heads. A 42-in. reinforced-concrete conduit extends from the channel of Whitewood Creek, which is about 200 ft. from the station building, to the latter and is continued into the building as a 30-in. main from which the circulating pumps take suction. The cooling water is discharged from the condensers into a second 30-in. main beneath the floor of the basement of the turbine room; this main terminates at the building line in a second 42-in. reinforced-concrete conduit leading back to the creek.

Owing to a scarcity of water in the creek at certain seasons, a dam has been erected across the channel of the latter, and a specially devised cooling system has been added to the end of the discharge conduit. This cooling system is only used when there is an insufficient quantity of water coming down the creek. It consists essentially of a manifold of standard hub-and-spigot cast-iron pipe, ranging from 24 in. to 16 in. in diameter, with special crosses having 5-in. flanged outlets for lateral pipes fitted with a series of sixty 3-in. Schutte spray nozzles. The manifold pipe is carried by concrete piers; the lateral pipes are each supported at the middle by a truss rod equipped with a turnbuckle and attached to a strut on the manifold. This arrangement has entirely prevented vibration. The laterals are made up of 5-in. and 3-in. pipe, with a total length of 22.5 ft. from the center of the manifold to the center of the outer nozzle, two of which are carried by each lateral. The nozzles are spaced 15 ft. apart on centers in all directions. Each nozzle is designed to spray 9,000 gal. of water an hour under a pressure of 12 to 15 lb. per square inch, but two valves in the manifold permit part of the nozzles to be cut out of service machine direct-connected to a 75 h.-p. three-phase 2,300-volt induction motor. The steam-driven exciters are against the rear wall of the turbine room; the motor-driven exciter is on a concrete platform at the front side of that room and level with the floor of the latter.



Switches and Switchboards in Turbine Room.



Three Main Units in Turbine Room.

The complete distribution of the spray by this method is shown in one of the illustrations. The dry air of the locality causes sufficient evaporation from the spray to cool the water satisfactorily.

Three exciter units for the main generators are provided. Two of these each have a 25-kw. 125-volt direct-current generator driven by a steam turbine. The third is a 60-kw. 125-volt

The switches, transformers and so forth are on the concrete platform along the front side of the generator room. Two switchboards are provided, one for the 2,300-volt circuits and the other for 11,000-volt. Three single-phase 2,300-volt lines are carried from the 2,300-volt board to Deadwood and three to Lead for commercial lighting. Two circuits for street arcs are also carried to Lead, and one to Deadwood from this board. The exciters are also controlled from the latter.

The two 1,500-kw. units and the 11,000-volt transmission lines are equipped with motor-operated three-phase oil switches. These motors are controlled from the second switchboard by the remote control system can be operated at voltages from 70 to 150 volts, the current being obtained from the exciter units. The transmission line switches can also be operated by hand in an emergency.

The 11,000-volt bus bars are in separate brick and concrete compartments in the space under the concrete platform carrying the oil-switches and transformers. The generators are connected to the ends of the bus bars, and disconnecting switches are provided in the latter between the generators and the circuits leads which are taken off from the middle portion of the buses. Disconnecting switches are also placed between each motor-operated oil switch and the bus bars for safety during repairs and cleaning.

Two banks of transformers are arranged between the two switchboards, in order that current may be taken from either one to the other. One set consists of three 100-kw. oil-cooled type, and the other of three 185-kw. air-blast type.

A fireproof brick tower, 10x30 ft. in plan and three stories in height, is provided on the front side of the building for all transmission lines leaving the station. The 2,300-volt switchboard is placed in an opening in the building side of the first story of this tower, and together with its connections and equipment occupies most of that story although very ample room for reaching the back of this board is available. Current regulating transformers for the 2,300-volt lighting transmission lines occupy the second floor, and lightning arresters, choke coils and so forth, the third. The 2,300-volt lines in the tower are oiled-cambric insulated cable; the 11,000-volt lines are bare wire in separate brick cells and on 20,000-volt insulators.

The 2,300-volt transmission lines to Deadwood and to Lead are both 1½-miles long. The 11,000-volt lines extend to various mining camps within a radius of 10 miles of the station. None of these lines embodies any special features of construction.

Mr. N. E. Franklin is vice-president and treasurer, Mr. J. W. Springer, manager, and Mr. J. H. Fuller, engineer, for the Consolidated Light & Power Co. Messrs. Sargent & Lundy, of Chicago, are consulting engineers for that company and were represented during the construction of the station by Mr. H. Boyd Brydon, to whom this journal is indebted for the information from which the foregoing notes were prepared. The extensive piping work in connection with the station was done by Mr. W. H. Pope, of Chicago.

The Spraying System of the Whitewood Power Plant in Full Operation and under Light Pressure.

Continuity in Reinforced Concrete Beams and Slabs.

The question of rejecting or recognizing continuity in the design of reinforced concrete slabs and beams is one of the disputed features of such work that will probably not be settled for a long time. The continuity is necessarily assumed when it is assumed that beam and not arch action takes place. This assumption is generally considered to be correct except where the ratio of depth to span is great, but it is possible that more attention will be given to arch action when experiments have become more numerous and comprehensive. The subject was discussed by Prof. Lewis J. Johnson of Harvard University at a meeting of the Boston Society of Civil Engineers some time ago, and the necessity of providing for continuous beam action was strongly urged in his remarks. Slabs, beams and girders are continuous beams as built, and for better or for worse will act as continuous beams, in his opinion, if they act as beams at all. Objection to recognizing this fact in design seems to be based upon the supposition that designing beams as continuous would lead to mid-span sections good only for positive bending moments of about $1/40\ wl^2$, a figure which would be nearly correct for a load distributed uniformly over all spans at once, but would be fatally in error in the case of the far more probable instances of unequally distributed load.

Objection of a similar sort is applicable to design upon the basis of discontinuity, where ultra cautious design for a mid-span bending moment of $\frac{1}{8}\ wl^2$ is accompanied by a more or less complete ignoring of the negative bending moment of the supports. The assumption of simple beam action may thus prompt serious error on the side of danger quite as certainly as similarly improper application of the assumption of continuous action. That trouble from this source has not been more abundant Prof. Johnson believes to be due partly at least to the undoubtedly considerable tensile strength of the concrete in the wings of T-section beams and girders. But if it is not safe to count on tensile strength of concrete elsewhere, it is not safe to count on it here, he holds.

The logical course to pursue, he states, is to recognize that, if the action present is beam action at all, it is continuous beam action, and to design accordingly. This means careful attention to the extreme values of the flexures at supports as well as at mid-spans due to all possible distributions of the live load. The end sections are then designed to meet these extreme conditions, and so are the mid-span sections. This is standard practice among the Germans and Swiss. Of course in applying this method, as in any careful design, attention will be given to all important facts, such as stair or elevator wells interrupting the continuity in places; and in cases of doubt, assumptions unmistakably on the side of safety will, of course, be made.

The labor involved in these computations is not so great as it would seem. As a matter of fact, the extreme conditions under uniformly distributed live load will almost always be covered in case of a series of beams and slabs of equal spans by designing for a live load flexure of $1/10\ wl^2$ (l being measured from center to center of supports) at the faces of columns and girders, and the same amount at mid-spans; and this, too, regardless of the number of spans in the line. At the column faces flexure would be negative and at mid-spans positive, and in both cases would, of course, be combined with the dead load flexures. If the spans are short and the live loads large in comparison to the dead, top reinforcement may be required at mid-span to provide for resultant negative flexures there existent. The similar extreme values for girders subject to concentrated loads have not been so well established, but the need of them is recognized and it is hoped that they may be forthcoming soon.

If a designer prefer, let him use $\frac{1}{8}\ wl^2$ at the mid-span section, but let him not fail to provide fully for the bending at the faces of the supports, Prof. Johnson advises. He must not overlook the fact that top reinforcement is as logical a requirement as bottom reinforcement at mid-span. Moreover there is additional justification for top reinforcement in that it is of the greatest possible value in case of weakening of bottom rods by fire. The top rods through cantilever action may carry the load after the lower rods, in the far more exposed position of the two, have failed. In fact, top reinforcement does not seem to have had the attention which its merits from the fireproofing standpoint would seem to entitle it.

It may be objected that continuous beam coefficients based upon the assumption of unvarying moment of inertia may be inapplicable to reinforced concrete beams. This is certainly a fair field for research, but Prof. Johnson believes that the practitioner may well proceed for the present with his $1/10\ wl^2$, taking comfort from realizing that the negative bending moment over supports would not rise above $\frac{1}{8}\ wl^2$ even in the extreme case when the moment of inertia becomes zero at mid-span, the case of two abutting disconnected cantilevers, most unlikely to occur. The error in the $1/10\ wl^2$, if any exist, must be extremely small and unimportant.

For beams under a uniformly distributed load, the top steel at the column faces and through the column may or may not be the same in amount as at mid-span, depending upon the relative depth of the beam at the two points, but Professor Johnson sees no escape from the belief that the negative moment of resistance at the column face should be as large as the positive moment of resistance at mid-span. If, as is usual, floors are figured with T-sections, this may call for the German practice of materially deepening the stems at, and for considerable distances each way from, the supports, to make up for the absence of flanges on what is here the compression side of the beam.

This leads to brackets at connections of girders to columns and of beams to girders. These brackets complicate the forms and are sometimes unsightly. They can be obviated by making the depth of stem at mid-span as great as required at the column faces, proportioning the bottom steel accordingly. This interferes with headroom and adds to the quantity of concrete required. It may in some cases be practicable to diminish this depth by the use of steel reinforcement in the compression lower side of the beam at the support. Though this latter reinforcement would also be effective and necessary reinforcement from the arch point of view, the brackets will in many cases be preferred to either of these alternatives.

Even if all these considerations are kept in mind, continuous beam action is unavoidable, according to Prof. Johnson. It must be reckoned with and properly provided for in all reputable reinforced concrete practice, he asserts, for there must be no departure from the principle of providing at all points of a structure for the most unfavorable conditions it is reasonable to expect. Moreover, it will not do to assume that we err on the side of safety when we ignore continuous beam action.

An Extensive Wireless Telegraph System has been installed by the United Fruit Co. on its fruit steamers and at numerous points on the Gulf of Mexico and the Caribbean Sea, for communication between the offices, steamers in transit, and its plantations in Central America and the West Indies. A station was recently added at San Antonio at the extreme western end of Cuba.

Experiments With Submerged Tubes 4 Ft. Square.

By C. B. Stewart, in Charge of Hydraulic Research Work, University of Wisconsin.

The recent construction of large works in connection with the various lines of Hydraulic Engineering has emphasized the need of further experimental knowledge concerning the losses of head resulting from various forms of resistances interposed in flowing streams of considerable size. The loss of head resulting from the flow of water through submerged gates, tubes and orifices of considerable size and with various forms of entrance is one of the most important divisions of the general subject which needs experimental investigation. Practically the only reliable experimental data available concerning the flow of water through large orifices are given in a valuable paper by Mr. Theodore G. Ellis, entitled "Description and Results of Hydraulic Experiments with large Apertures at Holyoke, Massachusetts," and printed in the "Transactions" of the American Society of Civil Engineers for 1875. Mr. Ellis determined the loss of head for flow through apertures the dimensions of which were 2 ft. square and 1 x 2-ft. when discharging freely into the atmosphere, and also made a very few experiments on the loss of head for flow through submerged apertures 1 ft. square and 1 ft. in diameter under heads from 2 ft. to 15 ft. In nearly all the experiments of Mr. Ellis, the thickness of the edge of the aperture remained constant, about ½ in. for wood and ¼ in. for iron, and perfect contractions of the emerging stream were supposed to take place on all sides of the aperture. In the single case of the aperture 1 ft. square, the entrance was subsequently modified so as to have a curved approach on all four sides, and the resulting coefficients of discharge were determined.

In the experiments at the University of Wisconsin described in the present paper, the cross-section of the orifice or tube has been kept constant, being 4 ft. square, and the effects of changing the length of the tube and of modifying the entrance conditions by curved approaches on one, two, three and four sides respectively, for each of the various lengths, has been studied.

In future experiments on this subject at the University, it is planned to determine the coefficient of discharge for submerged tubes and orifices of various forms and areas of cross-section, with and without entrance modifications. It is hoped that the results of the experiments when completed will fairly cover the field of investigation laid out and be of material aid to the engineering profession.

The experiments were made at the new hydraulic laboratory at the University of Wisconsin (Engineering Record, April 21, 1906), which is located on the shore of Lake Mendota and furnishes an abundant supply of fresh water. Exceptional facilities were afforded for experiments on a large scale, and care was taken that errors of observation should be reduced to as small a percentage as possible. The accompanying plan of the laboratory shows the main features and arrangement for the experiments. The water was taken from the lake by a suitable inlet and raised about 12 ft. by means of a 30-in. Morris centrifugal pump, and delivered into a receiving basin which measures about 15 x 18 x 10 ft. deep. From the receiving basin the water flows through a flume 10 ft. wide, 10 ft. deep and about 68 ft. long, and may be used for operating a 30-in. turbine located at the end of the flume or may be wasted through gates underneath the turbine. The water flows back to the lake through a tail race 10 ft. wide, as shown. At the outlet end of the tail race is a sharp crested weir with end contractions suppressed and a crest 10 ft. long.

Suitable baffle boards were inserted in the receiving basin and at the entrance to the flume until it was found by trial that the water in the flume flowed in lines practically parallel to the sides of the flume.

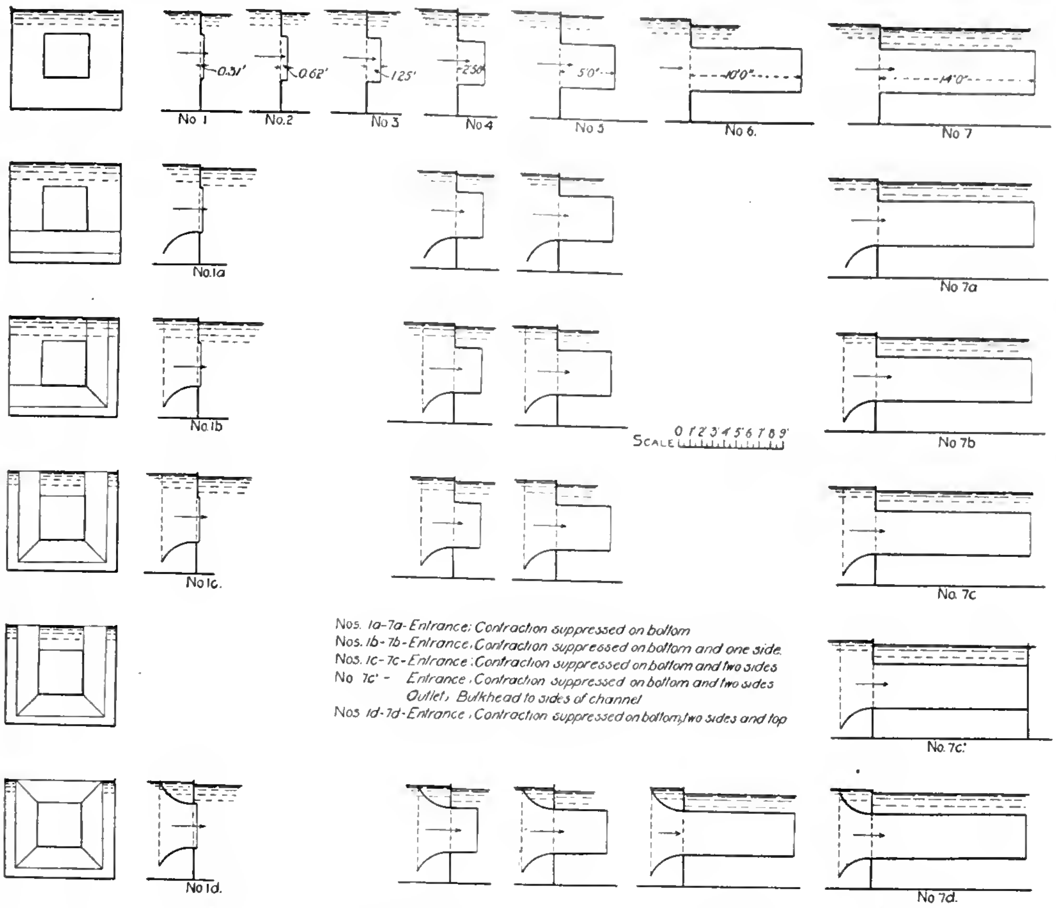
Details of Tubes with Suppressed Contractions.



Sections of Tubes Showing Forms of Entrances and Lengths.

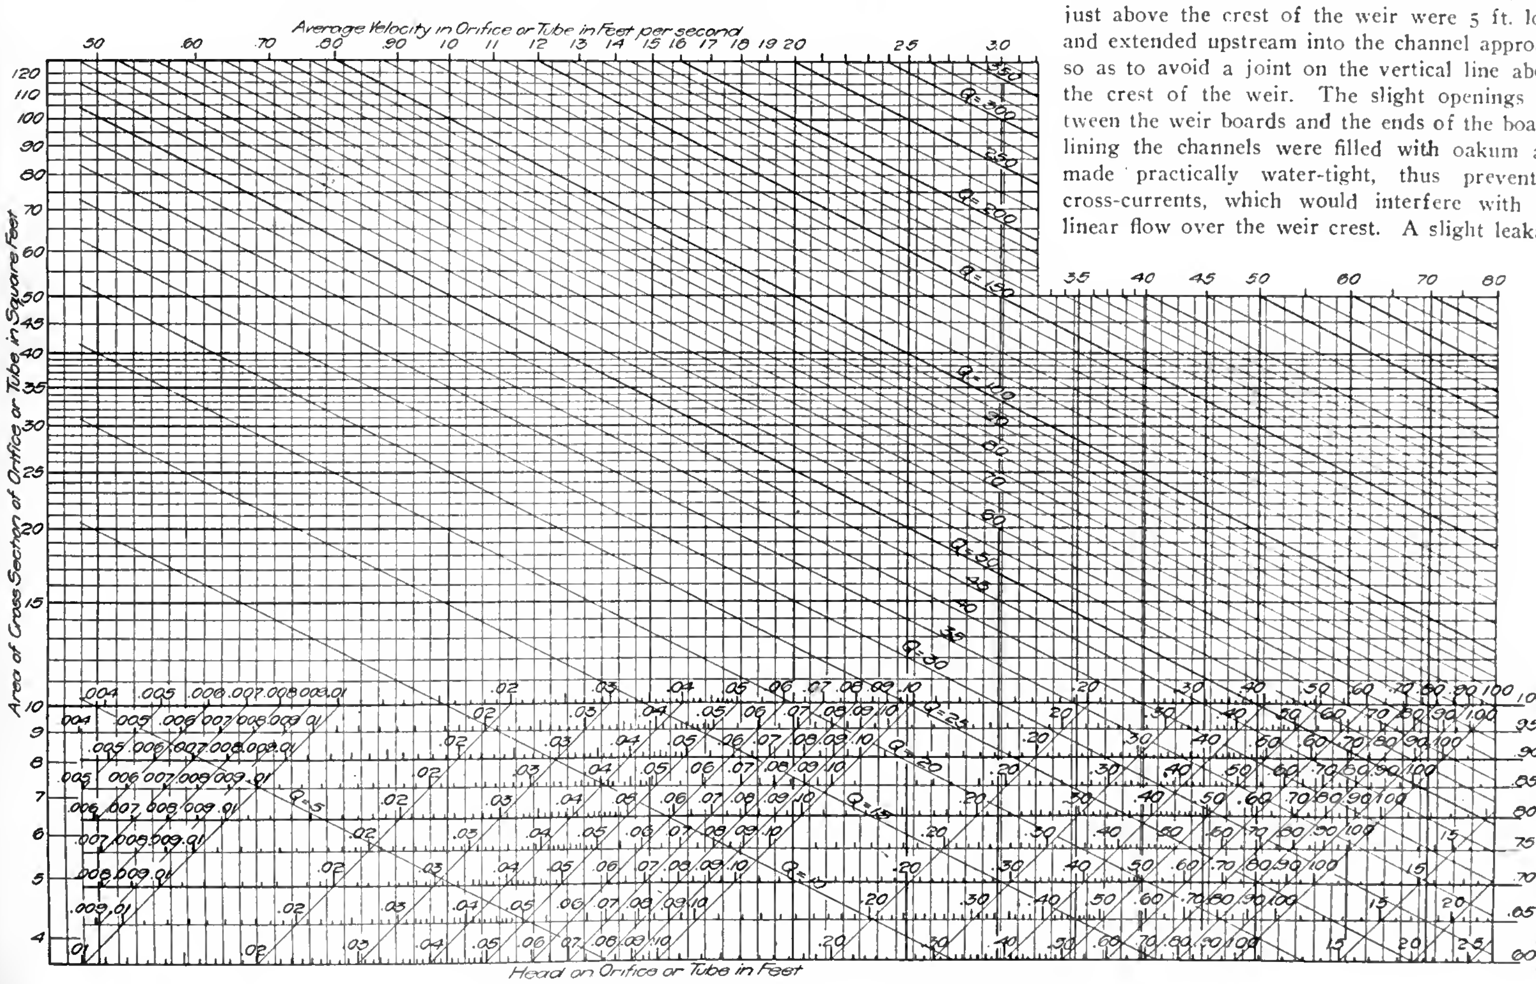


Diagram Giving Discharge Q for Submerged Tubes.

The bulkhead containing the tube experimented with was located about 24 ft. from the entrance to the flume.

The facilities for making a volumetric calibration of a weir whose length of crest is 10 ft. were not available, so the expedient of dividing the 10-ft. channel into three similar channels, each having a length of about 15 ft., and with a sharp-crested weir at the end of each channel, was used. In order to form a variable height of water surface on the downstream side of the bulkhead containing the submerged tube, the three sharp-crested weirs were made adjustable in height. The main feature of the weirs consisted of a fixed bulkhead, extending about 5 ft. above the bottom of the channel and a movable gate above the bulkhead, extending the full width of the 10 ft. channel and capable of being raised or lowered by means of two hand wheels, one on each side of the channel. The crest of the three weirs was made of a single plate of 6 x 3/16-in. wrought iron, bolted to the upper edge of the movable timber gate and beveled on the downstream side of the top edge to a thickness of about one-sixteenth of an inch. The joints around the weir openings were made water tight by means of gaskets formed of cloth insertion rubber tubing, one-half inch in diameter, the movable gate being drawn against the gaskets by means of lag screws passing through cleats adjustable vertically in the timber frame supporting the bulkhead and gate. Each of the three weirs had its own channel of approach about 15 ft. long. The sides of the channels were lined with one inch surfaced pine flooring boards so that all three of the channels of approach and weirs were practically alike, the only variation being that of slight difference in width of about one-half inch in the case of one weir. The board linings of the channel were extended downstream from the crest of the weir a distance of 1½ ft. and also below the crest of the weir, a distance of about 2 ft., so that the weirs had their end contractions suppressed and the filaments were guided in parallel planes after passing over the crest. The arrangement of the weirs with intervening spaces of about 8 in. between the ends allowed free entrance of air beneath the nappes.

The board linings around the crest of the adjustable weirs have to be removed each time the crests are adjusted. These boards were attached by counter-sunk flat head screws, and just above the crest of the weir were 5 ft. long and extended upstream into the channel approach so as to avoid a joint on the vertical line above the crest of the weir. The slight openings between the weir boards and the ends of the boards lining the channels were filled with oakum and made practically water-tight, thus preventing cross-currents, which would interfere with the linear flow over the weir crest. A slight leakage between channels of approach was unavoidable. The rubber tubular gaskets were horizontal at the top of the fixed bulkhead, and extended vertically upwards on each of the sides of the weir openings to the maximum height of water in the channel of approach.

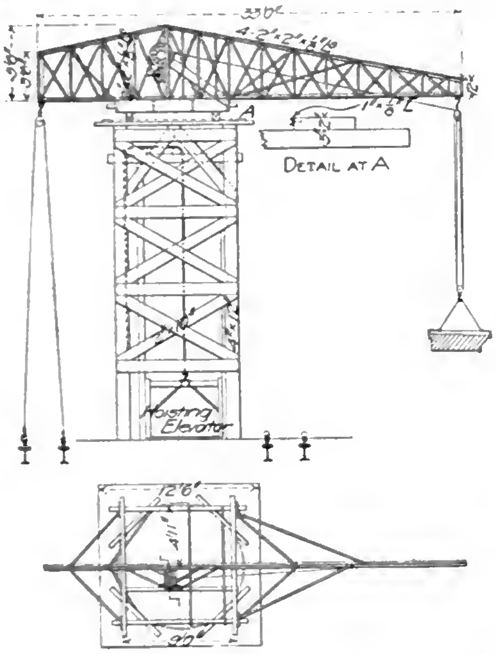
Before using the weirs for purposes of measurement they were tested for leakage by boarding above the crests of the weirs to a height of about

1½ ft. and filling with water. The tubular gaskets were very satisfactory and very little additional caulking was found necessary to make the weir channels water tight.

In the series of experiments with the submerged tubes 4 ft. square, the desired range of head on the tubes, zero to 0.4 ft., was possible without adjusting the height of the crest of the weirs.

The measurements of heads on the crest of the weirs were made by connecting the weir channels with still water basins located below the weirs, as shown in the illustrations, and taking readings of the elevations of water surfaces in the still-water basins by means of accurate hook gages. The connections between the weir channels and still-water basins were made by one-inch wrought iron pipes and one-inch rubber tubes. The tubes were attached to the basins by means of malleable iron unions and were easily disconnected. By lowering the outlet end of a tube and allowing free circulation of the water, the air in the connecting pipe and rubber tube could be easily removed.

The connections with the weir channels were made at points 8 ft. upstream from the crest of



Details of Turntable Crane.

the weirs, 5 ft. above the floor of the channel and about 2½ ft. below the crest of the weirs.

The plan followed was to study the simple forms of submerged tubes, 4 ft. square and of length varying from 0.31 to 14 ft., finding the losses of head and coefficients of discharge for the various rates of flow through the tubes. The entrance to the tubes of various lengths was then modified by introducing curved approaches, elliptical in form, and thus suppressing the contraction first on the bottom, second on the bottom and one side, third on the bottom and two sides, and fourth on the bottom, two sides and top. One of the illustrations shows the details of the submerged tube 2½ ft. long with the curved approaches on the various sides.

The submerged tubes with entrance square corners and of lengths varying from 0.31 to 14 ft. have been designated by series. The letters *a, b, c, c'* and *d* have been used with the various lengths or series numbers to designate the entrance condition. The subscript *c'* has been used to designate the same entrance conditions as the subscript *c*, but the outlet condition has been varied by the construction of a bulkhead to the sides of the channel at the outlet of the tube. One of the drawings show the forms of entrance and lengths of tubes used in the experiments.

The head, *h*, on the submerged tube has been taken as the difference of level between the surface of water above the bulkhead containing the submerged tube and the surface of the water at the outlet of the tube. The table gives a summary giving the coefficients of discharge for the various submerged tubes used in the experiments.

One of the diagrams is a graphical solution of the equations $Q = C a \sqrt{2gh}$ and $Q = av$, used for submerged tubes and orifices. The ordinates on the left side of the diagram represent values of the cross-sectional areas *a* and vary from 4 to 120 sq. ft. The abscissas marked on the lower part of the diagram represent values of the head *h* on the submerged tube or orifice. These values of *h* have been platted on horizontal lines, each line representing values corresponding to a certain value of the coefficient of discharge, *c*, as shown on the lower right hand part of the diagram. The abscissas marked on the upper horizontal line of the diagram represent values of the average velocities *v* in the cross-sectional area *a* of the orifice or tube. The oblique lines in the upper part of the diagram represent values of the discharge *Q*. The diagram is used like an ordinary diagram, having rectangular coordinates, except that the line on which the abscissas *h* is to be read varies in position and depends on the value of *C*.

The diagram may be used in a variety of ways: Values of *C* and *h* may be assumed, as, $C = .75$ and $h = .10$, the vertical line through $h = .10$ will intersect lines representing *Q*, any value of which may be selected, and the corresponding value of *a* determined by the horizontal line through the point of intersection of the vertical line and the line representing *Q*, as, for $Q = 50$, $a = 26.3$. By producing the vertical lines to the horizontal line on the upper part of the diagram values of *v* may be determined, thus, for the above example, $v = 1.91$. The diagram may also be used by assuming values of *a* and *Q* or *v* and *Q* and the resultant values of *h* read on the horizontal lines corresponding to some value of *C*, as shown on the lower right-hand part of the diagram.

The diagram will be found of special service in preliminary study where it is desired to study the relative effects of changes in a portion of the equation $Q = C a \sqrt{2gh}$, as the effects on *h* of certain changes in *C* for a given area of cross-section and discharge.

A Railway Motor-Car Test for long-continued high speed was made by the Union Pacific on Aug. 22 between Omaha, Neb., and Denver, Colo. The total distance of 570 miles was covered in 16 hr. and 34 min. The schedule time of the regular fast train is 17 hr. 15 min.

A Special Turntable Crane.

The new police headquarters building now under construction at the northwest corner of Grand and Center Sts., New York City, is a massive stone and brick structure surmounted by a clock tower which rises about 40 ft. above the roof of the fifth story, as shown in an accompanying illustration. This tower is two stories high and will be capped by a hemispherical dome supported on steel trusses about 200 ft. above the building foundations. The material hoist for the building rises in a shaft under the dome. The construction of the tower up to the level of the architrave presented no unusual difficulties; above this level, however, the necessity of continuing the material hoist up to the base of the dome to serve the masons on the brickwork inside the tower and the fact that a boom derrick could not be used, owing both to lack of room inside the tower and the absence of guying-points, required the construction of a special revolving crane which was designed, built and erected on the work in three days.

This crane, which is clearly shown in accompanying illustrations, consists of a horizontal truss 33 ft. long, of the form shown in the drawings, mounted near its one-third point on a revolving table which is supported in turn at the level of the dome base on a 3-in. plank platform on top of the hoisting elevator framework, the latter having been specially braced and reinforced to carry the additional load. The truss is made up of 2x2x⅛-in. angle bars, four being combined in cruciform section for the upper and lower chords, two being used for all verticals, and single bars forming the X-bracing. The turntable consists of a frame, 9 ft. square, made of 3½x12-in. yellow pine beams placed on edge and braced across the corners with shorter pieces of the same sectional size. The four cast-iron wheels on which the table turns are 6 in. in diameter with 1½-in. flat face. They are pivoted to the lower edges of the corner pieces of the framework, the pivot point in each case being directly above the center of the wheel. A plank circle, about 9 ft. 10 in. in inside diameter and faced on its inner edge with ⅛x1-in. channel bar with the flanges turned toward the wheels, is nailed to the 3-in. platform to guide the turntable wheels which rolls directly on the planks.

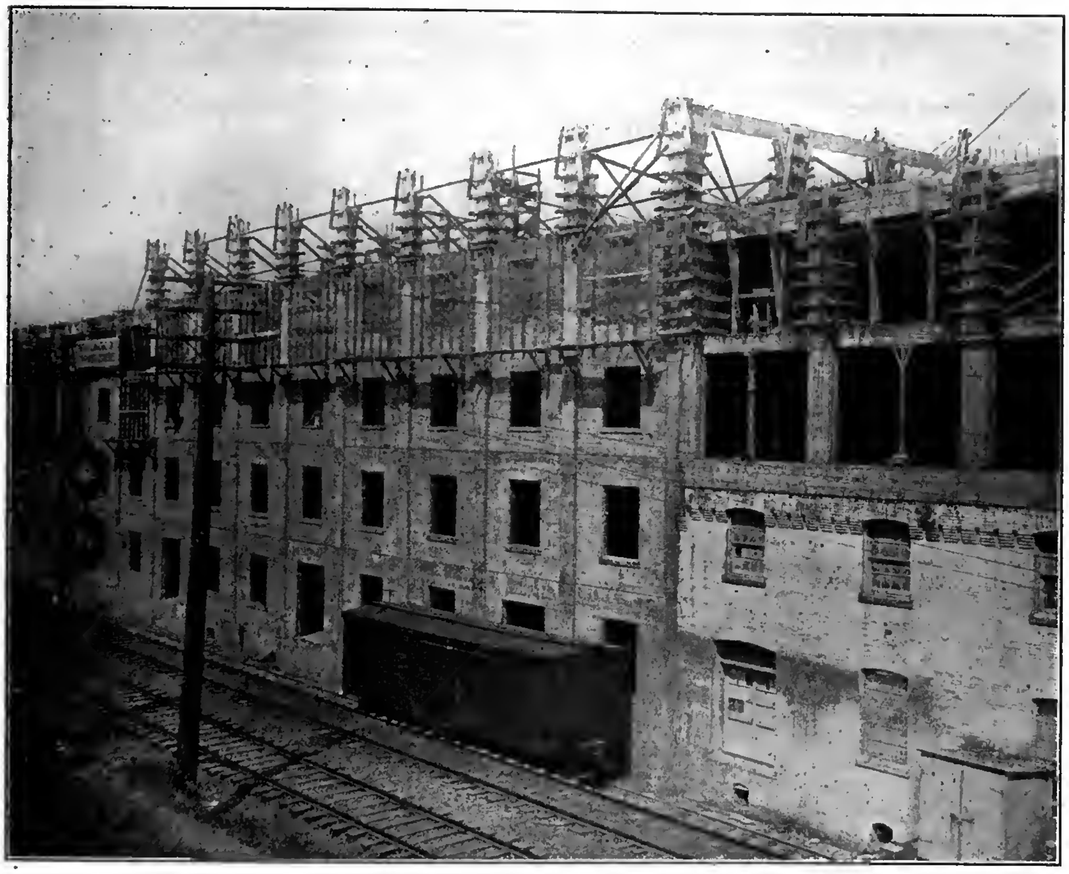
The manually-operated winch is fixed at one side of the truss over the turntable bearings on one side of the winch, being attached to a vertical truss member and those on the other side to a pair of vertical angles held in place at top and bottom by struts and braces in horizontal planes, as indicated on the drawings. To balance the overturning moment caused by the weight of the long arm of the crane and its load, the short arm was anchored to the beams of one of the tower floors by a tackle, as shown on the sketch.

All the stone and terra-cotta placed above the columns was delivered to the upper floor of the tower, about at the level of the architrave by the material hoist, which at the same time served the brick masons building the tower lining. The stone ornaments, some of which weighed over 1½ tons, were run on to the hoist at the first floor level on a four-wheel truck; when the hoist reached the level of the tower floor the truck was run off the hoist platform and across the floor to the inside of the wall opposite its final position outside; the stone was then hoisted, swung over the wall top and lowered to place with the crane tackle.

The crane truss was laid out full size on one of the lower floors of the building where it was riveted up in sections which could be easily handled. These sections were then carried up to the top of the hoist tower where the crane was assembled in place.

The building was designed by Messrs. Hoppin & Koen, architects, New York City, and Messrs. Gillespie & Walsh are the general contractors. Mr. Michael J. Garvey, superintendent, designed and erected the crane and other incidental apparatus described.

AN EARTH CURRENT of unusual strength was recently experienced on the telegraph lines of the Canadian Pacific Ry. in Western Ontario and Manitoba. The current was strong enough to set fire to the switchboard at Fort William.



Plaster Mill Buildings, Showing Brickwork of Building 5 A.

New Buildings of the King Plaster Mills, Staten Island.

Buildings 5 and 5A, now under construction as a part of extensive improvements to the plaster mills of J. B. King & Co., at New Brighton, on the north shore of Staten Island, New York, are five-story reinforced concrete structures occupying contiguous and irregular areas, as shown on accompanying plans, and designed to support floor loads of 200 to 600 lb. per square foot. They are located immediately on the bank of the Kill von Kull, a navigable stream, with their first floors about 5 ft. above mean high water. Behind the buildings is the right-of-way of the Staten Island Rapid Transit R. R., which provides a switch track for the several buildings of the plant. Behind the two buildings under consideration the tracks are about 4 ft. below the main floors.

Both buildings are founded on piles, 8 to 30 ft. penetration, driven through three sorts of material; riprap along the south side where a fill had been made by the railroad company; good soil outside the riprap; and old cribwork along the water's edge. In Building 5, where a floor load of 600 lb. per square foot is provided for on all floors, sixteen piles in general were driven for each interior column. In 5 A, which is designed for 200-lb. floor load per square foot on all floors except the sixth, where 600 lb. is provided for, there are in general six piles under each column and a continuous foundation girder distributing part of the column loads on intermediate piles.

Building 5.—The column footings in Building 5 are of the truncated pyramidal form and are in general 8 ft. square with their bases about 8 ft. below the first floor. The pile heads are embedded in the concrete 6 in., and 3 in. above their tops is a double series of ⅞-in. Ransome bars about 6 in. on centers each way. Owing to the unstable character of the foundation soil along the water front the three lines of interior columns immediately back of the north wall of the building were tied together and to the north wall columns at the tops of the footings by ties extending from the wall inward. Each tie is made up of two 1-in. Ransome bars encased in concrete to protect them from corrosion.

There are six complete lines of interior columns extending longitudinally through the building, the lines being 15 ft. on centers and the columns in each line 14¼ ft. on centers; besides these there are two incomplete lines similarly spaced, as shown on the floor plan. With a few exceptions the interior columns are octagonal in all except the fifth story, where they are square with the corners slightly chamfered. The typical interior column has the following dimensions and reinforcement in the various stories, the size being given as the side of the enclosing square: Below the main floor, 34-in., four 1-in. square rods and a spiral of ¼-in. wire 31 in. in diameter with 2-in. pitch; first story, 30-in., four 1¼-in. round rods, 7/16-in. wire, 27-in. spiral, 3-in. pitch; second story, 26-in., four 1¼-in. rods, ⅜-in. wire, 23-in. spiral, 2¼-in. pitch; third story, 22-in., four 1-in. round rods, ⅜-in. wire, 19-in. spiral, 3-in. pitch; fourth story, 17-in., four 1-in. round rods, 5/16-in. wire, 14-in. spiral, 2¼-in. pitch; fifth story, 12-in., four ½-in. Ransome bars, ¼-in hoops 12 in. on centers. The vertical rods in each column are continuous through the first and second stories; at the third floor there are 1-ft. gas pipe sleeves and the rods above are continuous through the third and fourth stories. In addition to the vertical reinforcement mentioned there there are also in each column in each story where spirals are used, three or four small rods to which the spiral is wired to preserve its pitch.

These were not considered in designing the columns.

The north and south wall columns are rectangular in form, varying from 20 x 24-in. below the first floor and in the first story, to 18 x 24-in. in the second and third stories, and to 16 x 24-in., in the fourth and fifth stories. The reinforcement is four vertical Ransome bars, 7/8 to 1/2-in., with 1/4-in. hoops 12 in. on centers. Across the west end of the building the usual wall columns are replaced by interior columns to provide for future extension in that direction. The east wall columns are carried up to the third floor beside a brick wall which will be referred to later. They are nearly square and somewhat heavier than the north and south wall columns. The first and second story columns are 12 ft. 6½ in. long from floor to floor. In the third and fourth stories they are 2 ft. shorter and in the fifth story they vary owing to the pitch of the roof.

The main floor girders extend longitudinally through the building and are in general 10 in. wide and 20 in. deep not including the 4¼-in. floor slab. The reinforcement consists of two 1⅛-in. and three 1-in. Ransome bars with ⅜-in. stirrups properly distributed. The floor beams are 4 ft. 9 in. on centers and divide the floor slab into panels, 4 ft. 2 in. x 14 ft. 2 in. They have three 1-in. twisted rods and 5/16-in. stirrups. The floor slab is 4¼ in. thick, including a ¾-in. finishing coat, and is reinforced across the beams with 5/16-in. Ransome bars, 30 ft. long and 5½ in. on centers. Each floor panel is bonded longitudinally with two ⅜-in. bars.

The typical wall girders, which are important only during construction when they serve as ties and carry the weight of the wall forms and concrete, are 4 in. wide and 20 in. deep and have one 1-in. bar and ⅜-in. stirrups. When these girders are poured six 5/16-in. rods, 2 ft. long are inserted in the concrete and left projecting from the upper surface of the beam to bond the wall to it.

The building is divided about on its north and south center line on all floors by a 6-in. concrete fire wall set into vertical 4 x 1-in. recesses in the columns. This wall is reinforced by vertical ⅜-in. bars 24 in. on centers and horizontal ⅜-in. bars 18 in. on centers. Wherever partition walls are required, and many are necessary to form bins, 1 x 4-in. recesses are left in the proper columns and vertical bond bars are inserted in the girders and left projecting above the floor to hold the bottom of the wall. Slot openings are left in the floor above all partition walls through which to pour the wall concrete.

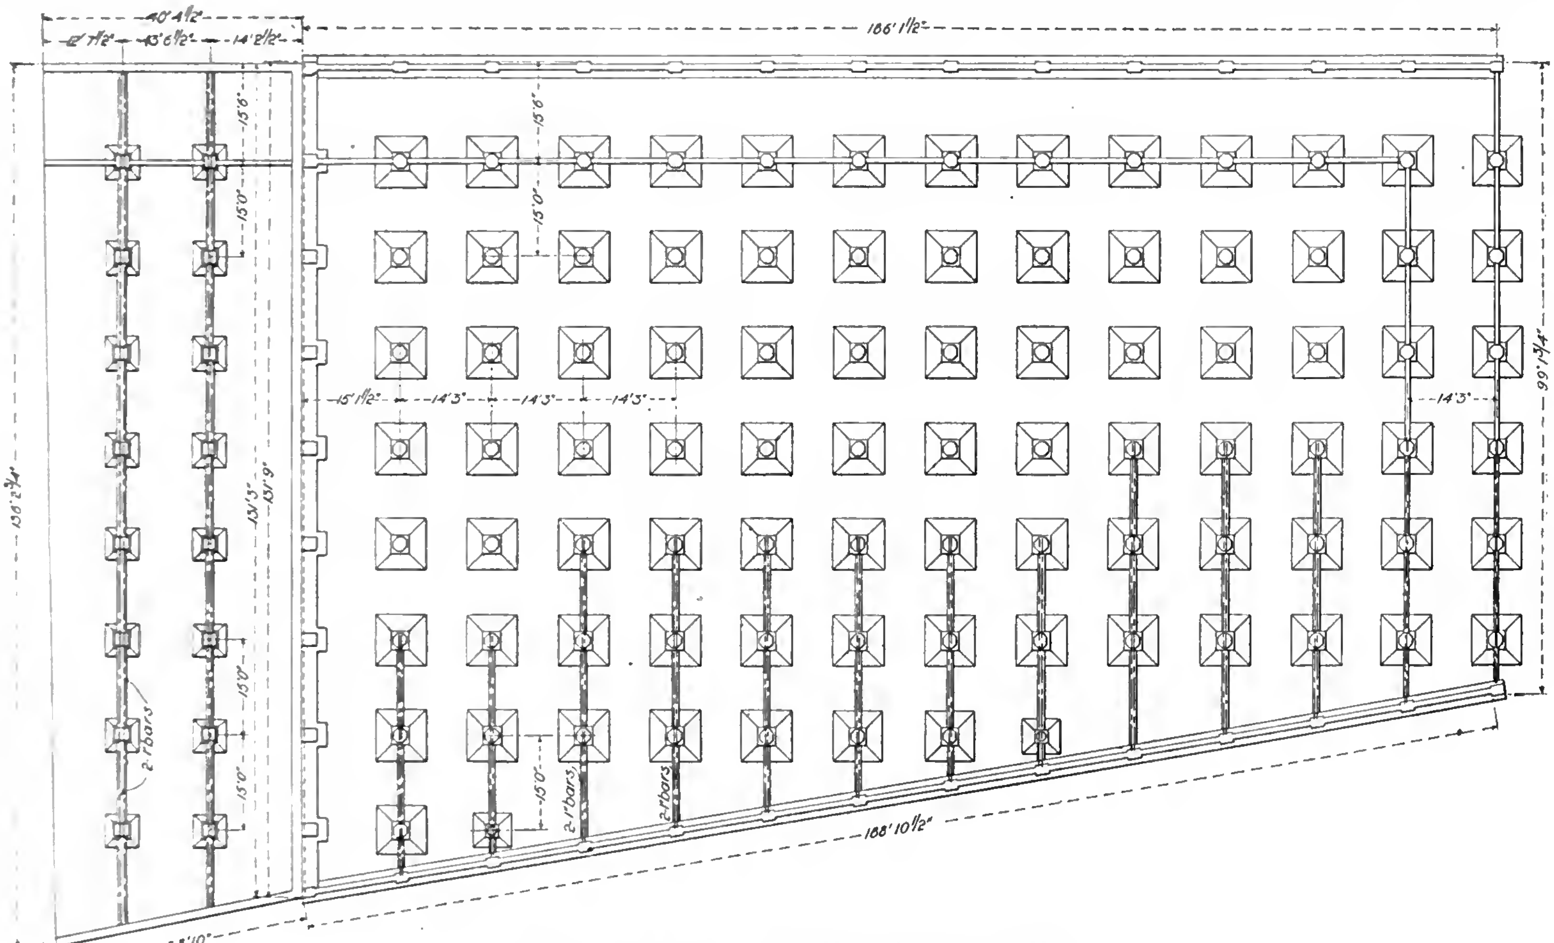
Building 5 A.—This building is immediately east of and adjacent to Building 5, and occupies a site upon which formerly stood a two-story brick building of mill construction, in fact, the north, south and west walls of the old two-story building form the walls of the lower two stories of the new building. Its east wall is the west wall of a five-story brick mill building. This wall is 20 in. thick and is securely founded on piles.

Structurally, Building 5 A is in general much like Building 5. It is much lighter, however, its floors having been designed to carry 200 lb. per square foot, except the second, which is designed to support 600 lb. per square foot. It is about 40½ ft. wide and 135 ft. long, both these dimensions varying owing to the irregularity of the site. There are two longitudinal lines of interior columns 15 ft. on centers in general in each line, dividing the building into three longitudinal bays, 12 ft. 7½ in., 13 ft. 6½ in., and 14 ft. 2 in wide. The transverse girders carry floor beams 4 ft. 4¾ in. to 6 ft. 4 in. on centers. The floor slabs are 4 in. thick except in the east bay of the second floor which is 5½ in. There are no wall columns on the east side, the ends of all girders on that side being set into the brick party wall 9 in. A recess 4 in. deep is also cut into the brick wall to receive the floor slabs. On the west side the same construction is used up to the top of the brick wall; above this there are wall columns resting on the brick wall and bonded to the wall columns of Building 5.

The north wall of the old two-story brick building had broken loose from the side walls, owing to the unstable character of the foundation material along the water front, and to secure this and guard against slipping, the interior column foundations were securely tied together throughout the whole length of the building by longitudinal lines of 1-in. bars encased in concrete and resting on top of the foundation girders. The base of the north wall was firmly secured to this system at numerous points by tie rods and plates.

Construction Details.—Building 5 A was started first but work on the two buildings is now being carried forward simultaneously. The concrete used in the columns is a 1:2:3½ mixture of Alpha or Atlas Portland cement, Cow Bay sand, and beach gravel. For the girders, beams, floors and walls a 1:3:5 mixture was used. The sand and gravel is delivered on the work by the owners from their large sand washing and drying plant at Port Washington, Hempstead Harbor, on Long Island Sound. It is brought to the bulkhead line in front of Building 5 in lighters; shoveled into buckets; and hoisted to a platform at the level of the second floor where it is dumped into large two-wheeled hand carts and hauled to storage piles on the second floor. These storage piles have at times been so deep that the load on four bays amounted to 1,200 lb. per square foot, but there was no noticeable deflection. The derrick hoist is operated by a Lambert portable single-drum hoist driven by a 7½-h.-p., 200-volt, G. & C. Electric Co. motor. The sand being thoroughly dry is closely compacted, 86 per cent. of it being equal to 100 per cent. of the same material undried. The cement is delivered from cars on the switch track to the first floor of Building 5, where it is piled near the mixer.

The mixer, a Ransome machine, is placed near the center of the first floor. Cement is delivered by wheelbarrow on an elevated platform beside the mixer and sand and gravel are introduced through a hopper on the second floor, being brought from the storage piles in wheelbarrows. The mixer delivers to a Ransome self-dumping bucket elevator with a hopper on every floor. Both mixer and elevator hoist are operated by



Foundation Plan of King Plaster Mill Buildings.

a 40-h.-p., 200-volt, motor made by the Eddy Electric Manufacturing Co., Windsor, Conn. The motor, Mundy friction hoist, and mixer are placed in a line in the order mentioned. The motor is belt-connected to the shaft of the hoist and the mixer is chain-driven by a sprocket on the hoist shaft, the drum being thrown in or out by a clutch. One man operates the hoist and attends the motor and mixer, a system of electric signal bells having been arranged for use with the elevator. Current for the motors is supplied from the private plant of J. B. King & Co.

The wire for the column helices is formed in coils of the proper diameter at the shops of the contractor. On the work it is formed into helices with the proper pitch on a long framework, T-shaped in section, the T being the right size to fit the inside of the spiral and one of the three leaves being hinged to permit the easy withdrawal of the completed helix. The pitch is adjusted according to marks on the frame and longitudinal rods are wired inside to preserve the spacing.

The forms present no unusual features. Cement block spreaders with a bolt hole through the center are used in the interior walls only. The small pieces needed in the forms are cut in a shop on the first floor in which are installed a circular saw, boring machine, and planer, operated by a 10-h.-p. 250-volt, General Electric motor. Several blind windows are to be filled with 4-in. concrete slabs made on the floor in front of the openings in tin-lined forms. A piece of rod bent in U-form and securely fixed in the back of each slab serves as an attachment for hoisting them into place with a hand tackle and portable derrick frame.

The buildings described were designed and are being built by the Turner Construction Co., New York City.

Book Notes.

It is rather difficult to understand just what purpose Messrs. W. S. Franklin and Barry MacNutt had in mind in writing their "Elements of Mechanics," for its text is such a contrast to that of successful textbooks on the same subject as to be startling. The orderly development of the principles of pure mechanics which is necessary to enable the student to grasp the fundamental facts of the subject is apparently abandoned in a measure in favor of somewhat disconnected sections on problems in applied mechanics. Prof. Franklin is the author of other books of high merit, which make it surprising to see his name attached to one of such a disjointed character. It may be that it will prove a useful class-room adjunct to a more vigorous course given by other means, but from the viewpoint of the usual class-room methods it seems about as useful as a text-book as the works on light and heat written by the late P. G. Tait and still regarded as unequalled examples from a master's hand of how an elementary book may become a mystery. And yet there are a good many sections of Messrs. Franklin and MacNutt's book that are inspiring to an ambitious beginner in physics, even if they have a tendency toward superficiality. (New York, Macmillan Co., $1.50.)

A book on detailing steelwork has been written under the title of "Notes on Construction in Mild Steel," by Mr. Henry Fidler, M. Inst. C. E. The preface is a particularly good statement of the complexity of the subject, which is the most troublesome part of structural steel design. The author repeats the familiar remark that the ability to analyze correctly the stresses in a roof truss and the ability to design a good riveted connection are not quite one and the same thing. Close study, observation and experience are needed for a draftsman to become a competent detailer and even then the knowledge of the real expert has not been acquired. This must be gained by becoming familiar with the treatment the steel receives in the furnaces, mills and shops, in order that the real degree of approximation of practical methods to theoretical assumptions may be known, and by learning in the field the procedures of the erection gangs and the troubles they have to overcome. The American reader should recognize, also, that the young engineers of Great Britain have not taken courses in technical colleges to the almost universal extent customary in the United States, and a British book on steel detailing is consequently required to go into matters that seem rather out of place to those who, as undergraduates, received a thorough grounding in metallurgy and the properties of materials. For this reason the numerous tables of tests of steel in the first half of the book have a value to the British draftsman which an American engaged in similar work will find some difficulty in appreciating. Nearly a fifth of the book is devoted to the chapter on the manufacture, physical and chemical qualities of mild steel and the second chapter gives in condensed form the same class of information regarding rolled sections that American engineers are accustomed to obtain from mill handbooks. The remainder of the volume is a discussion of detailing girders, columns, roofs and marine steelwork and of the methods of protecting steel surfaces. The numerous illustrations are mainly from drawings prepared for regular engineering purposes, and throughout the book are useful notes of special devices or methods of a kind that rarely get into print. The book is one that should prove valuable in any large detailing office and in the libraries of technical colleges. (New York, Longmans, Green & Co., $5.00.)

Mr. Allen Hazen has rendered a distinct service to all who wish to know about municipal water supplies by writing "Clean Water and How to Get It," a book which is both authoritative and free from the technicalities that interest sanitary and engineering specialists only. At the present time considerable harm is occasionally done by city authorities who, with the best of intentions, are misled by half-knowledge into undertaking works that should never be constructed. A careful reading of this book should prevent such ill-judged decisions; it has been written particularly for mayors and aldermen who have been chosen to office from walks of life in which they have had no water-works experience, and can be aided in serving their cities by clear statements of principles, illustrated by examples from large and small works which are fulfilling their purpose well. The book opens with a description of impounding reservoirs and explains the changes that take place in the quality of water stored in them under various conditions. A brief chapter on supplies from small lakes points out their similarity to those obtained by impounding streams. The chapter on supplies from the Great Lakes summarizes the views of the leading authorities concerning such a source, and calls attention to their danger on account of sewage contamination. The author states plainly, and deserves hearty applause for doing so, that while Chicago and Cleveland have succeeded in getting better water by spending millions in driving tunnels far out under the bottom of the lakes to secure supplies free from contamination, they have failed to get thoroughly good water. In the chapter of supplies from large rivers the author makes statements regarding sewage purification that are particularly important in these days of a growing public demand for the universal purification of sewage discharged into rivers. "The fact must be fully recognized," he asserts, "that the discharge of crude sewage from the great majority of cities is not locally objectionable in any way to justify the cost of sewage purification. Looking at the matter as one great engineering problem, it is clearly and unmistakably better to purify the water supplies taken from the rivers than to purify the sewage before it is discharged into them. The volume to be handled is less and the cost per million gallons of purifying water is much less than the cost of purifying sewage. It is also very much more effective to treat the water, because the methods of water purification are more efficient in stopping germs of disease than are the methods of sewage purification." Ground-water supplies are discussed in one of the most interesting chapters in the book, which explains the effect of different conditions on their quality and quantity, and the results of the action of water on iron pipes is described in an equally important chapter containing considerable information not readily found elsewhere. The next five chapters are on water purification and related subjects and are excellent outlines of what are now considered the best ways of purifying different waters and of removing turbidity, color and iron. That these methods can be improved as conditions demand is stated by Mr. Hazen in the following confident forecast: "It may be reasonably anticipated that far more efficient methods of purification will come to be used in course of time and in discussing the advantages and disadvantages of polluted waters after purification for use by cities through a long term of years with steadily increasing amounts of pollution, it will not do to consider only the methods of purification now in use. Better methods will be available for the more difficult service when they are needed." The subject of water pressures is given a chapter by itself and so is the designs and construction of works, and some wholesome advice is given in them which, if followed, would result in a gratifying reduction of charges or in improvement in service in some cities. The cost of waterworks is taken up briefly in another chapter. The chapter on the use and metering of water and that on the financial management of public works are different in character from the rest of the book, as they are mainly arguments in favor of the author's opinions concerning subjects which offer a wide field for controversy. (New York, John Wiley & Sons, $1.50.)

Letters to the Editor.

Lattice Bars in the Quebec Bridge.

Sir: I notice in The Engineering Record and elsewhere that a discussion has started on the question of secondary stresses, and yet I doubt if any of us for a moment believe that secondary stresses had anything to do with the failure. One particular lower chord section seems to be considerably under discussion, while it is evident that other lower chords were of quite the same section, that is, some 760 sq. in., something like 16 in. radius vertically and approximately 19 in. horizontally, with stresses within limits that no one would expect to cause failure. But we are all confronted with the fact that these members had only 2.8 per cent. of the weight of the section of the member in lattice and its rivets, while it is a fact that our practice shows that of moderate sizes in lightest section, 8 to 15-in. channels, the weight of lattice and its rivets of a two-channel members varies somewhat, but is about 30 per cent. of the weight of the two channels; that is, practice uses about eleven times as much relative weight of lattice on small-size columns as were used on the compression members of the Quebec Bridge. That this may be the real cause of failure, I am not prepared to assert, but

I am prepared to hazard the opinion that none of us will build latticed members in excessive sizes with as small lattice bars and as few rivets in their connections in the future as we may have done in the past.

The relation of lattice to the member is not specified anywhere in any general specification. That the individual lattice with its rivets should have some relation to the stress of the member surely appeals to us as reasonable since the failure of the Quebec bridge, and yet no one has ever put in print anything that has come to my notice on the subject.

Horace E. Horton.

Cost of Aerial Cableway in Making a Fill.

Sir: In making a single-track, 175,000-yd. fill, the Williams Bros. & Morse Co., of Cleveland, Ohio, saved $1,700 by using an aerial cableway in preference to a timber trestle. The fill was 400 ft. long and 95 ft. deep, between Stations 377 and 381 on the Lake Erie & Pittsburg Ry., now under construction from Cleveland to Pittsburg. A detailed, accurate account of all expenditures made on the cableway for material and labor was kept, and a careful estimate was made by Mr. A. E. Williams, of the Williams Bros. & Morse Co., of the least probable cost of a trestle which would have been necessary to meet the same conditions as were presented to the cableway.

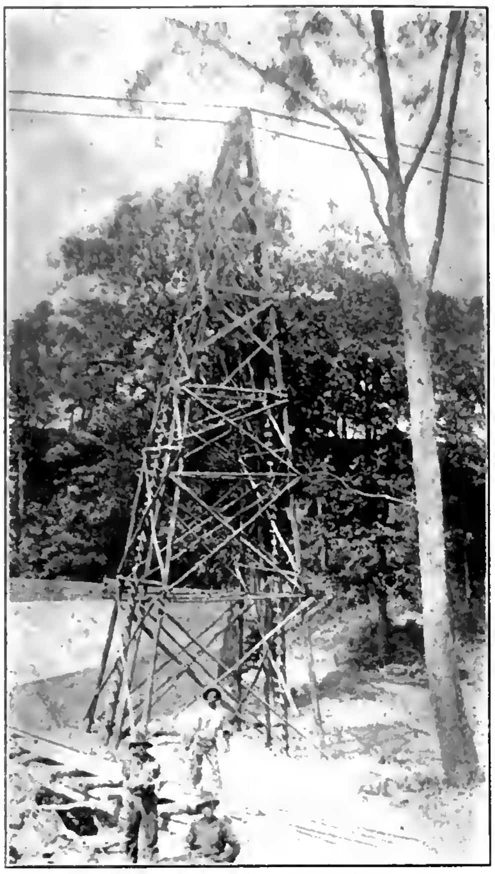
Frequent accidents on cableways have rather shaken the confidence of contractors in this means of providing a bridge for the dump cars, but it seems that these mishaps have been due to improper construction and the use of cables that were not large enough to stand the heavy strains. But in this case the cableway has well withstood the loads that have been put upon it, as the anchors and wooden supports were made extra heavy, and a 2¼-in. Roebling galvanized bridge cable was used.

Method of Anchoring Cables.

General View of Cable Road.

The anchors on either side were 400 ft. apart, and an A-frame was erected to support the cable in the middle; this made the span 200 ft. The anchor at the north bank consists of a log 18 ft. long, 24 in. thick, imbedded in solid rock. Two eyebolts screw into the log and are fastened by heavy nuts over 8-in. cast-iron washers. Connecting with these eyebolts are two 10-ft. chains with 10-in. links made from 2½ in. iron. These chains were put in to keep the cables from twisting by covering the chains with heavy weights. Two 3 in. turnbuckles, with a spread of 3 ft., made the connections between the chains and the cables. The cables were leaded into the turnbuckles. These turnbuckles, which were forged for this work, were used for taking up the slack.

The anchor at the south end consisted of a log 25 ft. long and 24 in. thick, placed in a new fill of sandstone 10 ft. deep. Three-inch planks were driven in front of the anchor log, two eyebolts 22 in. long and 2½ in. in diameter were screwed into the anchor log and fastened with nuts over cast washers 8 in. in diameter and 2 in. thick. The eyebolts connected with clevises by means of 3-in. pins. The cables were leaded into these clevises. A rise of 1 ft. in 3 ft. brings the cables to grade and to the end timber supports.



The Central Tower.

The fill is being made from the south end of the cableway and bents are put in as the work advances to help support the weight of the cars. The support for the cables on the north bank is made of 10-in. logs resting on mud-sills. There are two 6-in. hickory rollers on which the cables rest to allow them to accommodate themselves to different lengths.

The A-frame which supports the cables in the center is made of two bents of four timbers each. The lower 50 ft. of the frame is made of 10-in. round timbers and the upper 42 ft. of 8x8-in. square timbers. The cables on the top of the A-frame are 8 ft. above grade. The bents rest on 10-in. mud sills. They have a batter of 1½ in. to a foot. The frame is 32x26 ft. at the bottom.

A train consists of from six to twelve 4-yd. cars. These are emptied at the south end of the ravine and are pushed out onto the cableway as fast as they are emptied. The car rails are spiked to ties which rest on stringers. These stringers rest on 8-ft. logs fastened to the cables with U-bolts. The cables are 7 ft. apart. Most of the fill is being made from a sandstone cut about a half mile distant. This sandstone has a slope a little steeper than 1½ to 1.

The following is the actual cost of the aerial cableway: 1,000 ft. of 2¼-in. Roebling galvanized bridge cable, $600; 2½-in. eyebolts and clevises for both ends, $108.30; 2 3-in. turnbuckles at north end, $120; 2 2½-in. iron chains at north end 10 in. long, $62.40; 4 8-in. cast washers 2 in. thick, $2.46; timber for A-frame, all bracing and cross ties (other timber obtained on ground), 3,200 ft. at $34, $108.80; lower 50 ft. of A-frame, round timber, 56 ft. long, bought in tree, $32; cost of team work for hauling round timber and pulling timber to place for erecting, $65; carpenter labor on A-frame and end bents on bank, $231.40; time of superintendent, getting material and overseeing work in general, $60; common labor in digging trenches for anchors and putting up cableway, $112; nails and iron in A-frame and bents, $29.40; total cost of cableway, $1,531.76.

A conservative estimate made by Mr. Williams of the probable cost of a timber trestle for this opening, figuring on square 8x8-in. timber cut from native timber: 98,000 ft. (including all uprights, planks for bracing, stringers, etc.), at $26, $2,548; labor for putting up trestle, $6 per M., $588; spikes, $98; iron drift bolts, $40; total cost of trestle, $3,274.

Saving effected by using cableway: Estimated minimum cost of trestle, $3,274; actual cost of cableway, $1,531.76; difference in favor of cableway, $1,742.24. Yours truly,

Cleveland, Ohio. J. D. Mooney.

Tar-Macadam Roads are now being laid in several English localities by a method developed by the engineer of the Eton and Slough Rural District Council. After the upper layer of old macadam has been removed a coat of tar cement is spread and broken stone rolled into it until the tar shows on the surface. Such work has been done at about 42 cents per square yard.

THE ENGINEERING RECORD

Published Weekly by the

McGraw Publishing Company

James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.

MAIN OFFICES:

239 West 39th Street, New York.

BRANCH OFFICES:

Chicago: Old Colony Building.

Philadelphia: Real Estate Trust Building.

Cleveland: Schofield Building.

San Francisco: Atlas Building.

London Office: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico	$3.00 a year
Canada	$4.50 a year
Foreign subscription	$6.00 a year
25 shillings. 25 marks. 31 francs.	

Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of The Engineering Record on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

Remittances.—Remittances should be made by check, New York draft, or money order, in favor of The Engineering Record.

Changes of Address.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

Back Copies.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.

Date on Wrapper indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

Club Rate.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. The rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 16,000 copies are printed. Total circulation for 1907 to date, 582,500 copies, on average of 14,563 copies per week.

TABLE OF LEADING ARTICLES.

Portable Electric Plants.

The increasing use of electrical equipment in various construction work brings to mind the somewhat undeveloped state of portable plants for such service. Of course it often happens that work is being carried on within easy reach of central-station service, and in such cases it is a simple matter to make suitable arrangements for it. Yet it is common enough to find construction in which electric hoists, cranes and drills would be extremely useful, to say nothing of electric lighting, in localities where no available plants are within reach. If the works are of sufficient size it may be feasible to install a regular temporary plant as was done in the Kern River tunneling operations of the Los Angeles Edison Co. In this case a regular hydraulic transmission plant was put in and very successfully used throughout the period of construction. It is rare, however, to find need for power generation on so large a scale. In most instances a really portable equipment is needed, one that can easily be taken from place to place ready to operate motors and other apparatus whenever needed. Some few portable plants designed for various purposes are in existence, but it seems obvious that a great deal more can be done in this line, especially since the automobile has made small gasoline equipments so familiar that they are taken quite as a matter of course.

It is certainly no difficult matter to plan a combined auto truck and portable power station of say 40 or 50 electrical horse-power capacity, using a four-cylinder gasoline engine direct-connected to its generator and quite capable of furnishing power and lights on a considerable scale. The load conditions are not, of course, good, but they are certainly more favorable than in the case of the scattered steam engines now used. The gain in economy and facility is of no small moment, and there are many electrically-driven tools available for which there are no steam-driven equivalents. So far as economy of operation is concerned, there is certainly advantage in using gasoline engines rather than steam engines in the smaller outputs, while the electric equipment requires a smaller working force. In the matter of lighting for night work, the judicious use of arc lights is probably the best thing yet devised, the flaming arc having been used with particular success in excavations and other places which are exceedingly difficult to light with ordinary lamps or torches.

The small portable power plant certainly has a useful field, and were apparatus more readily available, it would be oftener tried. Very possibly some of the readers of The Engineering Record may have had experience with portable plants of one sort or another, and they would do their fellow engineers a good turn by giving them the benefit of the experience. In these days of difficult labor conditions, the more the better of auxiliary power apparatus. It has already demonstrated its usefulness, and the only trouble is that its field is as yet too contracted.

Compression Members for Bridges.

The built-up compression members used so universally in American bridge practice, commonly of laced channels or channels laced on one side and riveted to a cover plate on the other, the channels being either rolled or built, are members of such every-day construction that the usual procedures involved in their design have long since come to be accepted without any question whatever. The fundamental principles of long-column resistance as established many years ago, are fully recognized, the moments of inertia of cross-sections being computed in all cases as if there could be no possible question of all component parts of the column being held rigidly in their proper relative positions under all degrees of loading up to that causing failure. There is always an implicit, if not explicit assumption that the lacing, rivets, batten plates and other details are provided with sufficient dimensions and in numbers requisite to insure no distortion of the normal cross-section under any loading to which the column may be subjected. These assumptions obviously involve conditions imperative for a proper resisting capacity of the member. No matter what may be the cross-sections of the various parts of which the column is composed, if those parts are not held in their proper relative positions by sufficiently strong lacing or other spacing details and with a sufficient number of rivets of suitable size, it is clear that the column may fail to carry even a small fraction of the load for which it is designed.

Ever since the beginning of bridge construction in this country there have been many experimental investigations made for the purpose of securing complete information regarding the effects of shop processes on structural material in course of fabrication. These experiences have yielded data of so great value that there is afforded fairly complete knowledge of the effects of such manipulations as punching, shearing, cold straightening and other similar operations employed in the manufacture of built compression members. So full, indeed, has this information become that engineers have strangely failed to consider the necessity of testing full-size members of this class as completed and ready to perform their functions in the finished structure.

Forged eye-bars have been the subjects of ceaseless investigation as full-size members, until, it would seem as if there could be little left to ascertain regarding their action under any conditions of loading. Suitable dimensions of heads, the proper shape of the neck, the relation between width and thickness, the thickness of head or rather thinness inducing failure by dishing, the conditions for proper forging and other elements of the eye-bar problem almost without number, have been so amply treated as to leave little still to be desired. Indeed it is not too much to say that the eye-bar has come to be probably the most completely determined member used in a modern bridge. The pursuit of experimental knowledge regarding the properties of eye-bars has apparently been so absorbing that corresponding information regarding built-up compression members, although not less important, has been almost completely neglected. During the last quarter century scarcely ten full-size built-up compression members have been tested to destruction and not one large member of that class has ever been so tested. When it is remembered that members of the largest eye-bars yet forged have been subjected to the most careful experimental scrutiny for all degrees of loading up to failure, it must be admitted that the contrast is sufficiently remarkable to cause the gravest apprehensions in the minds of engineers having great compression members to design. This observation gathers much additional force from the fact that the number of full-size built steel columns tested to the present time is so insignificantly small that there would practically be no error in stating that there have been no such tests. All the full-size column tests made in the United States arsenal at Watertown, Mass., and reported in the executive documents of the 47th, 48th and 49th Congresses were of wrought iron, and they afford nearly all the experimental data available for the use of engineers in the design of built-up compression members.

Probably the most important single feature of the ordinary long column is the lacing bars or other similar spacing details. The maintenance of the proper relative positions of the component parts of such columns on which the carrying capacity wholly rests depends absolutely upon the lacing bars, and yet no comprehensive experimental investigation has yet been made to determine their proper sizes and distribution. The maximum panel distance of the lacing in terms of the thickness of angle leg or channel

flange to which the lacing may be riveted is approximately known as is the maximum unsupported width of a web plate for these built compression members, but the dimensions of the lacing bars on which the safety of the entire structure really depends has not even been approximately determined by experimental investigation. The design of those bars is, therefore, almost wholly a matter of the engineer's judgment.

As startling as this condition is regarding the designs of such an important part of built-up compression members, many experienced engineers know that the full-size column tests already alluded to yield some valuable information regarding the design of lacing bars, although it is of an inferential rather than of a positive character. Furthermore those tests have furnished bases for tables of standard lacings for built compression members composed of rolled or built channels from six inches up to thirty-four inches in depth. Although such lists have never been subjected to a series of crucial tests by the actual loading of large columns to failure they certainly accord with the older tests of columns on which they are based.

There has been a tendency at times to economize too much in these details of large structures. This is a mistake as the total metal required for such purposes is always a small percentage of the total metal in the structure, and it requires but a comparatively small amount of metal, properly disposed in such details, to make all the difference between safety and fatal danger. The component parts of great compression members, especially when there are three or four heavy webs, can be held in their normal relative positions only by correspondingly heavy lacing bars or plates, as can be at least approximately concluded from the proportionate bars employed in the latticed channel columns of wrought iron tested at Watertown.

While it is probable that great steel compression members may be safely designed by inference from those early tests, there is still the danger resulting from a legitimate but wide difference of engineering judgment, when acting by such a remote inference. An extended series of tests of full-size steel built compression members is imperatively needed to determine many important open questions on which depend the safety of the structures in which they act, as has been forcibly evidenced by at least one great bridge wreck.

Railway Maintenance and Chemical Research.

Among the problems which are constantly facing the modern railway manager the question of maintenance easily stands in the front rank of importance. Enormous sums of money are expended yearly on every large system to make good the effects of wear and tear, and the increasing traffic and higher speeds of train operation on railways are subjecting the engineering materials and equipment used in transportation to service tests that demand the best quality of supplies for economical performance. Both steam and electric railways are such heavy consumers of timber, fuel, lubricants, iron, steel and other great staple products that the purchasing agent's office is thronged from morning until night with sales engineers and representatives of supply houses; and the stream of correspondence, orders, requests for bids, and the like, never stops flowing. Important as are improvements in the design of locomotives, rolling stock, power plants and general machinery, it is becoming clear that there is a broad field for the saving of money in the purchase and use of supplies. But the physical and chemical characteristics of the materials must be thoroughly understood before intelligent selection and wise application of supplies can be made in bulk.

The co-operation of engineering and purchasing departments has become the regular thing in progressive organizations, and in so far as the physical properties of materials are concerned, operating companies are thoroughly alive to the importance of drawing specifications on the basis of engineering tests. It is only very recently, however, that the relation of chemical research to the engineering field, and particularly to railway maintenance, has begun to be appreciated. The chemical side of power plant work has been referred to in these columns, and the chemistry of the boiler-room is receiving widespread attention. A less general appreciation exists of the ability of the chemist to solve some of the problems of maintenance in busy railway systems, or at least to co-operate in their solution with the experts of the operating staff.

The purchase of steel rails, is, of course, an exception as far as the time element is concerned. It is nothing new to draw rail specifications on the basis of microscopic, physical and chemical tests. Information of this character is absolutely essential to the securing of durability and reliable service. Few engineers outside the sphere of laboratory influence, however, realize the scope of work or the specialization in progress which have lately fallen to the lot of the consulting chemist. It is not too much to say that the single question of fuels has become a special branch deep enough to provide the expert chemical engineer with a life work, and similarly the preservation of timber and the study of lubricants are now subjects of sufficient breadth to occupy the entire attention of specially qualified men. The organization of chemical specialists is a natural outgrowth of this progress, and its power to reduce the total cost of a given material in its life and service in heavy railway work is being demonstrated daily in the cases of companies which have decided to supplement the advice of the engineer with the recommendations of the chemist in holding up the hands of the purchasing agent to enable the latter to buy at the maximum point of advantage as markets rise and fall.

No maintenance problems can be properly solved unless the materials involved are thoroughly understood. In the case of electric railway trolley wheels, for example, an analysis of wheels showing both long and short lines is a necessary condition to the finding of the wheel which shall in the long run be the cheapest, allowing for the differences in cost, mileage and scrap value. Similarly the study of trolley wire composition, the constituents of bearing metals, suspension cars, crossing frogs, ties, insulating compounds, oils, greases and other materials and supplies must supplement the tests of tensile or compressive strength, viscosity, flash and fire points, specific gravity, porosity and other physical properties which enable accurate specifications to be drawn in the interest of reduced maintenance through increased durability.

It is needless to emphasize the importance of chemical analysis and calorimeter tests of fuel in these days when British thermal units, and percentages of carbon, sulphur and ash count for so much with intelligent consumers. At the same time, it is not so generally appreciated that the quality of fuel burned in a given locomotive furnace or under the boilers of a power plant has a direct bearing upon the depreciation of grates and tubes, which demands the report of the chemist before complete data are at hand to judge the fitness of a given fuel for given conditions. Again, it is one thing to specify coal of a certain character and another to make sure that it is delivered and stored in the most acceptable way.

The cost of lubrication is a subject of great importance in railroad circles, and some of the best engineering chemical work has been done with a view toward determining the quality of lubricants best adapted to a given service. The preservation of ties, poles, trestles, and other timber structures is another point of contact between chemical research and railway maintenance, and although the Government has done and is doing a vast amount of work in the field there is room for the commercial chemist to enter more extensively than he has yet done in the general effort to forestall decay and renewal expenses. The study of paints and varnishes is still another question of far-reaching consequence jointly to the laboratory and the operating company, and the attention it is receiving from the Association for Testing Materials is an indication of the general appreciation of its importance. In the scientific purchasing of the immediate future the specifications distributed to competing supply houses will bear the impress of expert chemical knowledge no less than physical, especially in work on a large scale which involves the durability factor.

The Diversion of Underground Waters.

The ownership of underground waters and the right of property owners to divert such waters from their lands have long been the subject of legal controversy. The first important English case of this sort was decided in 1840 and since then there have been a number of decisions which have pretty definitely settled the law regarding underground waters in Great Britain. An excellent account of them was given some years ago in a paper by Lord Robert Cecil, of which a comprehensive abstract was printed in The Engineering Record of Dec. 2, 1899. It was there pointed out that according to the British law there is no property in underground water, but on the other hand, each landowner may pump from his land what water he can get, with two exceptions, viz., he must not directly or indirectly take water already contained in a surface stream, nor must he abstract water flowing underground in a known and definite channel. He has a perfect right to drain the supplies to all his neighbors' well, however long they may have been enjoyed by their owners. So, too, he may pump until springs miles away have ceased to flow. Further than this he may not go. Once water is in the channel of a stream above or underground, it is safe from underground depredation. Many criticisms have lately been made regarding this British law. What was entirely equitable fifty years ago, when underground supplies were of little account, may no longer hold true. Formerly, where a question arose between the draining of a well and the shutting down of a mine, public policy required that the owner of the well should suffer. As the population of cities has grown it has become more and more necessary, where the water is drawn from wells, to drain large tracts of the underground water they contain. The inhabitants of these districts are loud in their complaints of the damage due to their property on this account, while those who are engaged in conveying water to large centers of population claim that the few people in the country must be sacrificed for the many in the towns.

Attention has been called by The Engineering Record a number of times in recent years to decisions of this subject in the United States. Such a controversy arose in connection with the ground-water supplies of the Borough of Brooklyn and attracted much attention. It has also arisen a number of times in other States, and it is a matter of congratulation that in most of these cases the courts have recognized that the

decision should be based, not on the precedents established by a British common law, but on the equities of the case. The climate and geological conditions in different parts of the United States vary, generally being different from those of Great Britain, and a recognition of this fact leads to the inevitable conclusion that what may be justice in one climate and under certain local conditions may be injustice in another. The Minnesota Supreme Court states this very clearly as follows: "Nothing is better settled than that the fundamental principles of right and justice on which the common law is founded and which its administration is intended to promote, require that a different rule should be adopted whenever it is found that, owing to the physical features and character of a State, and the peculiarities of its climate, soil, products and water supply, the application of a common-law rule tends constantly to cause injustice and wrong rather than the administration of justice and right."

This satement was made in a decision in the case of Erickson v. Crookston Water Works, Power & Light Co., 111 N. W. Rep. 391. The company bought two artesian wells in the Crookston artesian basin, well known among those interested in underground water supplies on account of its special features, and by deepening the wells and pumping from these the company obtained a large supply of water which it mixed with an inferior river supply and sold for domestic and other purposes. This heavy pumping from two wells lowered the water level in the ground to such an extent that wells in the vicinity were rendered practically useless, and the suit was brought to prevent it. It was natural to expect an interesting decision in this case, because in the matter of surface water the Minnesota Supreme Court had previously taken a view which was novel at the time it was announced. In the case of Sheehan v. Flynn, the liability of the landowner for diverting surface water to the injury of another was made to depend upon the necessity and reasonableness of the act. Although this rule is subject to considerable criticism even at the present day, it has been followed to a greater or less extent in many Western States. It is natural, therefore, to expect that the decision in the present case involving underground supplies would be similar in its reasoning, following the precedent originally established by the New Hampshire Supreme Court, which was particularly referred to in Lord Robert Cecil's address. In fact, the highest court in the State of New York has made a decision of somewhat like tenor in some of the cases growing out of the use of ground water for supplying the people of Brooklyn.

In Forbell v. New York, 58 N. E. Rep. 644, the court stated: "In the absence of contract or enactment, whatever it is reasonable for the owner to do with his sub-surface water, regard being had to the definite rights of others, he may do. He may make the most of it that he reasonably can. It is not unreasonable, so far as it is now apparent to us, that he should dig wells and take therefrom all the water that he needs in order to the fullest enjoyment and usefulness of his land as land, either for the purpose of pleasure, abode, productivness of soil, trade, manufacture, or for whatever else the land as land may serve. He may consume it, but must not discharge it to the injury of others. But to fit it up with pumps and wells of such pervasive and potential reach that from their base the defendant can tap the water stored in the plaintiff's land and in all the region thereabouts, and lead it to his own land, and by merchandising it prevent its return, is, however reasonable it may appear to the defendant and its customers, unreasonable as to the plaintiff and the others whose lands are thus clandestinely sapped and their value impaired."

Another case which deserves attention on account of the clear reasoning to be found in the decision as well as because of the precedent it establishes in a State where underground waters are specially valuable is that of Katz v. Walkinshaw, 74 Pac. Rep. 766. In this case the underground waters were found below an impervious stratum, the water-bearing material being fed from the rainfall on the slopes of the mountains encircling the valley. When the impervious stratum was perforated, true artesian wells were formed. The court held in this case that such percolating water rising through an artesian well was not a water course, so as to confer riparian rights upon the owners of the surface. It was further decided that the owner of a portion of a tract of land underlaid by such a water-bearing stratum cannot remove the water from wells for sale, if the remainder of the tract is thereby deprived of water necessary for its profitable enjoyment. A somewhat similar decision has been rendered in Texas.

The Minnesota Supreme Court has agreed with these views. It has decided that a water company had no vested right to deprive the neighboring land owners of water, naturally furnished by artesian wells, by pumping the water from its own wells to such an extent as to lower the whole underground water level. It will be seen that this is diametrically the opposite view to that of the British common law. It is in harmony, however, with a minority opinion by Lord Wesleydale in the famous case of Chasemore v. Richards, decided in 1857. Lord Wesleydale stated that a land-owner ought to exercise his right in a reasonable manner, with as little injury to his neighbor's rights as may be. He doubted the legality of a water purveyor's act in abstracting water for the use of a large district in the neighborhood unconnected with his own estate, for the use of those who had no right to take it directly themselves and to the injury of those neighboring proprietors who had an equal right with themselves. Each person who was supplied with water by the purveyor might not have been able to dig a well on his own land and take the like quantity of water, so that the purveyor may have taken much more than would have been abstracted if each had exercised his own right. These opinions of Lord Wesleydale have not been unheld in Great Britain because of the belief of the court that it would be impracticable to determine what was a reasonable use of underground waters. It will be seen that the American courts have been deterred by no such fear, and that in many of our States, as mentioned above, what is legal in respect to underground waters is made to depend solely upon what is reasonable.

Notes and Comment.

Economy of Manufacture in cement mills is brought to the front in Mr. Potter's interesting paper on the use of electricity in such plants printed in The Engineering Record, Sept. 21. The change taking place in such works at the present time as a result of the introduction of electricity and various other improvements is particularly noticeable. Attention is being paid everywhere to methods of reducing the cost of manufacture without deterioration in the quality of the product. That there is plenty of opportunity for improvement is generally admitted by cement manufacturers. The industry suffered in one sense from the fact that its product is mainly consumed during the months when work can be carried on readily out of doors. As a result of this fluctuation in demand, there is an accumulation of stocks every winter, so that when spring arrives it is natural for the manufacturer to feel very apprehensive concerning the future, for he generally has a large amount of capital locked up in unsold product. The manufacturing problem, then, is to meet economically a demand which is not unlike that thrown on central electric stations. There is a peak load which must be provided for by special means, an average load from which profits must be derived and a minimum load which must be brought up as high as possible in order to keep down manufacturing cost. Of course electricity will not be of much use in equalizing supply and demand, although it is certain that it will be a help in reducing operating expenses. There has been a tendency among some of the older companies to look upon electricity as too unreliable for a mill operating with such clouds of abrasive dust as arise in cement work. It is only necessary to refer to the many plants where electricity has been in satisfactory service for years to show that these fears are unfounded. One result of the adoption of electrical machinery, has been, however, the demonstration of the uncertainty new existing regarding the actual demand for power in cement production. Mr. Potter's statement concerning the good results which will inevitably follow careful investigation of this feature of cement works deserves consideration. Until it is known just how much power is required to operate the heavy machinery with different kinds of materials, it is out of the question to design the most economical electrical drives.

An Evidence of Civic Pride that deserves more than passing attention has recently been received from Frankfort-on-the-Main. The public works of this city have long been noted among engineers. The sewerage and water systems have been places of pilgrimage for twenty years, and the harbor works are among the most interesting in Germany. The city has been growing quite rapidly, and instead of allowing it to develop without restraint, a great deal of thought has been paid to the laying-out of all the suburbs. The pavement and methods of street cleaning are in keeping with the other public works, and taken all in all, there is probably no city in Germany which better repays examination by those interested in municipal works. This is so well known that a host of visitors connected with such affairs elsewhere go to Frankfort annually on inspection tours. These visitors have always been welcomed warmly and all possible information placed at their disposal. Nevertheless, the burden of supplying data to so many callers has been a somewhat serious matter and accordingly the city engineering department has prepared an excellent guide to all the public works under its charge. This has been published in an attractive form, editions being available in English, French and German. Such a book not only saves the members of the engineering staff of the city a considerable amount of time in answering the general inquiries of visitors, but it also insures to the latter absolutely accurate information free from defects that might creep in when general statistics are compiled hastily. The book is particularly interesting because it is printed by the city for free distribution to all who are interested in the Frankfort undertakings. It indicates a pride in the works built at the expense of the municipality which is rarely shown so clearly. There are a number of cities in this country which have public works of high character. Boston, for instance, contains many undertakings of this sort, and yet even Boston, noted for its municipal self-esteem, has not been so proud of its excellent engineering works that it has been willing to spend a few hundred dollars preparing a guide to them for the many visiting officials of other cities.

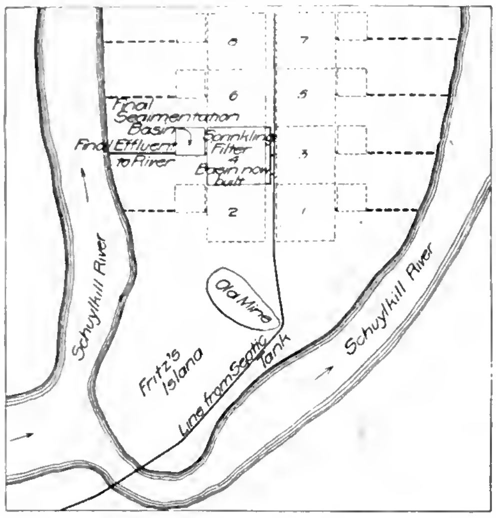
THE SEWAGE PURIFICATION PLANT AT READING, PENNSYLVANIA.

The city of Reading, Pa., is at present completing part of an interesting sewage purification plant which is the nucleus of an extensive system to be developed as the needs of the city require. The new installation consists of a sewage screening device, a septic tank, a sprinkling filter and a final settling basin.

The purification of the sewage of Reading was begun about 12 years ago when the present separate sanitary sewerage system was built. The system drained by gravity to a pumping station on the banks of the Schuylkill River in the lower part of the city and was pumped about 6,600 ft. to a filter plant. The treatment of the sewage was begun at the end of the gravity system and before pumping, by being passed through a 12-in. straining layer of fine coke, held in place by iron screens. The filter had two decks, one above the other, each deck having an area about 50x250 ft., the upper deck being supported about 10 ft. above the lower by an iron framework. The filtering material on the decks consisted of layers of graded slag, covered with sand. The sewage was thoroughly aerated by dropping freely through the air some 10 ft. to the lower bed. The results with this combination of a screening device, and double filtration accompanied by aeration are stated to have been quite satisfactory at first, the effluent being clear and of a good sanitary quality, but as the amount of sewage increased owing to new house connections to the sewers and the use of the coke strainers was discontinued, the filter became overtaxed, and required a great deal of attention to relieve clogging of the surface.

In 1905 the city contracted for the construction of about 60 additional miles of sewers, and in consequence the purification problem again became prominent, the more so, too, because the Department of Health of the State of Pennsylvania by an act of the Legislature had been given supervision of the discharge into rivers of the effluents of all sewers built after the passage of the act. Since the city was unable to issue bonds for the construction of the additional purification works, it was decided to call for bids for the construction and operation by a contractor of the necessary plant. The proposed contract was for a 5-year period, the compensation being a fixed sum which was to cover both the operation and the construction of the additional purification plant and the operation of the present pumping station. Mr. O. M. Weand, a Reading contractor, offered the only bid.

Study of the Problem.—Before the contract was closed the city decided to have the sewage problem thoroughly studied in order to determine the most efficient and economical purification system for the local conditions, and accordingly Messrs. Hering & Fuller, of New York, were retained as consulting engineers in March, 1906, acting in coöperation with the city engineer, Mr. Elmer H. Beard. Mr. S. J. Lewis was the assistant engineer in immediate charge. The investigation was begun at once and a small but well-equipped laboratory for making chemical and bacteriological analyses was installed by the city for the prosecution of the work. It included a study of the composition and quantity of the sewage, the performances of the old filter and of the devices suggested by Mr. Weand, when operated separately and in combination, and a comparison of these data with practical experience in purifying similar sewage elsewhere.



Plan of Filter Beds.

The average volume of sewage was about 2,000,000 gal. per 24 hr., at the time of the report of the city and the consulting engineers in July, 1906, and at times of very wet weather increased to about 2,750,000 gal. The sewage was found to be quite dilute, and was essentially of a domestic nature, though mixed with a limited quantity of trade wastes. A further investigation has also been made of these wastes, and it has been determined which shall receive preliminary treatment before being admitted to the sewers, and which may be admitted without such treatment, those requiring treatment being such as would interfere with the normal operation of the purification devices. The average composition of the sewage in parts per million was found to be as follows: Oxygen consumed 40, chlorine 100, total suspended matter 113, of which 78 parts were volatile and 35 parts fixed. About 40 per cent. of the organic matter was in suspension, and about half a part of nitrogen was found as nitrates. The average bacterial content was 2,200,000 per cubic centimeter.

Results of the Experiments.—In order to study the old filter part of it was restored to its original condition with fresh material. Both the upper and lower beds consisted of a 4-in. layer of 2 to 3-in. slag, 1 in. of ½-in. slag, 2 in. of ⅛ to ¼-in. pebbles, and 12 in. of clean, sharp, washed sand of medium size, the layers being in the order named starting from the bottom upwards. Raw sewage was applied to the upper bed at a rate of 1,000,000 gal. per acre per 24 hr., the rate which the filter was expected to handle when it was designed. Though the sewage was quite dilute, it was found difficult to operate the filter at this high rate. The effluent was nonputrescible and fairly clear, the suspended matter averaging 19 parts per million or 13 per cent. of the content of the applied sewage, the organic matter being reduced 74 per cent., and the nitrates increasing from 0.5 to 3.2 parts per million. The bacterial removal was from 66 to 76 per cent., and the liquid was almost saturated with oxygen both before and after its passage through the lower bed. The sewage was applied intermittently, 4 hr. periods of dosing and resting giving best results.

Sprinkling Filter for Sewage Purification, Showing Distributing System and Drains.

With this rate it was necessary every two or three days to remove a slimy deposit, ⅛ in. thick, from the surface of the upper bed, amounting to about 41 cu. yd. for each million gallons of untreated sewage that was filtered. The conclusion reached by the engineers was that the cost of maintenance was too great, even though the effluent was good, a conclusion agreeing with the general feeling that the sewage applied to filters should first be freed of the greater part of the suspended matter.

The preparatory devices proposed by the contractor consisted of two moving screens fastened together, one of 80 and the other of 40 meshes to the linear inch. For test purposes such a screen of brass cloth was built, together with a

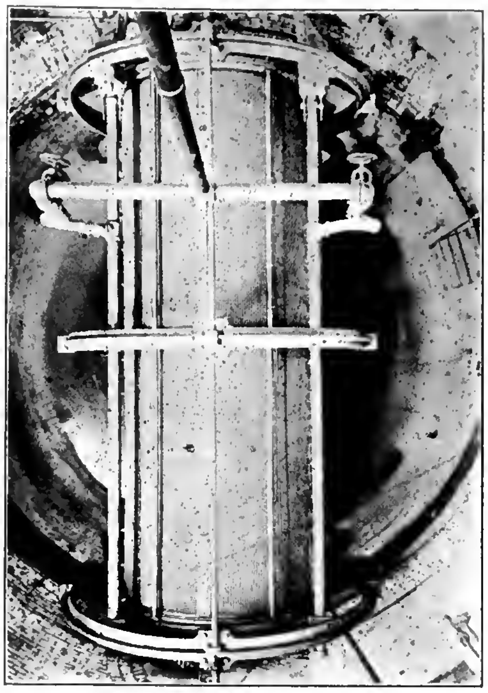
box or flume about 3 ft. deep, 10 ft. wide and 40 ft. long filled with coke. The sewage was passed onto the screen and fell through to the flume, the fine screen retaining quite a quantity of coarser suspended matter, a portion of which was discharged at one end of the screen. The suspended matter remaining on the screen was removed by steam jets. The volume of wet sludge, containing 73 per cent. of water, averaged about 1/3 cu. yd. per million gallons of sewage treated. The rate of application of the sewage to the screen was limited only by the quantity that can be treated by the coke strainer and the filter. The total suspended matter removed by the screen which has been locally termed a "segregator," was 20 per cent., and by the segregator and coke strainer combined 47 per cent.

When the filter was worked with the sewage already treated by the preparatory devices just discussed, the highest rate found advisable was the same as when the filter was treated with raw sewage, 1,000,000 gal. per acre per day, but the clogged material removed from the sand surface averaged but 11 cu. yd. per million gallons treated. The effluent was practically of the same quality as obtained when the filter was treated with raw sewage, the benefit of the preparatory devices being found in the reduction by about 75 per cent. of the clogged sand which must be removed.

Plan Recommended.—The report of the city and the consulting engineers, made to the Board of Public Works, after comparing purification experiences at Reading and elsewhere, finally recommended the following plan. 1. The sewage should first be thoroughly screened, the removal of the fibrous materials in certain of the local trade wastes being a special reason for so doing. 2. The well-screened sewage should be further treated by straining through coke or by sedimentation in a septic tank to remove still more of the suspended matter, the septic tank, in proportion to the work done, being much the cheaper of these means. 3. The aeration of the sewage effected by the double-deck filter is very important, but for economical reasons should be done by means of sprinkling filters, the filtering material being not less than 5 ft. thick and the particles not smaller than 1/2 in. 4. There should be sedimentation in shallow basins, holding one or two hours' flow in order to remove the scales of deposited material which have dried and peeled off the coarse filtering material.

This system is expected to produce a non-putrescible effluent and remove 90 per cent. or more of the bacteria in the original sewage.

The engineers further recommended that the present filter be dismantled and the framework be used in constructing a septic or settling tank for preparatory treatment, that the upper portion of Fritz's Island lying in the Schuylkill River half a mile below the old plant be purchased by the city as a site for the sprinkling filters, and that a contract be executed with Mr. Weand for the construction and operation of the purification plant.



Top View of Segregator, Looking down into Well.

Piping and Valves for Automatic Device for Dosing Filter Bed.

In accordance with these recommendations the contract with Mr. O. M. Weand was executed, which requires him to provide eventually for purifying a maximum of 7,000,000 gal. of sewage per day, to contsruct a second filter bed as soon as the increase in house connections demands it, and to operate the purification works and pumping station for five years. The contractor is to be paid a fixed sum yearly, and at the expiration of the contract the new works constructed and the improvements made revert to the city.

Accordingly the pumping plant in the city and the old filter were turned over to the contractor, and the new works commenced. The quantity of sewage to be treated at present requires the construction of only one bed, with an area of one acre, it being estimated that this will produce a non-putrescible effluent with a maximum rate of 3,500,000 gal. per acre per day, with the present dilute condition of the sewage during wet weather.

Pumping Plant and Screening Device.—The sewage pumping plant, to which the sewers drain by gravity, is located on the bank of the Schuylkill River in the lower part of the city. It has been used continuously since the installation of the original filter plant until the operation of the latter was discontinued on account of the new construction. The building contains an engine room, boiler room, and two wells, 20 ft. in diameter in which the coke strainers of the former purification system were located. In one of these wells the new rotating screening device, called a "segregator" by the contractor, has been installed, the other well being idle and reserved until such time as the quantity of sewage will make it necessary to duplicate the present apparatus.

The segregator, which has been patented by the contractor, consists of a screen 6 ft. in diameter and 16 ft. long, which revolves about a horizontal axis. The screen proper is of brass wire cloth, 40 meshes to the linear inch, which is fastened to a heavier "body" screen of 3/4-in. mesh galvanized iron wire by being soldered at intervals of about 6 in. in each direction. The revolving frame consists of three heavy cast iron rings, one at each end and one at the center of the screen, held in position by six 1 1/2-in. extra heavy pipes, through which bolts have been passed and screwed up tight. These rings carry iron strips, running the length of the barrel, which divide the circumference into eight segments, and carry bolts for attaching the removable strips holding the 40-mesh screen in place. The latter is made in these small segments so as to be easily removable to facilitate repairs, while the heavy body screen is in three pieces and attached permanently to the revolving frame. The latter revolves on the three heavy rings, which bear on six 12-in. cast iron wheels, two being attached to each of the three stationary rings, constituting the stationary frame of the segregator, and concentric with the heavy rings of the revolving element. The wheels on each ring are placed a short distance on either side of the lowest point of the screen, and a third 12-in. wheel at the top of each ring serves merely as a guide. The heavy rings of the stationary frame are held in position by three 1 1/2-in. extra heavy pipe, with bolts through them, as described for the revolving frame.

Attached to the outer rings on each side of the top of the screen are hangers carrying two 3-in. pipes, to each of which 15 cleaning jets are at-

tached, for directing water, steam or air against the outside of the screen. The jets are on 10-in. centers, and the two header pipes are made to travel 12 in. laterally, so that the travel of each jet overlaps 1 in. on the travel of each of its two neighbors, assuring the thorough cleaning of every part of the screen. The header pipes are connected to the stationary pipe by flexible pressure hose. The cleaning jets are 3-32 in. in diameter and can be operated under any perssure up to 200 lb. per square inch, though it is expected that 20 lb. will be sufficient to wash the sludge from the inside of the screen. Valves are provided to supply the jets with water, steam or air, or all three or any two of these together. The condenser water will generally be used, the heat helping to remove the sludge on the screen. The segregator makes 3 r.p.m., the power being transmitted by a link belt from a 2½-h.-p. engine.

The sewage enters the revolving screen at one end through a 24-in. main, the center of which is in the axis of the screen. A circular baffle plate 8 in. beyond the end of the pipe breaks the flow and spreads it to the circumference of the screen. The cleaning jets operating under pressure will loosen the sludge, which otherwise would clog the fine mesh, and thus a clean screening surface is always offered to the raw sewage. The sludge, gradually working to the open end of the screen opposite the sewage inlet, will be caught by a bucket conveyor and raised to the floor of the station, where a spiral conveyor will carry it to a hopper, to be discharged into bags. These bags will be placed in a Shaum & Uhinger centrifugal wringer, with a 42-in. basket, making 800 r.p.m., and the liquid forced out of the sludge. The latter will then be sold for fertilizer or mixed with coal for use as fuel, tests showing that it burns well.

The steam plant contains three 60-h.-p. Orr & Sembower boilers, two combined circulating and air pumps for the condenser, and two duplex compound-condensing plunger-pattern Snow pumps of 5,000,000 gal. capacity each.

From the pumping station the sewage, after passing through the segregator, is forced through 6,600 ft. of pipe to the septic tank located on the other side of the Schuylkill River at Millmont. The first 250 ft. is of 36-in. cast iron pipe, the next 450 ft. under the river of 30-in. pipe, and the remainder of 20-in. pipe.

Septic Tank.—The septic tank occupies the site of the former filter and utilizes part of the iron framework of the latter. Its elevation is such that the flow through the succeeding stages is entirely by gravity, even to the final discharge of the purified effluent into the river. The tank is not covered, measures 51 ft. 8 in. by 253 ft. inside and is 17.35 ft. deep. The sewage will normally stand 1 ft. below the top of the wall, and at that stage the tank will have a capacity of about 1,600,000 gal., giving an average period in the septic tank for a 3,000,000 gal. per day flow of about 12¾ hr. and for a 7,000,000 gal. per day flow of about 5½ hr.

The tank is of reinforced concrete, the reinforcing consisting of round rods, and the concrete of a 1:2:4 mixture, using Lehigh Portland cement, and slag, with a maximum size of 1½ in. The sewage enters the tank at one end through a 14-in. riveted steel header about 45½ ft. long, supported by two concrete columns, and the 20-in. vertical pipe, through which the sewage comes through the floor of the tank and enters the header. Twelve 5-in. holes 45 deg. below the horizontal are cut into the header, spaced 3½ ft. on centers. The header is 11 ft. above the floor and about 6 1-3 ft. below the top of the wall.

The outflow is over a timber weir and into a trough at the end of the tank opposite the inlet header, the crest of the weir being 1.15 ft. below the top of the wall. The weir and trough run the width of the tank and are supported by timber posts and by the 24-in. vertical effluent pipe, which is bolted to the bottom of the trough. The latter, which is 2 ft. deep, is anchored to the walls by spikes driven into wooden plugs set in the concrete. A 2-in. scum board, with its bottom 1 ft. below the crest of the weir, is mounted 5 in. in front of the latter.

An overflow weir 32 ft. 3 in. long, with its crest 0.7 ft. below the top of the wall, has been built in one of the side walls near the discharge end of the tank, and is fitted with a scum board. An apron projects 10 in. so as to throw the overflow away from the wall. Four baffle walls 4 ft. high, being part of the old filter structure, extend across the width of the tank, dividing it into five equal bays.

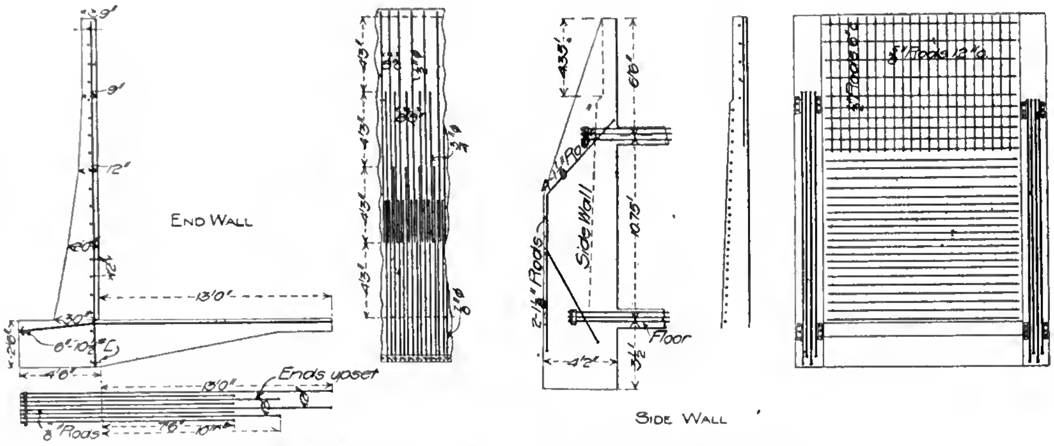
The side walls of the tank are 9 in. thick at the top and 18 in. at the bottom and are supported by reinforced buttresses 24 in. wide, spaced 12 ft. 9 in. on centers. In addition to being supported by these buttresses the side walls are tied together in the planes of the buttresses by two sets of round steel tie rods anchored in the buttresses and enclosed in concrete, one set being placed in a concrete "beam" 12 in. deep, and 14 in. wide on the floor of the tank, and the other set in a "beam" of the same section, with its center 10½ ft. above the lower one. The portion of the side walls below the upper "beams" and 1½ ft. above them has horizontal reinforcement, the wall acting as a girder, with the buttresses as supports. The portion above the "beams" has vertical as well as horizontal reinforcement and is figured as a cantilever, the stress being carried to the lower part of the wall rather than to the buttresses directly. Each buttress encloses one of the cast iron columns of the framework of the old filter, and two similar columns and one concrete column support each of the upper "beams" at the quarter points of the width of the tank. The buttresses are 4 ft. 2 in. long from the inside of the walls.

The end walls are 30 in. thick at the bottom and 9 in. at the top and, not having any tie rods running between them, are supported by vertical reinforcing rods, which carry the stress as a cantilever to a reinforced toe extending 13 ft. inside the tank.

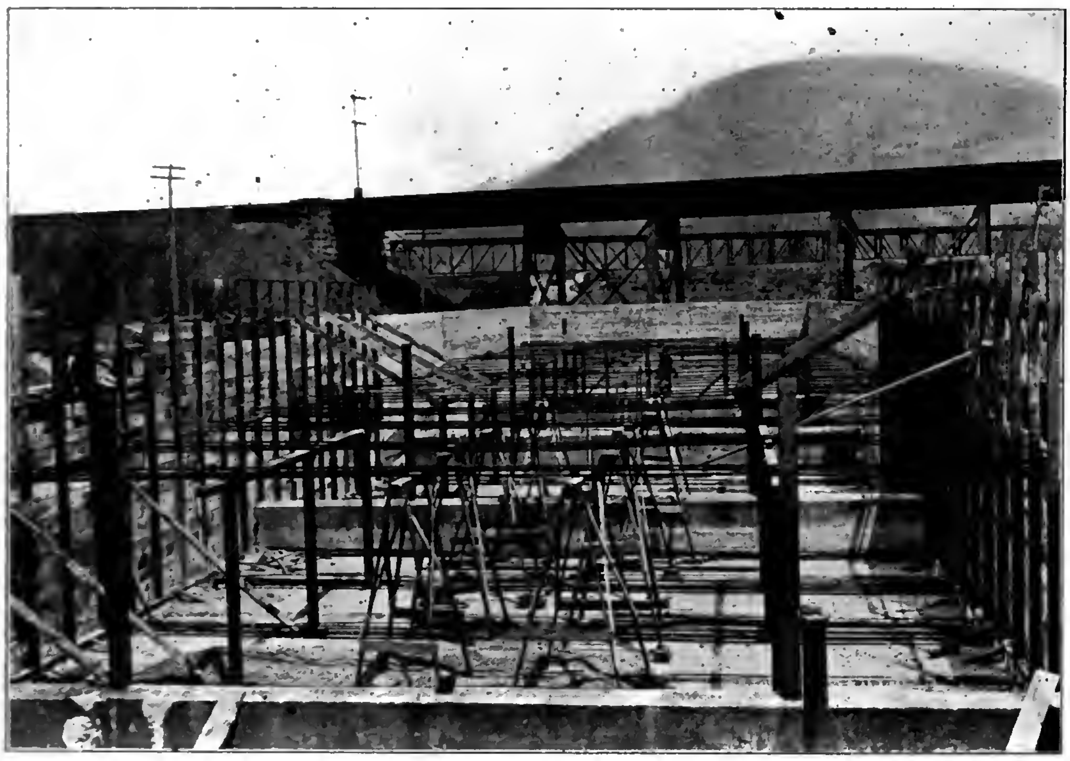
The horizontal steel in the end walls varies from ⅝ to 1 in. in diameter and is placed 12 in. on centers, while the vertical rods are ⅞, ¾ and ½ in. in diameter, spaced 3 in. at the bottom, not all of the rods running to the top of the wall. The rods in the toe are ⅞ in. on 3-in. centers and are anchored at the outer ends to 6-in. 10½-lb. channels.

The horizontal rods in the side walls are ⅞ and 1 in., with spacing varying with the height and diameter of the rods, from 5 to 7 3-16 in. The vertical rods are ½ in. on 6-in centers. In the upper, or cantilever, portion of the side walls are horizontal rods ⅝ in. diameter, spaced 12 in.

There are four 1⅛-in. rods in each buttress. In the lower tie "beam" there are four 1⅛-in. rods, and two ⅞-in. rods, anchored at both ends in the buttresses to 6-in. 10½-lb. channels. In the top "beam" there are four 1-in. rods and two ⅞-in. rods, anchored as in the lower "beam."



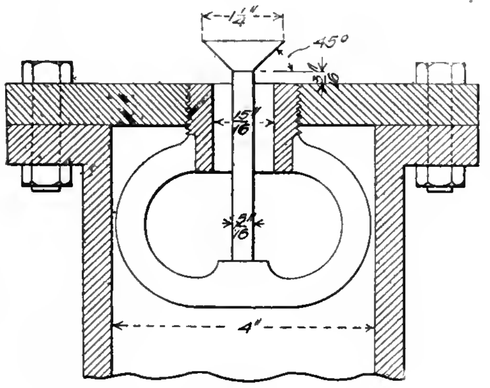
Reinforcement of End and Side Walls of Septic Tank.



Septic Tank under Construction, Showing Tie Rods Exposed.

The concrete was hand mixed and placed very wet in watertight forms. No water-proofing was applied, to insure water tightness. After the walls had been built, scaffolding was erected inside the tank for mixing the concrete for the "beams," and the materials delivered to it over runways extending along the top of the wall. A by-pass will be built around the tank so that the sewage can be diverted to the filters when the tank is being cleaned.

The effluent from the septic tank will flow under pressure, due to the elevation at which the tank is built, to the filter beds, about 2,500 ft. beyond. The pipe will be laid under an independent contract and will pass under a small creek and the smaller branch of the Schuylkill



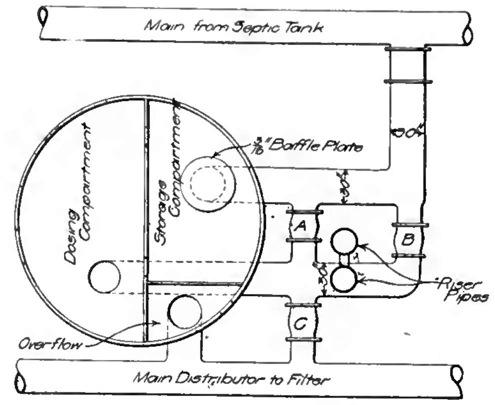
Sprinkling Nozzle for Filter.

River, the filter beds being on an island. The pipe will be 30 in. in diameter, built of concrete.

Filter Plant.—The site of the filter plant is a 30-acre tract on Fritz's Island, which slopes downward, looking up the river and to both sides, so that the effluent can readily be discharged into both branches of the stream. The situation is almost ideal for a filter plant, the more so because it lies considerably below the septic tank site. The highest part of the area is 12 ft. below the weir level and 17 ft. above the river at normal low water and slopes gently toward both branches. The filter floor is 8 ft. lower, the excavation on the area covered being from nothing to 5 ft. The ground has been laid out for eight beds of one acre each, four on either side of the 30-in. main from the septic tank. Each bed will have a separate dosing apparatus and a final settling basin, the latter being placed on the lower side, away from the filter influent main, so as to be filled by gravity from the bed. The settling basin in turn will discharge by gravity into the river. At the present time only one bed has been built, and it is so far completed that it can at any time be put in operation in a few hours. The work now waits on the completion of the pipe from the septic tank.

The filters are of the sprinkling type, the nozzles operating under a head varying from 7 to 2 ft., so as to distribute the sewage uniformly over the area served by each nozzle. The circumference of the spray is at its maximum under the highest head and gradually diminishes to about 3 ft. circumference. When the head drops to 2 ft. the flow ceases and the bed rests from 2 to 4 min., after which sprinkling again commences under a head of 7 ft. The filtering material is a 6-ft. bed of blast furnace slag, varying in nominal size from 1½ to 4 in. The bed as it now stands is 5 ft. thick.

Dosing Apparatus.—The dosing apparatus, which automatically controls the flow of sewage to the nozzles, is located between the main from the septic tank and the filter bed midway of the side of the latter. It consists of an elevated wooden tank 19 ft. in diameter divided by interior walls into three compartments of unequal size, the flow into and out of which is controlled by three butterfly valves operated by floats. The largest compartment is called the dosing compartment, the next in size the storage compartment and the smallest the overflow compartment. A 30-in. riveted steel pipe connects with each compartment through the bottom of the tank. The sewage coming from the main from the septic tank flows through a 30-in. pipe at right angles to the former and then into another 30-in. pipe parallel to the side of the filter bed. This pipe terminates in the storage compartment, which is always open to the flow from the septic tank. Two butterfly valves are placed between the pipe leading to the storage compartment and a parallel one to the dosing compartment. A third butterfly valve is interposed between this latter line and the main distributor to the filter, the latter being

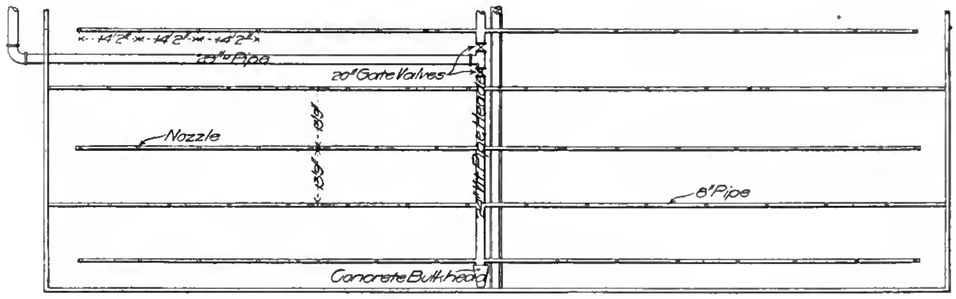


Dosing Apparatus.

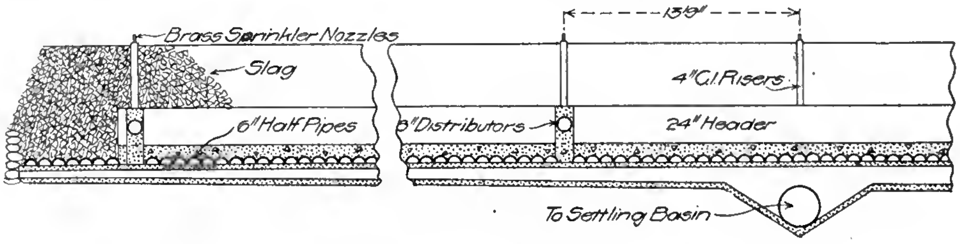
likewise connected to the overflow compartment by a short length of pipe. Cast iron riser pipes, containing the floats which operate the valves, are connected by 8-in. nipples to the 30-in. pipe leading to the dosing tank. All of the piping is of 3-16 in. riveted steel, except the float pipes. The valves are 20 in. in diameter.

The operation of the apparatus is as follows, the valves being described by the letters on the accompanying diagram: Starting at a time when there is no flow from the nozzles, valve A is open and B and C are closed. The sewage is then filling both the dosing and storage compartments, the level being the same in both, since they are connected through valve A. As the water rises valve B gradually opens, and when the compartments are full, equal to a head of 7 ft. on the nozzles, B is wide open, A closes and C opens, allowing the compartments to drain onto the beds and also the sewage to flow through valve B directly from the septic tank. When the head on the nozzles has dropped to 3½ ft. valve B closes, shutting off all connection between the septic tank and the nozzles and allowing the storage compartment to refill. The discharge from the dosing compartment continues until the head on the nozzles is 2 ft., when valve C closes and A is opened, restoring the starting condition. A weir is provided between the dosing and overflow compartments to allow a discharge in case the sewage rises over 7 ft. above the nozzles. The cycle of operations described will take from 7 to 8 min., the interval of rest being from 2 to 4 min. of this period. A patent on the apparatus has been applied for by the contractor, Mr. O. M. Weand.

Filter.—The filter bed is rectangular and covers exactly one acre. The main distributor, consisting of a 30-in. glazed tile pipe, runs 46 ft. each side of the dosing apparatus and connects at one end with a 30-in. glazed tile pipe and at the other with a reinforced concrete pipe 28 in. square, both of which run to the center line of the bed. Here they connect with a 24-in. vitrified tile pipe header, which runs the full length of the bed and has in it four valves, one on each side of the two influent main connections, so that each valve can cut off one-fourth of the bed when it is desired to give it a rest. From this header, every 13.7 ft., the 8-in. vitirified tile lateral distributors are taken off, extending at right angles to the header. The 4-in. cast iron pipe risers which carry the sprinkling nozzles are set vertically in tees at intervals of 14 ft. 2 in. in the laterals, the risers on adjacent laterals being staggered. The tops of the risers are 5 ft. above the axes of the laterals and about 1 ft. above the persent top of the slag.



Plan of Filter Distributing System.



Section through Filter Bed at Main Drain.

The main and lateral distributors and the header are built on concrete foundations, which for the 8-in. laterals are carried half way around the pipe on each side. All the joints are made with cement mortar. The laterals are joined to the header by cutting a hole through the latter, inserting the lateral and building around the connection a concrete ring about 4 in. thick, reinforced on each side of the smaller pipe with a ⅜-in. rod passing around the header pipe. About half of the cast iron riser pipes are set in the vitrified tile laterals with cement mortar and the other half with Pottsite, and a pier of concrete is carried up around each joint to a point 10 in. above the top of the lateral. A heavy concrete bulkhead at each end of the header takes up the thrust and relieves the cement joints of strain.

The sprinkling nozzles are of the stationary type, a modification of those adopted for the Columbus purification plant, and consist of an inverted frustum of a cone, carried by a rod passing through and in the center of a 15-16 nozzle orifice. The cone slopes 45 deg., is 1¼ in. in diameter across the top and is carried by a 5-16-in. rod, the junction of the rod and cone being 3-16 in. above the plane of the orifice. The cone,

rod and orifice are of brass and are set in a cast iron plate, which is bolted to the top of the riser with the aid of lugs cast onto the latter. A gasket insures a tight joint. This nozzle was adopted by Mr. Weand after numerous experiments.

The effluent drainage system is built on the floor of the filter, which consists of 4 in. of 1:3:6 slag concrete made with Lehigh Portland cement. The floor slopes 1 ft. from the two sides parallel with the distributing header to the center of the bed, and on it at right angles to the header were laid standard bell end 6-in. vitrified tile pipe split in halves longitudinally and placed with the convex sides up on 10-in. centers. A thin cement mortar was used to bed them well on the floor. The joints between the half pipe were laid open, so as to allow ready access for the effluent, and the pipe was covered with 5 and 6 in. pieces of slag, hand placed.

The half pipe drains to a longitudinal concrete trough parallel to and immediately to one side of the distributing header. The trough is 2 ft. wide, 4 in. deep at the ends and 12 in. deep at the center of the bed, so as to get a good slope for drainage. It is covered with concrete slabs 36 in. wide and 4 in. thick, supported above the half pipe on concrete sills. The main effluent drain connects at right angles with the trough at the center of the bed and runs beneath the filter floor to the final sedimentation basin. It is a 30-in. pipe, made of moulded segmental concrete blocks put together in place in the field with cement mortar.

The bed lies partly above and partly below the original ground level, and the sides in the excavation are built of rough stones plastered with concrete and cement mortar. Above ground the walls are vertical and of dry rubble for about 18 in. above the half pipe, and for the remainder of the distance to the top of the bed of large chunks of slag, having a batter of about 2 on 3.

The slag for the filter was obtained from an old blast furnace dump in Reading and was hauled to the site of the septic tank in bottom dump cars on the Philadelphia & Reading Ry. From this point wagons hauled it to the beds, where a dumping platform with inclined runways at each end was built at the level of the tops of side dump cars running on a track of 30-in. gauge. This track was shifted to different parts of the bed, a turntable being installed when needed. Three spurs were built at the dumping platform so that three cars could be loaded at once. On account of the large quantity of slag required a convenient dumping arrangement was built for the railroad to discharge the slag at the septic tank. The track was carried across on concrete piers, between which was an inclined timber apron that threw the slag out upon a loading platform, built at the height of the bottom dump contractors' wagons, which carried the material to the filter.

The slag was broken to size by hand and screened with forks.

Final Sedimentation.—The final sedimentation basin, built in excavation, measures 100 ft. by 95 ft. 9 in inside the slopes, which are 1 to 1. Its depth is 4 ft. at the end nearest the filter and 5 ft. at the end toward the river. Since the object of the basin is to allow the sedimentation of the coarse flakes of dried material that have peeled off the slag of the filter bed, it is made quite small, the capacity being about 340,000 gal., sufficient for about 2¼ hr. flow at the maximum capacity of the bed of 3,500,000 gal. per 24 hr.

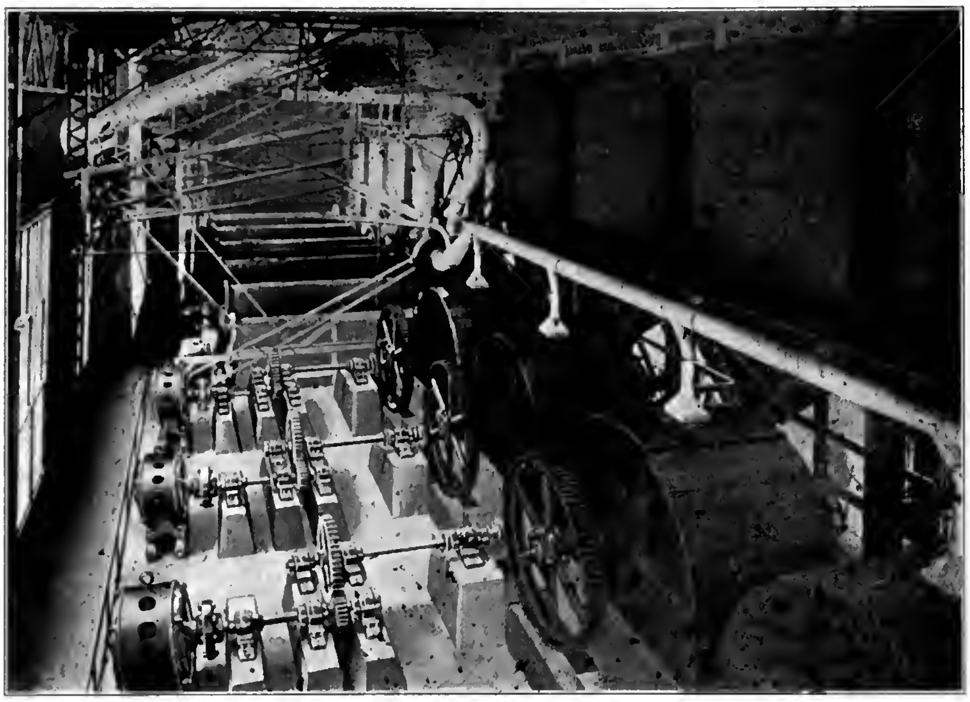
The basin is built of a layer of brick and cobble stones laid on the gravel and loam bed uncovered by the excavation and is plastered with cement mortar to make it tight. The effluent from the filter enters the basin through four ports, or openings with straight vertical sides, from a 30-in. concrete block pipe. It leaves the basin over a concrete weir extending the entire width of the side nearest the river and is then discharged into the stream. A 30-in. pipe by-pass, also of concrete blocks, allows the effluent to be discharged directly from the filter bed to the river.

The plant is being built by Mr. O. M. Weand, of Reading, under the direction of Mr. Elmer H. Beard, city engineer, and Messrs. Hering & Fuller, of New York, consulting engineers. Mr. A. L. Dabney is the representative on the work of the consulting engineers.

Electric Motors for Cement Mills.

By R. B. Williamson.

For driving the various machines used throughout a cement mill, electric motors are now almost universally employed, especially in the more modern mills, such as those for which Allis-Chalmers Co., of Milwaukee, has built and installed the complete equipment, the electric drive having here the same advantages of flexibility and economy that have been demonstrated in so many other lines of work. The elimination of belting and countershafting is specially desirable in a cement mill, where the gritty dust makes the maintenace of belts and bearings expensive.



Induction Motors Driving Ball Mills.

In some mills, particularly those located in the West, power is purchased from transmission companies, but usually each mill is provided with a steam plant of its own. In either case the alternating current system is almost invariably used in modern installations and it may be either 60 or 25 cycles, two or three phase. Although direct current has been used in a few cases, the present practice is to use alternating-current motors almost exclusively for this class of work. The polyphase induction motor has many advantages, not the least of which is the absence of commutator and brushes. The cost of maintenance is less than for direct-current machines, and in the dusty atmosphere of a cement mill, the simple "squirrel cage" rotor of an induction is much less liable to give trouble than the wound armature of a direct-current machine.

In these mills the motors are used for operating rock crushers, ball mills, tube mills, rotary kilns, hoists, conveyors, pumps; in fact, for all the machines used throughout a modern cement plant. In most instances the motors are run at or near full load continuously, and the service as a whole is specially severe. In nearly all cases they are of the squirrel-cage type with short-circuited secondary, a type that necessarily operates at constant speed. For variable speed work the induction motors are provided with a wound rotor, connected, through collector rings and brushes, to an external resistance. By this means the speed can be varied at the expense of lower efficiency. However, collector rings and brushes are undesirable features when exposed to cement dust, and these motors are used as little as possible; they are installed occasionally for operating rotary kilns where a variation in speed is sometimes desirable, and also for electric hoists; but for practically all other classes of work constant speed squirrel-cage motors are preferred.

Probably the most severe service is that demanded of motors for running ball and tube mills. These mills are used for grinding the raw material before calcining, and also the clinker from the rotary kilns. For driving the ordinary size ball mill a 50-h.-p. motor is required, while for a 5x22-ft. tube mill a 75-h.-p. motor is usually installed; a 5½x22-ft. tube mill requires about 95 h.-p. and a 6x22-ft., 115 h. p.; the 5x22-ft. mill is the size generally used.

Ball and tube mills, especially the latter, are difficult to start. The material clings to the sides of the mill, particularly in the tube mill, where pebbles are used to effect the grinding, and at starting the whole mass has to be swung up until the first half revolution has been made. This demands heavy starting torque, usually amounting to one and a half to two times full-load torque. It is desirable, therefore, to use for these mills a motor having starting torque higher than for ordinary service; if this is not done, the motor will take an excessive current at starting, or, if the voltage drops to any great extent, the motor may even fail to start the mill at all. Motors for this service must be of liberal size to give the requisite starting torque and also operate continuously at full load in a dusty atmosphere, without undue rise in temperature. It must be remembered that in cement mills the fine dust gets into the ventilating passages in the motor, and they may in time become clogged up, thus materially increasing the temperature rise.

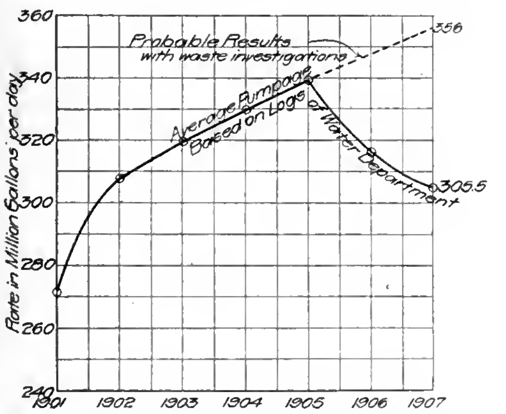
The starting apparatus used with these motors must also be of liberal design in order to carry heavy starting currents. Sometimes the mills are started by throwing the current off and on, giving them two or three swings until they

finally turn over. This is especially hard on the stator and should not be necessary if the motor has ample starting torque. All starters have oil immersed switches for changing the connections from "starting" to "running," and transformers are provided so that a reduced voltage can be applied to the motor at starting, thus reducing the current taken from the line. For this severe starting service where the motors are frequently operated by an unskilled class of help, the starters can be fitted with a device that prevents the handle from being left on a starting position; if left on a starting position it at once returns to the off position, thereby preventing a burn-out of the starter.

Motors for operating these mills are usually belted and run at moderate or slow speed. On 60 cycles, 50-h.-p. motors running at approximately 850 r.p.m. full load have been used for ball mills, but a slower speed motor is more desirable and 670 r.p.m. machines are now recommended. On 25 cycles, four-pole motors running at approximately 700 r.p.m. full load are used.

For 5x22-ft. tube mills a 75-h.-p. motor running at 670 r.p.m. full load on 60 cycles is suitable, while on 25 cycles speeds of 700 or 470 r.p.m. are available, the latter being preferred. Motors are belted directly to the main driving shaft on the mill from which the latter is driven through spur gearings.

As regards voltage and frequency, the majority



Average Total Primary Pumpage in Philadelphia for First Four Months of Year.

of cement mills are operated on 440 or 550 volts and frequencies of 60 or 25 cycles. Although there are instances where 2,200-volt motors have been used, the lower voltages are preferable on account of the greater security of the insulation on the motors and greater safety in working around them. There does not appear to be any settled practice as regards frequency, either 60 or 25 cycles giving satisfactory results; in many cases the frequency is fixed by that of the transmission system from which power is obtained and most plants supplied from such systems are operated at 50 or 60 cycles.

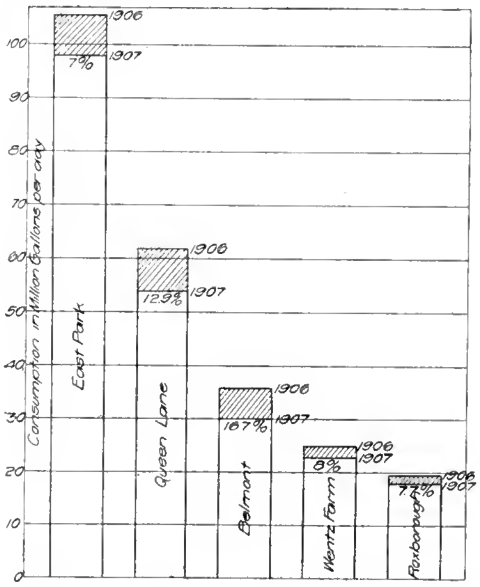
As regards mechanical features, it is important that the bearing sleeves be arranged so that they can be readily removed and relined. All bearings are made as dust proof as possible by means of felt dust guards, and journals are of liberal dimensions.

A New Use for Motor Boats has been found by the Austrian War Office, which is experimenting with them as substitutes for the iron pontoons used in constructing military bridges. Experience has shown that in building pontoon bridges much time is often lost because the pontoons break loose and must be towed back to position. With motor boats much time can be saved. These boats can be carried on wagons fitted with an inclined plane and a windlass so that the boats can be easily launched and taken out of the water.

Waste-Water Investigations in Philadelphia.

The Bureau of Filtration of the city of Philadelphia started under Major Cassius E. Gillette a broad series of waste-water investigations, which, during the past 20 months that the work has been in progress, have produced a number of exceedingly valuable results. The investigations were undertaken chiefly to determine the following conditions: First, to measure the amount of water delivered by each pump in the large stations in order to find whether the pumps were being operated economically; second, to ascertain whether the reservoirs were leaking; and third, to determine just what becomes of the water after it leaves the reservoirs.

Some work has been done along all of these lines. The investigations of the condition of the various pumps in the large stations were specially far-reaching, and showed that by making comparatively slight repairs the capacity of the pumps could be increased materially. The leakage from the reservoirs was found to be a very small percentage of the total quantity of water pumped. An imperative necessity for detailed waste in-



Decrease in Total Consumption of Five Districts.

vestigation in West Philadelphia and a lack of time prevented any of the extensive tests necessary to trace the entire output of water after it leaves the pumping stations. Although the investigations have been only well started it has been decided to discontinue them for the present, for reasons entirely foreign to the work itself.

The measurements of water were made throughout the investigations with pitometers. During the first year the work was done by representatives of the Pitometer Co., but since January 1, last, it has been under the supervision of the Bureau of Filtration, although conducted by experts formerly connected with the Pitometer Co. The photographic records of flow made by the pitometers and the analyses of these records furnish a great volume of interesting data, but an attempt will be made here to merely outline the results that have been secured.

Pump Tests.—The various pumps in all the large stations were tested to determine the relation between the amount of water actually pumped and the amount indicated by the pump registers, or, in other words, the percentage of slip. The actual quantity of water pumped by each unit was determined by measuring the flow through the discharge pipe of the unit with a pitometer, the duration of the tests ranging from 1½ hr. to 24 hr. In most of the original tests, however, records extending over 12 to 24 hr. were obtained; the shorter time tests were usually conducted to check those of longer duration. The amount of slip found in the various pumps tested varied from 3 to 72 per cent. of the registered pumpage. The amount of slip in all the pumps in the city was estimated, from the practically complete results obtained, to average 25 per cent. of the total registered pumpage. That is to say, the amount of water actually supplied to the city is about 75 per cent. of that shown by the pumping records to be furnished.

The results of a typical series of these pump-slip tests are shown in the accompanying Table 1, which covers a number of records made in testing the pumps in the Spring Garden station. The test of the No. 2 unit in this station, a 30,000,000-gal. Holly vertical triple-expansion outside-packed plunger pump, made Sept. 4, 1906, is worthy of special consideration. The actual quantity of water delivered by this pump, as shown by the 24-hr. test, was only 35 per cent. of the calculated displacement; a 12-hr. test of this same unit made shortly afterward indicated that the slip had increased to 72 per cent., that is, the actual output was only 28 per cent. of the calculated. On investigation of the pump valves and valve chambers, it was found that a number of the valves were misplaced and the suction chambers choked to a considerable extent by rubbish brought down the river during a sudden rise in the latter just previous to the tests. No reflection can be cast on the management of the station, however, because the pump was not running lame and presented no outward indications whatever of its serious condition. After repairs requiring less than two days to make, the slip of this pump was reduced to approximately 10 per cent.

The tests of the crank and fly wheel 20,000,000-gal. Southwark Foundry pump, No. 5 unit, in this station should also be explained. This pump on four distinct tests showed a slip varying from 44 to 65 per cent. of the calculated displacement. After an overhauling requiring one day this slip was reduced to 28 per cent., thus increasing its actual discharge by 8,000,000 gal. per 24 hr.

A 30,000,000-gal. Worthington duplex pump was thoroughly overhauled in February and March, 1906. Soon after it had been placed in commission a pitometer placed on its discharge to determine its output showed a slip of 15 per cent. The pump was then shut down to find the cause of the trouble which proved to be a quantity of waste, blocks and so forth that had lodged in the suction chamber and clogged the valves. After this debris had been removed the slip was reduced to 3 per cent.

The results outlined in the table show that the slip of the pumps tested varies between wide limits, the variation often occurring in a very short period. For instance, a single storm in October, 1906, occasioned an increase of slip at the Spring Garden station of 5 to 10 per cent. in each of the pumps. In practically all cases where tests determined large percentages of slip the pumps were considered to be in serviceable condition, judging from the operation. These and many similar service conditions make apparent the necessity for frequent and systematic pump-slip tests.

Reservoir Gaugings.—The outflow from various reservoirs from which the distribution mains are supplied was gauged several times during the tests to obtain accurate data regarding the amount of water furnished to different parts of the city, in order to determine the best distribution of filtered water. The amount of leakage, if any, in the different reservoirs was also measured by pitometer gaugings on the inlet and outlet pipes. The results of these experiments in connection with the Wentz Farm reservoir showed an apparent leakage of 700,000 gal. in 24 hr. A 24-hr. test of the Queen Lane reservoir showed no measurable leakage; the same result obtained with the East Park reservoir.

The data obtained by the reservoir tests fur-

nished a good foundation for a general pitometer survey of the distribution system of the Philadelphia water works. The results also supplied a basis for an interesting comparison of the per capita consumption, which according to the annual reports of the water department, had increased from 100 gal. per day in 1895. to 233 gal. in 1904. After the waste-water investigations were started in September, 1905, the per capita consumption was reduced to 227 gal. per day, and in 1906 to 218 gal. In this connection, it should be noted carefully that these figures are based on registered pumpage, but according to the pitometer measurements showing the large percentage of slip in the pumps—and these measurements are doubtless within 2 to 3 per cent. of being correct—the registered pumpage does not represent the true consumption, although it does represent the true relative cost of pumpage for these years. By pitometer measurements the average daily per capita consumption for 1906 was 165 gal., and during the first part of this year it was 150 gal.

District Tests.—The distribution system of the water-works in the main portion of the city was divided into several districts. Some tests were made in these districts, but the latter were not subdivided and the waste in them carefully traced, owing to the immediate necessity for concentrating efforts to reduce waste in West Philadelphia, where a shortage of water had presented a serious situation. The tests made in these districts were carried far enough, nevertheless, to show that the night rate was disproportionately high as compared with the day rate, indicating a large amount of waste. Practically all of these districts were covered with factories, small residences and tenements. In seven of the districts the night flow was found to be from 70 to 86 per cent. of the day flow. While a few large consumers, such as railroad terminals and factories working day and night, accounted for a portion of the high night rates in one or two of these districts, most of the night flow in the districts was believed to be waste, or unmeasured consumption. The necessity for diverting all the efforts of the experts conducting the waste-water surveys to West Philadelphia to relieve the situation there prevented further work, however, on these districts in the central portion of the city. The flow in the supply lines of certain large consumers was measured, nevertheless, showing in a number of cases very high night rates. Instances were found where practically the entire flow in a pipe line supplying a district would be taken by a single consumer, the night rates frequently equalling the day rates.

West Philadelphia is a residence district with an estimated population of 180,000 and is supplied with filtered water from the Belmont slow-sand filtration plant. When the investigations were started in June, 1906, the consumption was 36,000,000 gal. a day, or 200 gal. per capita, making it evident that considerable water was being wasted. The actual daily capacity of the Belmont filtration plant was determined by accurate pitometer measurements to be only 32,000,000 gal., which is reduced to 29,000,000 or 30,000,000 gal. when the river water is highly turbid. Since the capacity of the filters was not equal to the total consumption, the extension of the district to be supplied with filtered water was dependent on the reduction of waste.

Investigations to locate the waste in the West Philadelphia section were undertaken in a most comprehensive manner. The section was divided into twelve districts, which were of varying size according to the ease of isolating them by cutting off different supply lines and connections of the distribution system. When the consumption of each of these districts had been measured separately with pitometers, it became apparent that the per capita consumption was approximately equally high in all twelve of them. It was also found that the night rates of flow were disproportionately high as compared with the day rates, which, together with the high rates of consumption per capita, indicated that waste was occurring in all parts of West Philadelphia.

In order to determine as nearly as possible the actual night rates of consumption, block by block, throughout the entire section each district was subdivided. This isolation of subdivisions was accomplished by operating the gate valves on the boundary of an area as large as it was possible to cover in a single night so the entire supply entered the area through a single main. The flow in this main was measured by a pitometer, giving the night rate of consumption in the district. This night flow was then localized by a process of elimination, reducing the size of the area, block by block, the time of closing each gate being noted. Each change of flow thus occasioned was registered on the photographic record made by the pitometer, so it was a simple matter to interpret this record later and to determine the rate of consumption for each block.

The results of these investigations showed that a house to house examination of plumbing should be made. Accordingly, on July 25, 1906, thirty men started to follow up the pitometer gaugings by inspecting the plumbing in the districts. Although this system of day inspections greatly reduced the waste, it did not curtail all of it, as is shown by the following typical instance. After the first day inspection of a pitometer subdivision of 7 blocks, the night rate of flow was 252,000 gal. per 24 hr., showing that while some reduction had been made the night rate was still high. A second subdivision was made and a special inspection of the service connections was carried on at night with aqua-phones; the connections causing waste were then shut off and were not turned on again until repairs had been made. After this special inspection the night rate of flow in the same subdivision was found to have been reduced to 143,000 gal. per 24 hr.

The result of the pitometer survey in West Philadelphia is shown by the accompanying tabulation of the average daily consumption in that section as measured at various times.

This survey made it possible in October, 1906, to supply filtered water to half of West Philadelphia not so supplied previously and since then nothing but filtered water has been furnished to that section of the city. The necessity for reducing waste over the entire city as rapidly as possible made it advisable to carry forward the investigations without waiting for a complete pitometer survey. Sixty men were, therefore, added to the staff of inspectors in November, 1906, and the inspection work is still in progress. Although this day inspection of plumbing will undoubtedly greatly reduce the waste, the experience has been that the pitometer gaugings permit it to be reduced to a minimum. It is notable that since the inspections were started many premises have been re-inspected and reassessed where no inspections had been made for years.

		Gals. per 24 hrs.
March,	1906	35,000,000
June,	1906	36,000,000

Checking Circular Weirs.—An adjustable circular weir is placed on the 20-in. discharge pipe of each of the filters at the Belmont plant. In order to determine the actual capacity of these weirs several of them were rated with pitometers. Tests of these weirs when the plant was discharging 19,000,000 gal. a day indicated that they were over-rated about 10 per cent.; several tests under a discharge of 29,000,000 to 31,000,000 gal. per day for the plant showed these weirs to discharge 5 per cent. less than their rating.

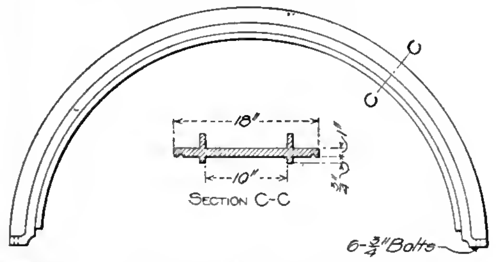
General Results.—In addition to results that have been noted as accomplished by this waste-water survey, many unexpected conditions of the water-works system as a whole, as well as the distribution system, have been revealed. The reduction in waste which has been accomplished is indicated by two accompanying diagrams. One of these diagrams shows the percentage of decrease in the total consumption of the five districts into which the water-works system is divided. The heavily shaded portion at the top of each of the areas representing the consumption for the different districts shows graphically the actual saving in that district, based on the average daily consumption for similar seasons in 1906 and 1907 from gaugings of reservoirs and main supply lines with pitometers. It may be noted that the greatest percentage of reduction was made in the district where the waste-water survey was most completely carried out, and the least, where

the smallest amount of survey work was done.

The second diagram is a curve showing the average total registered primary pumpage for the first four months of each year from 1901 to 1907, inclusive, this period being chosen in order to include the figures for the present year. Since this curve is based on the average registered pumpage, and the amount of water supplied to the city is actually 75 per cent. of these quantities, due to an average slip of 25 per cent. in the pumps, the points on the curve are all high. The curve as plotted, however, has the same general shape and represents practically the same percentage of saving, the registered pumpage values being taken in order to follow the logs of the water department from which the data was obtained.

The data from which these notes have been compiled was furnished by the Bureau of Filtration of Philadelphia, Mr. Fred C. Dunlap, chief engineer, and by representatives of the Pitometer Co.

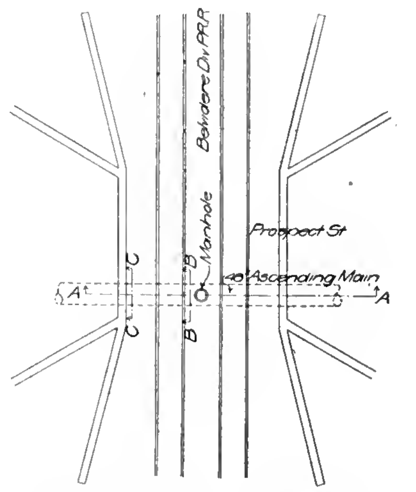


Cast-Iron Sleeve for Reinforcing Water Main.

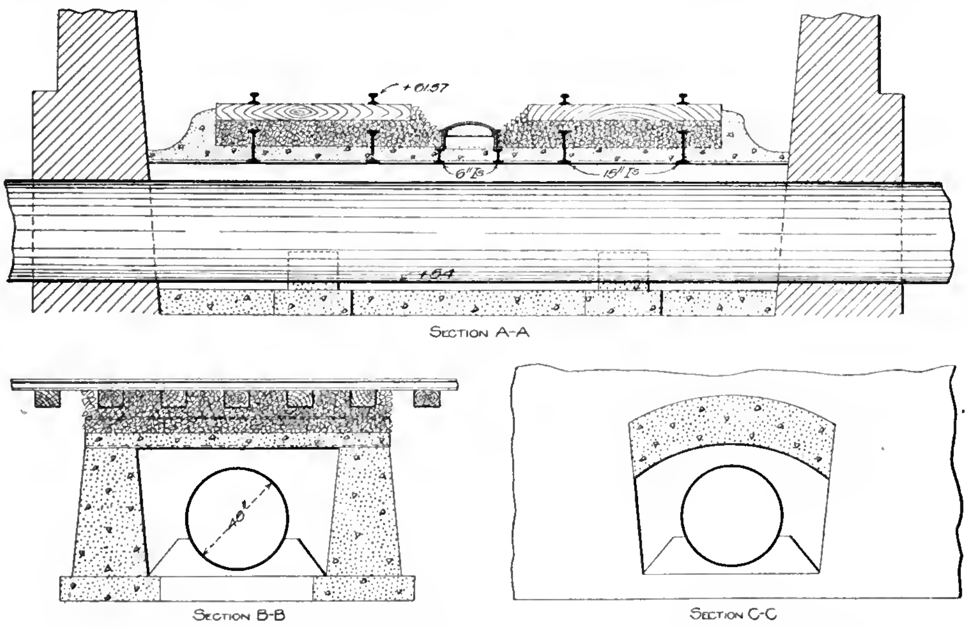
Asphalt Production in the United States in 1906 amounted to 138,059 short tons, valued at $1,290,340, as against 115,265 short tons, valued at $758,153, in 1905, an increase in 1906 of 20 per cent. in quantity and of 70 per cent. in value. Of this amount 24,085 tons were bituminous sandstone, 2,543 tons were mastic, 24,178 tons were hard and refined asphalt or gum, 9,900 tons were liquid asphalt or maltha, 12,947 tons were Wurtzilite and Gilsonite, 1,952 tons were Grahamite, and 62,454 tons were oil asphalt, according to the U. S. Geological Survey. The great increase in the production of hard and refined (or gum) asphalt in 1906 over that of 1905, which amounted to only 3,036 short tons, is due chiefly to the new refinery development in Texas, although the production of this variety in California in 1906 (8,178 short tons) is 100 per cent. in advance of the total for 1905. In the produstion of oil asphalt California stands almost alone, producing 62,361 short tons of the total quantity and showing a substantial increase over 1905. The Texas output is very small. Trinidad supplies about two-thirds of the American consumption.

Carrying a Steel Water Main under a Railway.

A 48-in. steel main under construction in Trenton, N. J., in connection with the improvements to the water supply system of that city, has been carried under the tracks of the Pennsylvania R. R. and the Delaware & Bound Brook R. R., under conditions requiring special construction to protect the pipe from excessive earth pressure and the jar of passing trains. The pipe, which is of the lock-bar type, is made of 5/16-in. plates and is delivered in 30-ft. sections so as to reduce the field joints to the lowest number possible. Sleeve-hub and lead joints are used, and at all bends these are reinforced with heavy cast-iron sleeves, of the form shown in an accompanying illustration, put on over the regular sleeve and and calked with lead in the usual manner.



Plan of Water Main Crossing.

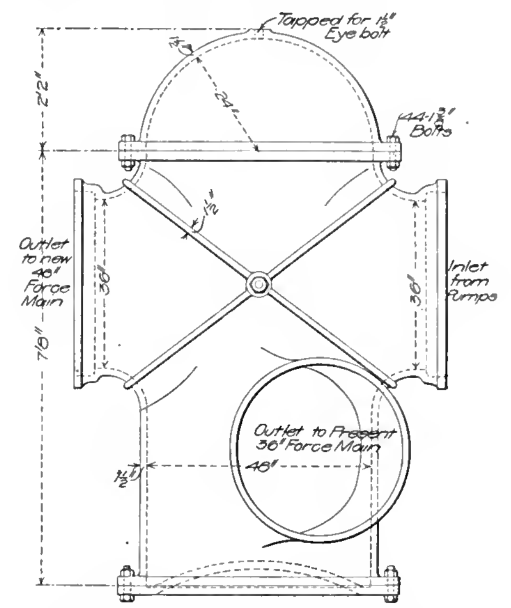


Plan and Sections of 48-Inch Pipe and Tunnel under Railroad Tracks.

For some distance the 48-in. main is laid along a street which passes over the Belvidere division of the Pennsylvania R. R. on a steel structure with stone masonry abutments. Here the pipe has been carried through the lower part of the abutments and under the tracks, with its top about 3 ft. below the base of the rails. Depressing the pipe below the tracks necessitated trenching from 10 to 27 ft. in depth, both approaching and leaving the bridge. Where the depth of trench exceeded 10 ft. it was thought unwise to depend on the ordinary steel pipes to carry the weight of the back-filled material. A cast-iron pipe might have proved satisfactory where the depth of trench was excessive but it was found that a steel pipe in a concrete tunnel would be no more expensive and even more satisfactory, owing to the ease with which it could be inspected and repaired if necessary.

The tunnel extends about 150 ft. above and 300 ft. below the bridge and consists of two heavy concrete walls carrying a 12-in. slab of plain concrete reinforced by 10-in. I-beams, except under the tracks where a 15-in. I-beam is placed under each rail, as shown in the accompanying illustration. Where the pipe passes through the opening at the bottom of each abutment a concrete arch was sprung across the top of the opening as a precautionary measure. Access is had to the tunnel through a manhole under the bridge between the tracks and through one at each end of the tunnel. A drain connecting with a sewer leads away from the lower end of the tunnel. The passageway is lighted with electric lights for which current is taken from the street lighting system, a switch being provided to make the connection when the tunnel is entered. The construction used in carrying the pipe under the tracks of the Delaware & Bound Brook R. R. is like that already described.

The connection of the new main with the reservoir is to be accomplished by inserting a stayed cast-iron Y-special in the present 36-in. ascending main within about 200 ft. of the present inlet. The leading end and one leg of the Y is to be the present line of main, and the other leg of the Y is to be connected with a 48 to 36-in. reducer, and then the 48-in. reducer is to be connected with the new ascending main. There is to be a gate valve, 36-in. and 48-in. respectively, provided for each of the ascending mains immediately back of the Y, so as to permit the use of either main separately or both together.



Special Connecting New and Old Mains.

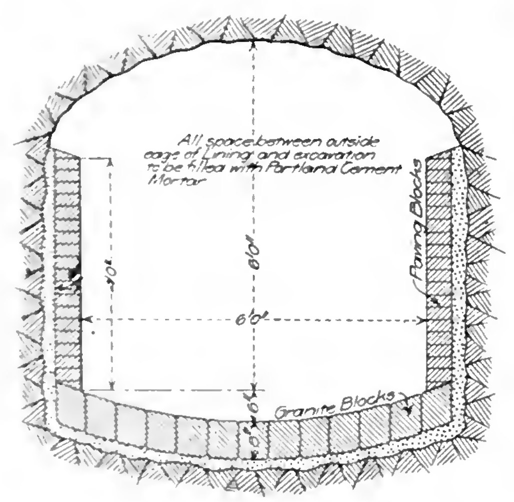
Mr. Newton A. K. Bugbee is the contractor for the ascending main, the plans and specifications for which were prepared by Mr. Chas. A. Hague, of New York City, consulting engineer. Mr. Alvin Bugbee is superintendent of the Trenton water works.

The Hardening of Hydraulic Cements was the subject of a voluminous paper read a few months ago before the Society of German Portland Cement Manufacturers by Dr. W. Michaelis. His conclusions are that hydraulic cements will be the more reliable and the more durable, the more limited the process of crystallization during their hardening, and hence he prefers cements low in alumina and lime. The surplus lime crystallizes and favors the formation of calcium sulpho-aluminate in the presence of aluminates and sulphates, he states, or the surplus lime is dissolved and carried off and in consequence the cement becomes porous. The alumina forms unstable crystals of calcium aluminate and, in the presence of sulphate solutions, the undesirable calcium sulpho-aluminates.

A Large Sewer Project in St. Paul, Minn.

The provision of a sewerage system for an area of 2,500 acres in the western part of St. Paul, which area is largely a manufacturing district that is developing very rapidly, involves several engineering features of large magnitude. The district is more or less rolling and has its surface drainage nearly all tributary to one watercourse. This watercourse is dry during a part of each year, but at times carries a large volume of water. The outlet of the watercourse is in the Mississipi River, which is about 150 ft. lower than the sewerage district and about one-half mile from the latter. The sewerage system is on the combined plan, the two main sewers which serve the district joining at a deep drop shaft in the bed of the watercourse; a tunnel, 2,500 ft. in length, extends from the bottom of this shaft to an outlet in the Mississippi River. The tunnel is finished, the drop shaft is approaching completion, parts of both main sewers have been built and the contract for the completion of these mains and the extension of the lateral sewers is to be awarded soon.

The 2,500-ft. tunnel from the river to the drop shaft has vertical sides, an arch roof and a curved invert, as shown in an accompanying illustration, its extreme height being 6.5 ft., and the clear width 6 ft. It was built entirely in excavation in a dense sandstone rock. The bottom is lined with 8-in. granite blocks laid in cement mortar, and the sides to a height of 4 ft., with vitrified paving blocks, also laid in cement mortar. The space between the lining and the excavation is filled with mortar. The tunnel is on a 1.4 per cent. grade throughout its entire length, so that the velocities through it are high and its capacity is quite large.



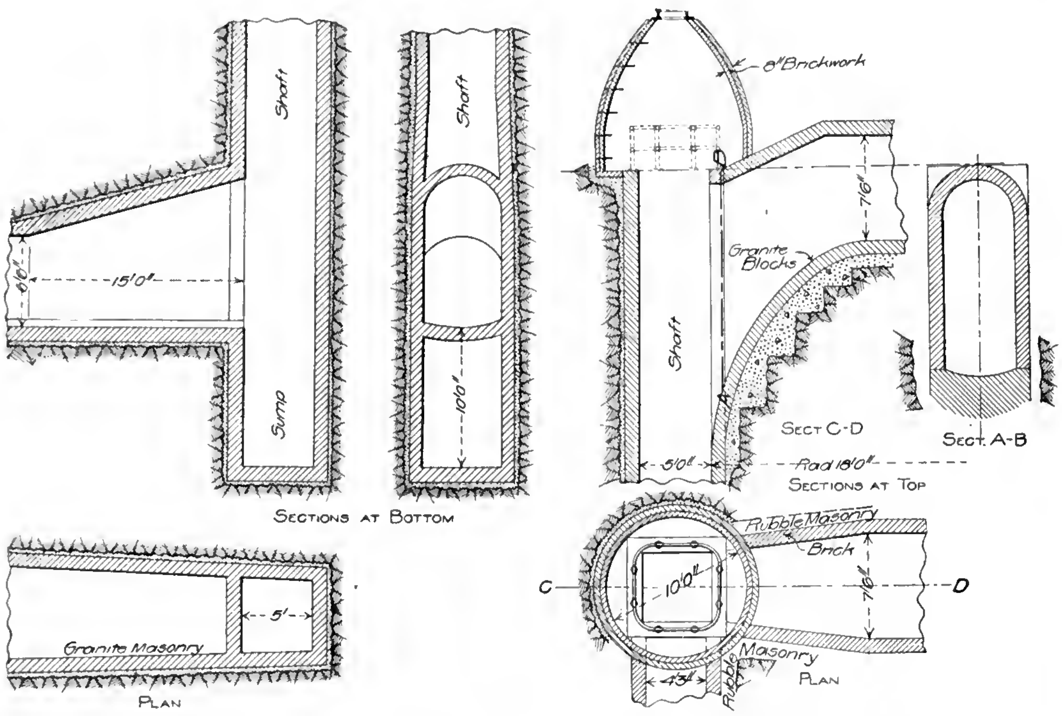
Cross Section of Outfall Sewer Tunnel.

The construction of the tunnel presented no unusual features, as the excavation was made through the sandstone without much difficulty. Work was started at the river end and driven through to the drop shaft. The excavated material was hauled back to the mouth of the tunnel at the river in small cars. From 2 to 4 men were generally engaged at the working face while the tunnel was being driven, one shift being employed. The tunnel was completed at a contract price of about $5 per linear foot.

The engineering work done during the construction of the tunnel is worthy of notice. The tunnel has a curve at the drop shaft and the alignment had to be carried forward from a single backsight. When the curve on the tunnel at the drop shaft had been run the center line of the tunnel intersected a 6-in. drill hole which had been put down on that line during the preliminary investigations made to determine the location of the tunnel.

The drop shaft has a total depth of 125 ft. from the ground level to the bottom and is 5 ft. square inside the cut-stone granite masonry with which it is lined. The two main sewers connect with the drop shaft near the top and on adjacent sides. One of these sewers is 7.5 ft. and the other 4.25 ft. in diameter up to the connections. The cross-sectional area of both sewers is increased at the connections and the side of the drop shaft is continued up as an arc of an 18-ft. circle to its junction with the invert of the sewer. The calculations that the flow of the sewage into the drop shaft will thus be diverted more directly down the shaft. The arcs of the circle at the connections are also lined with granite blocks to take the wear due to the high velocity of the sewage over them.

A sump, 10 ft. deep below the tunnel invert, is placed at the bottom of the drop shaft, so the sewage entering the latter will always fall on a water cushion. The outlet from the drop shaft into the tunnel is a large bell-mouth, 15 ft. long, which is designed to permit a maximum quantity of water to enter the tunnel.



Plan and Sections of Drop Shaft at the Upper End of the Outfall Sewer Tunnel.

The granite lining of the shaft ends just above the connections with the main sewers, or about 11.5 ft. below the ground surface. A bell-shaped manhole, 10 ft. in diameter at the base, is to be built from the top of the lining to the ground level. This manhole will be closed with a sealed cover, to prevent large pieces of debris entering or being thrown into the shaft. It is expected also that the shaft will rarely, if ever, have to be repaired owing to the very substantial way in which it is built.

The construction of the shaft has been carried on under exceedingly difficult conditions. The upper 20 to 21 ft. of ground at the site is ordinary glacial drift, below which is a depth of about 22 ft. of fine water-bearing sand containing some clay, which made it a very limpid quicksand. Under this quicksand was a thin layer of clay immediately overlying the sandstone rock through which the tunnel was driven. An excavation, 20 ft. square, was first opened at top and was lined with heavy wooden sheeting thoroughly braced and cross-braced. An attempt to carry the excavation through the quicksand in this manner failed completely, the contractor finally abandoing the work after the excavation had collapsed in the quicksand. The board of public works then assumed control of the work and has carried it practically to completion.

The timbering and sheeting in the collapsed portion of the excavation were first removed in order that a new method of handling the work might be started. United States steel sheet piling in 20-ft. lengths had been obtained meanwhile and was driven through the quicksand in such a way as to form the sides of a 10-ft. square. After the sand enclosed by the steel sheeting had been removed, the masonry lining of the shaft was then built up rapidly to avoid, as much as possible, any danger of the quicksand causing a blow-out. The steel sheeting held, however, under the great pressure brought on it and the lining was finished without any mishaps.

The excavation for the balance of the shaft through 35 ft. of rock was next carried down to the bottom of the sump. A steam drill, supplied with steam from the boiler of a hoisting engine at the mouth of the shaft, was used to make blast holes. Light charges of dynamite were exploded in these holes, without injury to the masonry lining which had been completed. The excavation thus made in the rock was smaller than that made for the portion of the shaft above the rock, so the lining already placed would not be disturbed. It was then trimmed out, commencing at the bottom, and the lining carried up to the top of the rock.

An 1,800-ft. length of the larger main sewer and a short section of the smaller one have been built. The 7.5-ft. sewer was built of three rings of hard-burned brick, and the 4.25-ft. one of two rings, all laid in cement mortar. Contracts for the extension of the 7.5-ft. sewer for 4,000 ft. in a 7-ft. circular reinforced-concrete section and the 4.25-ft. section for 3,500 ft., also in reinforced-concrete, are to be awarded soon. The lateral sewers leading from the mains will also be placed under construction at once.

The design and construction of the sewerage system for this district are carried on under the supervision of Mr. L. W. Rundlett, commissioner of public works of St. Paul. The sewer department is under the immediate direction of Mr. A. R. Starkey, assistant commissioner of public works, who has personally directed the construction work handled by the city.

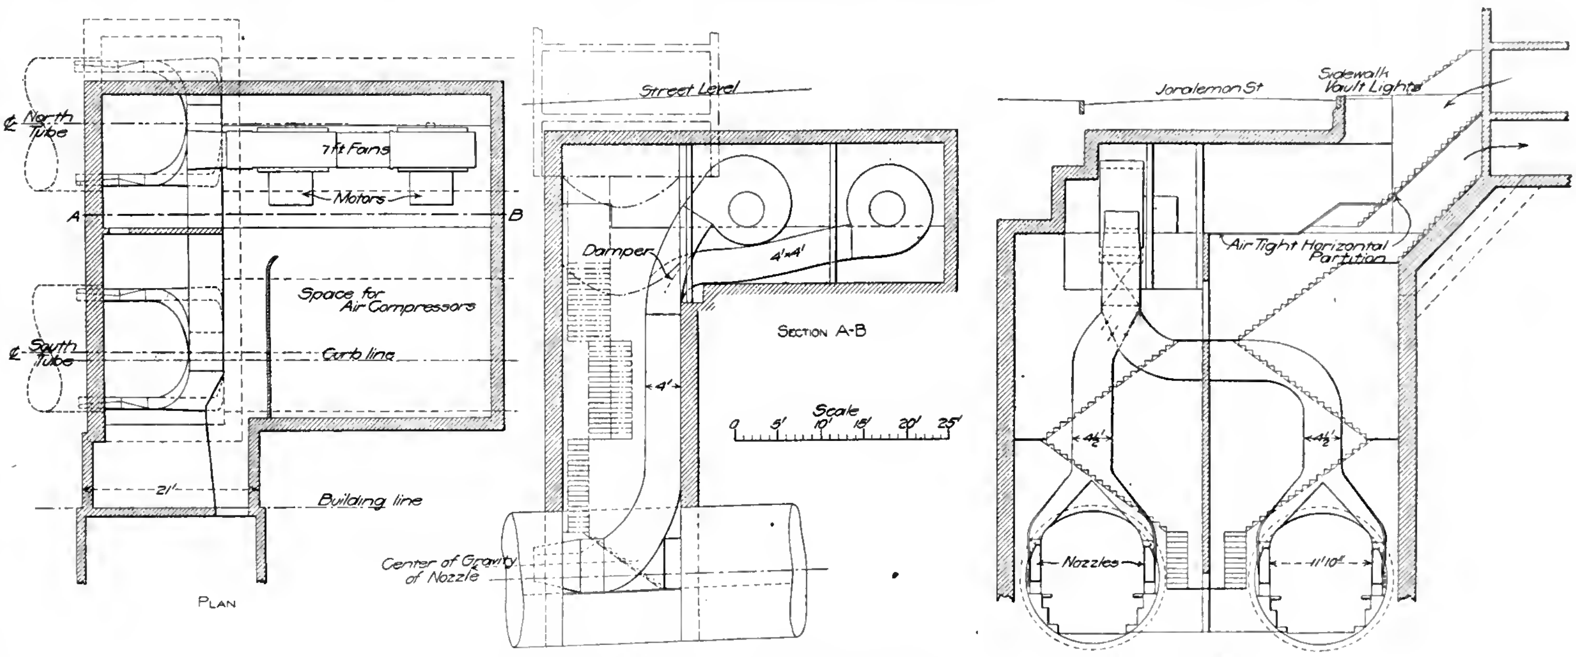
A Long Railway Tunnel will be built on the Midland Railway of Australia under Arthur Pass, the total length being about 28,000 ft., or about 5¼ miles. The contract has been let to J. McLean & Son. The section will be 17 ft. high and 15 ft., lined throughout. The material through which the tunnel will be driven is solid rock.

Ventilation of the Battery Tunnels of the New York Subway Extension to Brooklyn.

The two tunnels under the East River from Battery Park, Manhattan, to Joralemon St., Brooklyn, of the Brooklyn extension of the New York Subway System, have been practically completed and satisfactory progress is now being made with the work of their equipment, preparatory to the beginning of operation of trains within a few months. The subaqueous connection has been built as two single track parallel tubes, running from 26 to 28 ft. apart on centers and about 6,750 ft. in length. The tubes are cylindrical cast-iron shells, lined with concrete, having an inside diameter of 15½ ft. and they were projected toward the center of the river with gradients of 3 1/10 per cent., which are united at the lowest point near the center of the river by a vertical curve, with the tops of the tubes about 80 ft. below mean high water level in the river. The details of the construction of these tubes have been referred to in a number of articles in The dled through them, the conditions attending the problem of ventilation are without a doubt the most difficult that have ever been encountered, and the selection of a satisfatcory design was rendered far more difficult by the lack of precedent in application to conditions of this character. Owing to this a very careful study of the problem of tunnel ventilation was necessitated and the design was finally selected which embodies the more important features of the best practice in tunnel ventilation in this country and abroad.

Experience in the ventilation of railway tunnels where the smoke and gases from steam locomotives are to be dealt with, have indicated that the most effective ventilation may be secured where both ends of the tube must of needs remain open, by blowing air into them through jets or nozzles and in the direction of movements of trains. This method of tunnel ventilation will, in the case of a slow, heavy freight train, drawn by locomotives emitting dense black smoke, drive the gases ahead of the train and keep the atmosphere clear and comfortable for the train men to work in. While the difficulties of smoke and gas are not here encountered, the requirements for ventilation The most suitable location would, of course, have been one like that on the New York side, near the bulkhead line, but it was found impossible to secure rights on any of the water-front property or even in the first or second blocks nearest the river; only after a great amount of trouble and considerable litigation was an available site secured, which is at No. 58 Joralemon St., a private residence on the south side of the street and in the third block up from the river front.

After a careful study of the problem, the engineers in charge of the design decided that a volume of from 45,000 to 50,000 cu. ft. per minute should be introduced into either tube for the results desired with provisions for a slight increase over this amount for emergency conditions. With the space available for nozzles, however, the areas of the orifices were limited somewhat, which factor, of course, largely influenced the capacities of blowers selected. The nozzles although designed as large as possible for the spaces available are but 15⅜ in. wide x 4 ft. total height, the upper corners being cut off by the upper portion of the tube shells, and have



Apparatus and Ducts at the Brooklyn Ventilating Station of the Battery Tunnels.

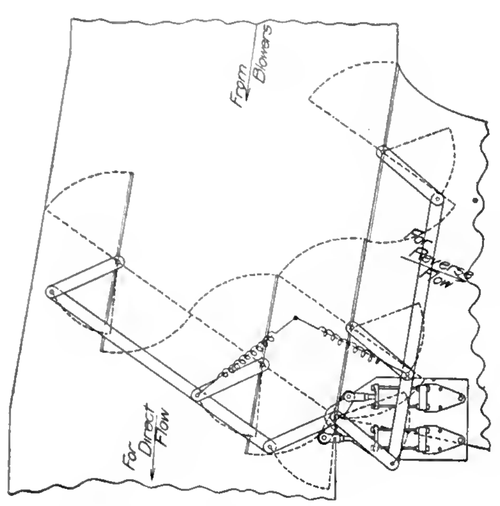
Engineering Record, notable among which are those in the issues of June 2, September 29, and December 22, 1906.

Owing to the length of the tubes and the restricted clearances within them when trains are in operation, some provisions for their ventilation were foreseen to be necessary, particularly in case of trains becoming blocked or stalled in the tubes. Under ordinary conditions of operation, it is expected, from the general experience in operation of trains through tubes of similar sections, that the piston action of the trains passing at frequent intervals in the same direction through each tube will suffice for all ordinary requirements for ventilation. This action of draft induced by trains in motion is, in fact, to be largely taken advantage of for ventilation, large openings to the tubes having been made at the shore ends to permit of free access of air behind all trains as they leave either side and correspondingly for discharge from in front of trains as they come up out of the tubes. But in order to provide adequately for any emergency conditions that might arise, it has been thought advisable to install a carefully planned system of mechanical ventilation which may be used continuously, if required, and which shall always be in readiness for emergency, sufficient reserve equipment being provided for this purpose. Owing to the length of the tubes and the character of the service to be han- are analogous, it being necessary to keep the atmosphere within the tubes frequently changing by driving a considerable volume of air through them, and essential that ample ventilating capacity be available in an exigency such as a stalled train. This method of ventilation was accordingly adopted, but difficulties of considerable magnitude were, however, encountered in securing convenient and proper location for the blower equipments near the ends of the subaqueous sections of the tubes and also of installing nozzles of sufficient size in the restricted spaces available in the tubes, to provide an effective blast. It was thought advisable to provide narrow nozzles on either side of the tubes in the spaces available above the bench lines which could thus be from 15 to 16 in. in width without restricting the clearance limits over trains and at the same time leave sufficient space next to the sides of the tubes on the horizontal diameter lines through which to pass a limited number of feeder cables or wires. With the requirement for admitting the blast in the direction of train movements, it was obviously necessary to install blowing stations on either side of the river, and a convenient location for the blower station was available on the New York side under the corner of Battery Park near the ferry stations, but a great deal of difficulty was encountered on the Brooklyn side in securing an available site in proximity to the water front. each a total cross sectional area of orifice of 5 sq. ft. Each tube thus has a total capacity of nozzle orifice of 10 sq. ft., each of the nozzles being supplied with air from the blowers through a converging connection from a delivery duct of 18 sq. ft. cross section. The blowers selected as best adapted to this duty with these particular sizes of connections were centrifugal downward-discharge fans with 7-ft. wheels, 4 ft. in width. Operated against a static pressure of 0.33 oz. blast, each fan has a capacity for delivering 46,500 cu. ft. per minute. The blowers are all ¾-housed steel plate centrifugal fans built by the American Blower Co., and 2 units are installed in duplicate at each blower station, it being thought that with this provision of reserve capacity, no combination of conditions will ever arise in which at least one unit cannot be kept in running order in each station. Each of the blowers is direct-connected to a 75-h.p. C. & C. interpole motor which is designed for operation on the 600-volt current from the third rail of the Subway propulsion system, and is fitted with control apparatus for a speed variation of from 300 to 413 r. p. m. The source of current supply has, also, been made doubly reliable by the extension of an independent feeder for this purpose from the substation of the Subway lines nearest to the blower stations, and a direct connection to the third rails in the adjoining tubes, although the latter will serve as an emergency

connection only and will not be used under ordinary conditions. They are also fitted with automatic starting switches arranged for distant control, so that the blowers may be placed in operation upon an instant's notice from the office of one of the despatchers of the Subway lines.

The interior arrangements of the blower stations and the apparatus and duct work are shown in the accompanying drawings. Each station consists of an underground chamber located near the surface, in which the blower and motor-drive equipments are located, and connecting with which are vertical shafts, 14 ft. in width, that are carried down to openings in both of the tunnel tubes. These shafts vary somewhat in longitudinal dimensions, being about 52 ft., inside, at the Battery Park station and but 45 ft. at the Brooklyn station, owing to the restricted width of Joralemon St., at that point. That in the Joralemon St. station is much the deeper, the tops of the tubes being there 48 ft. below the street level owing to a considerable elevation in the ground level at that distance back from the river front, while at Battery Park the tops of the tubes are but 25½ ft. below the surface. The shafts are divided vertically through the middle by partition walls so that the openings to either tube are independent and either may thus act as an exhaust chimney or flue from its tube for the discharge of air which is blown through or is driven out by the piston-action of the trains; in normal operation, however, this exhaust action will take place from the south tube at the Brooklyn station and from the north tube at Battery Park only, as the trains are to be operated on the usual "right handed" plan. The shafts at either end are arranged to be left permanently open to the outer air, the opening at Battery Park consisting of an irregular shaped grating of 252 sq. ft. area, directly over the shaft and that on the Brooklyn side, of a large passage which extends up into the building alongside of the station which was purchased for this purpose; this passage is 14 ft. wide and approximately 9 ft. in depth, and connects with a large opening up through the building into the outer air. The blowers have intake from the outside air through their operating chambers in the stations, that at Battery Park having an opening to the surface through a 252 sq. ft. grating, similar in shape to that for exhaust, while at the Brooklyn station a passage, 4 x 6½ ft. in cross-section, leading into the Joralemon St. building is made use of, through which air will be drawn in from an opening at the rear. Access to the operating chambers as well as also to the lower levels of the shafts are had by means of flights of iron stairs conveniently arranged, as shown in the accompanying sections of the station.

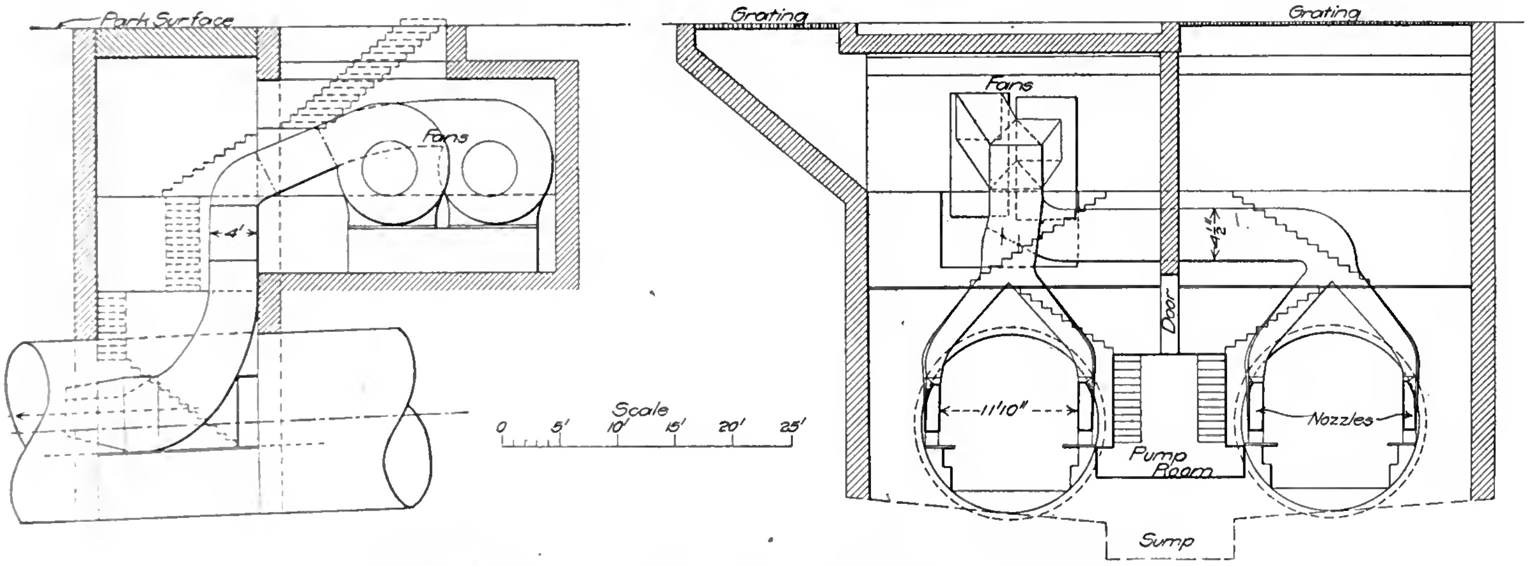
The duct connections from the blowers to the nozzles are simply arranged, consisting in general of a vertical rectangular duct of No. 18 galvanized iron, which extends from the delivery outlets of each group of two fans directly downward to the tube through which air will normally be blown, with cross branches to the other sides of the shafts to connect with the reserve nozzles for reversal of the flow in the tubes, if this may be necessary in emergency. The down delivery ducts are of 18 sq. ft. cross section which is ample to carry the maximum volume that can be delivered through the nozzles, and they divide over either tube, through a Y-connection, into two branches of 9 sq. ft. section which supply the two nozzles, the branches and connections to the nozzles being similarly proportioned and shaped on either side in order to equalize the flow from either nozzle. The blowers deliver through connections of 16 sq. ft. cross section which join at the top of the shaft into the down delivery ducts, special flap dampers being used at the joining to permit either blower desired to deliver independently, while in case it is desired to operate both blowers together, the dampers will assume a central position and thus not interfere with the delivery of either unit. The choice of these sizes of ducts is due to the fact that the capacity of the system is limited by the areas of the nozzle orifices, upon which the design of the blowers was based; the effect of the nozzles is such that even with the second blower in operation, the volume delivered through them would be increased but to a slight extent, probably not over 20 per cent. The control of the delivery to the nozzles in either tube is had through sets of louvre dampers in the ducts at points immediately beyond the joining of the cross branch to the vertical duct, which dampers are interconnected and so actuated that the blowers cannot deliver into the nozzles of both tubes at the same time; these damper mechanisms in the two stations are furthermore fitted for distant electric control, by means of which the interlocking arrangement is secured, and which also permits of instantly changing the direction of flow in both tubes from a distant point.



Interlocking Damper Mechanism.

One of the most interesting features of the blower installation is the above provisions for distant control of the dampers, as much study has been given to the matter of providing means for instantly adjusting the conditions of ventilation to the requirements of any emergency in the tunnels. Under all ordinary conditions of operation, it is expected that all requirements for ventilation will be met by the above-mentioned plan of directing the blast in the direction of train movements, i. e., eastward in the south tube from the Battery Park station and westward in the north tube from the Joralemon St. station, but with the heavy traffic that will be operated through the tunnels, an emergency may at any time arise, such as a stalled train or deranged electrical apparatus, in which it may be desired to quickly reverse the direction of flow of air. For this purpose the control of the dampers has been placed in the charge of the despatcher in the Bowling Green interlocking tower of the subway lines who is at all times in direct communication with all parts of the tunnels by means of a series of telephone stations, distributed at intervals of about 300 ft. throughout either tube; in case of any trouble reported to him he may thus instantly reverse the direction of flow, if necessary for the comfort of the passengers or workmen.

The distant control mechanism is of the electro-pneumatic type, the electrically-controlled pneumatic cylinders built by the Union Switch & Signal Co. for actuating signal mechanisms being used. As these cylinders are of the single-acting type, two are installed at each blower station, one for throwing the dampers in either position. They are mounted side-by-side on the side of the duct near the dampers and have their pistons connected to a rocker arm, pivoted at the middle, which carries a bell-crank so connected to the louvre dampers as to always maintain one closed while the other is open. The angles which the louvres assume when closed were so chosen in relation to the directions of flow that but about 60-deg. of movement of the vanes is required, and in order that the cylinders or levers may not stick in a partly opened position, positive throw spring attachments have been applied to the levers of either louvre which will always ensure completion of the motion of opening or closing, provided the cylinders throw the mechanism more than half way over. The electric air valves that control the pneumatic cylinders are actuated by the regular 16-volt direct-current supply for the signal sytem, a double-throw switch at the Bowling Green interlocker tower controlling both sets



Apparatus and Duct Connections in the Battery Park Ventilating Station.

of cylinders; when thrown in one direction, it actuates simultaneously the cylinders in both blower stations for the direct flow, while in the other direction, the cylinders for the reverse flow. In this way the adjustments of the sets of dampers are positively interlocked and it is thus rendered impossible through mistake to direct the blast into both ends of either tube at one time. No provision has been made for directing the blast in the same direction through both tubes at the same time.

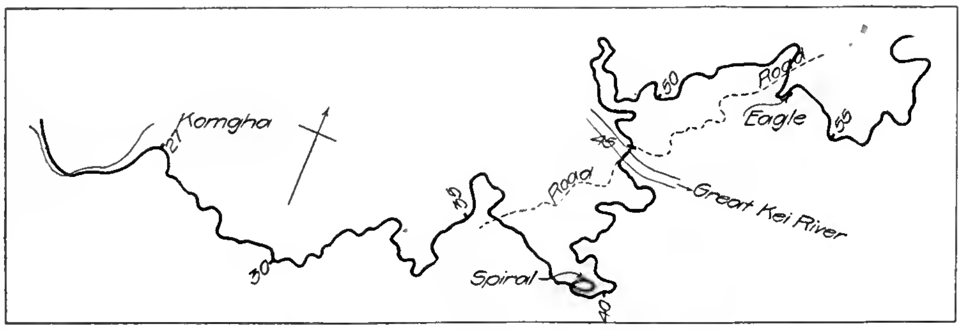
The provisions for ventilation thus made enable a great variety of conditions to be met. Under ordinary conditions, it is, as above stated, expected that the air in the tubes will be maintained sufficiently clear for the comfort of the trainmen and passengers by the piston-action of the trains passing through, while, if in hot summer weather, more ventilation should prove desirable for cooling purposes, the operation of one of the blower units for either tube will add considerably to the effect of the trains. It is, however, in the case of a serious emergency that the full value of the ventilating equipments would be realized. While there is no danger from fire in the tunnels, as cars of metallic construction only are to be operated on the Brooklyn extension, the smoke that would result from a burnt-out motor or other derangement of the electrical apparatus of the propulsion system could incite a serious panic amongst passengers; such smoke or obnoxious gases in case of a stalled train can, with the blowers in operation, be rapidly dissipated, and, by virtue of the provisions for reversal of flow, in such a manner as to be least offensive to the people at the scene of the accident. If, for instance, an accident of serious nature should occur to a train before it had reached the mid-point of the tunnel, the shortest distance of exit for the passengers would be in the direction from which the train had come, so that the regular flow of air in the direction of train movement would carry the smoke and gases in the opposite direction; if, on the other hand, the train had passed the mid-point of the tunnel when the accident occured the quickest exit would be toward the train's destination and a reversal of the flow of air would facilitate the same. By means of the system of telephones in the tubes, the trainmen may very quickly advise the despatcher if the reversal of flow is necessary, which is accomplished in the office of the latter by the mere throwing of a single-pole switch. Furthermore, if the blowers should happen not to be in operation, they could be instantly started by the mere throwing of another switch at the same point, one for either blower station, the blower motors being, as above stated, fitted with automatic starting equipments with distant control.

The ventilating system for the tunnels and the equipment were designed by the late Board of Rapid Transit Railroad Commissioners, of which Mr. Geo. S. Rice was chief engineer and Mr. D. L. Turner general inspector of stations. The details of the electrical devices were in charge of Mr. H. N. Latey, of the firm of Latey & Slater, consulting engineers to the late commission.

The Amabele-Butterworth Railway, South Africa.

The Amabele-Butterworth Ry., in the eastern part of Cape Colony, South Africa, one of the newest branches of the Cape Government Railways, starts from a station on the Eastern System about 50 miles from East London, an important town on the Indian Ocean. Its total length is 78 miles, but the central portion of the line from Komgha to Ndabakazi, 41 miles, is the only part interesting from an engineering standpoint, both the first part from Amabele to Komgha, and the last part from Ndabakazi to Butterworth, passing through easy country. From Komgha to Ndabakazi the road traverses the mountainous country of the Kei and Toleni Rivers, making it one of the heaviest lines in the Colony.

A short distance from Komgha, which is 27 miles from Amabele, the road starts down, from an elevation of 2,260 ft. above sea level, on its descent to the Great Kei River, the country traversed being very mountainous, and necessitating heavy earth work and masonry. At 39¼ miles from Amabele it became necessary in order not to exceed the maximum grade to build a spiral encircling a conical hill, and passing under itself through a short tunnel. This spiral is the only one on the Cape Government Railways. Between the spiral and the Great Kei River heavy earth work and a number of long culverts were necessary.



Mountainous Portion of the Amabele-Butterworth Railway.

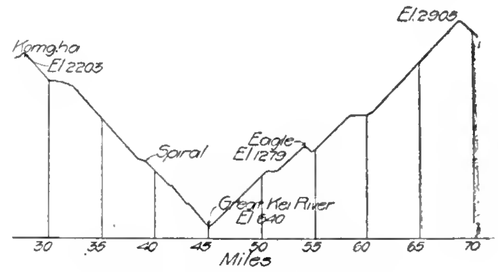
The distance from Komgha to the Great Kei River by railroad is 18 miles, though it is only 7 miles in a straight line and 11 miles by wagon road. This development was necessary in order not to exceed the maximum gradient of 1 in 36 or about 2.8 per cent. The difference in elevation between the two places is 1,563 ft., Komgha being 2,203 ft., and the river bridge 640 ft. above sea level.

The Great Kei River is crossed on a temporary timber bridge consisting of 22 spans of 25 ft. each. Owing to a difference in rail elevation of 21.95 ft. between the future permanent bridge and the present temporary one a switchback was put in, the line approaching it being built in a permanent position. This switchback lies almost entirely on a 2½ per cent. grade, is 3,000 ft. long and has a maximum curvature of 17 deg. 22 min.

East of the Great Kei River the ascent to Ndabakazi is commenced. For some distance the line follows up the valley, then rounds back 180 deg., by means of a 17 deg. 22 min. curve, and runs on the same side of the hill above the other line, until the Manqulu Valley is reached. At this point the upper and lower portions of the line are about 900 ft. apart horizontally, though the distance along the track is about 4 miles. Following up the valley to near its head the line crosses the Manqulu River on a viaduct of four 50-ft. spans, the rail level being about 51½ ft. above the river bed. The bridge is on a 2 per cent. grade and a 17 deg. 22 min. curve. After leaving the Manqulu River the line crosses over the divide to the Toleni Valley at Eagle, and from this point on the most difficult work is found. Heavy embankments are necessary and in one instance a rather complicated drainage system in which two culverts unite into one under the bank. The line for some distance hugs the precipitous cliffs that fall almost shear to the Toleni River, about 400 ft. above the water, and in this stretch a great length of retaining wall was built. Two tunnels, one 351 ft., and the other 578 ft. long were driven through projecting spurs. The Toleni River is crossed on a bridge of two 100-ft. spans.

The total quantity of earth work, exclusive of tunnel excavation, is 1,598,000 cu. yd., which omitting the last three miles near Ndabakazi, since they contain neither fill nor excavation, amounts to 42,000 cu. yd. per mile. With the exception of three cuts through rock and disintregated ironstone, nearly the whole of the work is loose shale, both soft and hard, with occasional ledges and boulders of solid rock. In one section, a mile in length, nothing but very hard rock was encountered. Various explosives were experimented with but dynamite gave the most satisfactory results.

Toward the completion of the work concrete arches with stone faces were adopted for culverts because of the saving in masonry and time of construction, but most of the openings under the track are built of hammer-dressed coursed rubble laid in cement mortar. Wherever possible, culverts have been placed high up in the bank to save masonry, drains being extended up into the



Profile beyond Komgha.

draw from the bank to catch the water. The total number of openings under the track including bridges, culverts and iron and tile pipe, is 366, or 8.9 openings per mile. At mile 55 the line crosses a deep double gully on a high bank. A culvert has been fixed in each gully and they join under the embankment into a common outlet. One culvert falls one in seven and the other, one in three, the roof of the latter being stepped down. The length of the present construction measures 133 ft., and had two separate openings been built the total length would have been about 260 ft.

In an endeavor to reduce the quantity of concrete used in one of the culverts a special design was drawn up for an 8-ft. semi-circular arch. The side walls battered one in five and the invert was curved. The length of the culvert was 13.1 ft., and the quantity of concrete 207 cu. yd., or a little over 7 cu. yd. per lineal foot.

The sand for the concrete had in general to be hauled quite a distance, such material as was found close to the various culverts being of poor quality. The sand that has given the best results is a sort of rotten ironstone found close to the main road in the Kei Valley. This was put in bags and conveyed by wagons to the various culverts. Trials were made of sand from the Great Kei River but as a rule did not give satisfactory results. In some places it was found difficult to get water for mixing the concrete and at one point it had to be carried up by men a distance varying from 200 to 300 ft. above the river. The total quantity of masonry in the 41 miles is 28,050 cu. yd., an average of 684 cu. yd. per mile.

There are three tunnels on the section of the line from Komgha to Ndabakazi, the shortest, the

one on the spiral, being 60 ft. in length and meriting no special description. It is on a 17 deg. 22 min. curve and as the formation was a soft shale it was lined with masonry. Tunnel No. 1 is 352 ft. long and lies entirely on a 14 deg. 28 min. curve. Tunnel No. 2 is 679.8 ft. long, the greater part of it being straight and the end on transition curves. The straight section is 527.4 ft. long. The cross section of both tunnels is 14 ft. wide on the straight portions and 16 ft. 4 in. on the curved portions. Shelters are provided every 66 ft. alternately on either side of the tunnel. The material in tunnel No. 1 is a very hard close grained rock and the lining for the walls and the arch is 18 in. of concrete. In tunnel No. 2 the nature of the rock is variable. The section through the softer rock will have a 24-in. concrete wall with an 18 in. arch, and where the harder rock is encountered the thickness of the wall will be reduced to 12 in. The drain in tunnel No. 2 will be in the center, but in tunnel No. 1 will be placed on the inside of the curve against the side wall.

Owing to the comparatively short lengths, the work of setting out these tunnels was not difficult. In tunnel No. 1 the first portion of the curve was discarded for driving purposes and a sub-tangent fixed at the mouth of the tunnel, the length of this sub-tangent being 231 ft. Although tunnel No. 2 commences and ends on transition curves, it was just possible to clear the sides of each entrance and run a straight line through, offsetting the curves. Two chains or 132 ft. from the Komgha entrance to the latter tunnel the line was crossed by a gully into which a cross cut heading was driven, meeting the center line 39 ft. from the face of the mountain. By this means 4 faces were worked at one time.

The rails are second-hand, weighing 60 lb., and the ties are of treated jarrah wood 7 ft. 10 in. long and 5 in. thick, 11 being used to a 30-ft. rail. The joints in the latter are laid square on the tangents and staggered on curves. The minimum depth of ballast below the ties is 5 in. The ballast used is a disintegrated granite found along the road. Track laying and ballasting is done by contract at $25 per chain of 66 ft.

The maximum curvature is 17 deg. 22 min., all curves sharper than 10 deg. 52 min. being transitioned, the length of the easement being 105.6 ft. The maximum grade is 1 in 36 or about 2.8 per cent., compensated 0.035 per degree of curvature. The maximum super elevation is 4⅞ in.

The work was done in short contracts varying from ½ to 2 miles in length, according to the quantities of earth work or masonry and the ability of the contractor. As a rule the earth work and masonry were let to different men, but experience showed that to combine the two under one contract was more satisfactory. The average price for earth, measured in excavation and including a free haul of 528 ft., varied from 56 to 68 cents per cubic yard. Solid rock varied from 87 cents to $1.00 per yard, and tunnel excavation from $5.00 to $6.20 a yard. The average cost of masonry was $11.95 per yard, concrete $11.08. The total cost for the 41 miles was $2,209,135, an average of $53,881 per mile.

The survey and the location of the line were made by Mr. A. M. Tippett, chief resident engineer for the Cape Government Railways.

Steel Ties will be used on the Bessemer & Lake Erie Railroad next year according to recent plans. About 70,000 ties will be necessary for renewals and repairs in place of wooden ties now in use, the lines on which they will be used aggregating 90 miles. The United States Steel Corporation during the present year has sold about 3,000 tons of steel ties, and on the roads it controls about $500,000 worth are in use, sufficient for about 160 miles of track.

Earth Slides.

Mr. H. Rohwer, formerly chief engineer of the Missouri Pacific Ry., has contributed to a recent bulletin of the American Railway Engineering and Maintenance of Way Association some notes concerning earth slides which are based on his long experience in railway work. After pointing out the fundamental fact that slides are formed when masses become disconnected, and hang on a slope steeper than the plane of friction due to the character of the material and its ability to resistance, he states that water being one of the most influential elements in reducing this resistance to a minimum, it is well to provide for proper drainage before slides set in. The golden rule is to "keep the water away from the roadbed." The study of geology is frequently overlooked by the engineer having charge of location, and he gives but little attention to the possibility of encountering slides caused by either the grade or location of line. If drainage is of so much importance, why not place the line, circumstances permitting, where drainage can be rendered most effective, allow sun and wind to act upon the roadbed, and pay close attention to the manner of constructing it?

When delegated to investigate the cause of slides in an embankment of one of the main trunk lines in the Middle West, constructed about the year 1861, Mr. Rohwer found the slopes considerably deranged. The embankment, about a quarter of a mile in length and over 22 feet high in the middle, was continually settling, and notwithstanding the attention given it by the operating department, this evil continued to exist. Trackmen, when called upon to remedy similar breaks, usually apply stone, which on account of the greater weight, increases rather than diminishes the evil and the cause of the slide is thereby not removed, in Mr. Rohwer's opinion. The method employed not being effective, piles were driven and a bridge constructed along and over the fill for such distance as was deemed necessary. As the piles did not rest in original ground, they swayed to and fro, and the maintenance of the line and grade became a matter of great annoyance and cost. About the time this pile bridge required renewal, Mr. Rohwer was asked to make an investigation of the trouble and to recommend what should be done to improve the safety of the road, and, if possible, prevent the slides and dispense with the trestle.

In digging a trench on each side of the track along the foot of the slope and parallel with the track, considerable seepage from the bank poured forth, leading to the belief that the water was retained in the bank by some cause or other, and was seeking an outlet. Mr. Rohwer then had intercepting drains constructed, extending towards the center of the embankment at intervals of 25 to 50 ft., according to the amount of water apparently confined in the embankment. The drains were then filled with stone—the heavier at bottom and the lighter on top—covered with cinders. This method accomplished the object of draining the embankment and rendered it stable so that the trestle could be removed, and no further difficulty at that point has been experienced.

In prosecuting this work, the drills were extended into the center of the embankment, and it was discovered that a number of partly decayed logs were embedded therein. Upon inquiry it was ascertained that the contractor at the time of construction had logs hauled in at night. The earth on the outside covering up this deception, the water was retained in the inside of the embankment, softening the material dropping into it, and with the heavier material on top, was forced to the sides, and thus creating slips or slides. In the case above cited, the slide sounded a timely warning, so that the proper remedy could be employed. However, crevices formed under the roadbed are much more dangerous, the latter producing slides without giving notice, this often being the case where the roadbed rests on the debris hanging on the side of bluffs, especially when bordering on a treacherous stream like the Missouri River.

Water coming down ravines can be readily conducted across the roadbed by bridges or culverts, but in such cases care must be exercised as to outlet. However, water falling on the sidehill between ravines or creeks and dropping from bluffs into the debris where it cannot readily be intercepted, will enter the roadbed, penetrate the underlying loose strata and find its way over and along the harder strata, thus creating the earth slides to which reference has been made. This water keeps the ground under the track in a constant moist state, a menace to the safe operation of the road. Oftentimes it will form crevices, and when once formed they will increase and may reach to the very surface, only to be discovered after a wreck has occurred, and are then usually termed "a washout." Again, the water may soften the material until it becomes slushy and will produce a slip at the foot of the lower slope. Borings made by Mr. Rohwer over a distance of seven miles on parts of tracks so situated showed that the roadbed developing such defects was invariably located directly against a bluff or perhaps resting on material underlaid by slanting rock, which rock forming a part of the bluff, had been eroded by the action of the water, either river or surface, or both combined.

If the water is collected at frequent intervals and conducted across the track either by means of small boxes (if pipe cannot be utilized) or conveyed in open ditches plastered with cement or rammed with small stone so as to prevent the water from penetrating into the roadway, the danger referred to can be greatly diminished.

The most remarkable slide coming to the notice of Mr. Rohwer was encountered on the White River Ry. at the entrance of a long tunnel, its magnitude precluding all thought of removing it. The disturbance first manifested itself at what might be termed a sidehill cut. In removing the footing, the mass of clay seemed to lose its hold on the rock whereon it rested, and began breaking off, first showing cracks insignificant in size and their location being confined to the right-of-way, but later reaching far out into the adjoining hills, bringing down trees and forming breaks in the surface 15 to 25 ft. in height and perpendicular in appearance.

The Omaha tunnel, 2,650 ft. in length, penetrates a sag in the Ozark Mountains, consisting of a so-called boulder formation, lime and rock being found intermixed with clay, a hydrated silica of alumina of brownish color, due to the presence of iron oxide. This clay is very plastic, especially so in the approaches where action of water is not constant, as in a tunnel. Here the layer of clay was from 5 to 100 ft. thick, underlaid with strata of solid rock of smooth surface and slanting at an angle of from 5 to 10 degrees toward the creek, along which the line had been located, then in course of construction. The grade of the roadbed entered the rock 20 ft. below the surface; in other words, the approach to the tunnel has a 20-ft. rock cut with clay in the slope overlying it.

As soon as cracks appeared on the surface, extra precautions were taken against surface water. The surface ditches were given steeper grades, and, where possible, bottoms were cemented so that the water could drain off more quickly, thus reducing chances of penetration to a minimum. In spite of this the ground continued to break and started to move toward the open cut, at first dropping into it little at a time, gradually increasing until after a rather heavy rain the

entire cut filled up with this stuff, involving an expenditure of one dollar per cubic yard for its removal. Though the moving masses had adopted a slope of nearly two horizontal to one vertical, the breaks continued, stretching for more than 150 ft. into the hill above the grade of the roadbed, and over 500 ft. distant from it.

To prevent similar occurrences during the time of operation, involving delay and expense, Mr. Rohwer had the rock cut arched over for a distance of 600 ft, from the portal of the tunnel. But an arch, framed of timber in order to furnish clearance, without protection against side pressure, cannot be relied upon as a permanent safeguard against slides. To make it serve, however, should the mass continue to move, the clay bank was removed for a distance of 12 ft. from the edge of the rock cut and holes were drilled into the rock 8 to 10 ft. in depth, and from 10 to 15 ft. apart in a row along the foot of the new bank, shots being placed therein and fired simultaneously by means of an electric battery. The rock was broken but not scattered, a trenchlike crack appearing at the surface. The writer then had logs cut from the timber, of which an abundance was found in the immediate neighborhood and these logs were placed alongside each other with the butt end in the rock crevices, the other end overhanging the timber arch, and resting upon its top. The material under the logs and between the logs and the arch was tamped, thus forming a solid flooring over which the material could slide, as was contemplated, distributing it over the entire arch and serving as a weight instead of a thrust.

The further object of cracking the rock was to permit the water coming through the clay to escape, thus leaving the footing dry and in better position to act as a support. The plan worked very satisfactorily. The first rain produced another slide, the logs carrying the material over the arch. With the drain in the rock at a distance of 12 ft. from the edge of the cut and over 30 ft. from the foot of the new slope, a good foothold had been created which served the purpose, for no further movement of the overhanging masses, estimated by the engineer in charge as reaching the enormous quantity of 130,000 cu. yd.; has taken place since that time, 1904. The few sticks of timber in the arch which had moved, were displaced not more than an inch.

This experience led Mr. Rohwer to the conclusion that many similar slides formed by masses moving along a rock surface might be checked by boring holes down to rock, lowering dynamite and breaking the surface by means of blasts and actual practice has confirmed this view.

An Investigation of Manhole Explosions at Aberdeen, England, disclosed the fact that coal gas leaking from street mains may become odorless by filtering through a moderately thick layer of earth without losing its explosive effect.

Crocker's Reef Dam across the Hudson at Ft. Edward.

By Herbert Spencer, C. E.

For the improvement of the Champlain Canal, extending from Waterford to Fort Edward, via the Hudson River, and from the latter place to Whitehall, on Lake Champlain, a series of dams will soon be in course of construction. The Crocker's Reef dam across the Hudson River is the first of this series to be constructed, and will serve to maintain the Barge Canal level for a distance of seven miles.

The accompanying views and sketches show the main features of the work and the methods employed by the contractors during construction. The dam is in two sections, the east spillway being 480 ft. long, and the west spillway 280 ft. long. The bottom of the river is rocky on both sides of the island, the rock being a shale formation, very common in this locality. One of the illustrations shows the lay-out of the east channel, with the sections; the west channel is similar, except that the abutment walls are not so long.

Method of Placing and Filling Cribs for Coffer-Dam; Crocker's Reef Dam.

Work was started on the dam proper on May 24, 1906, the contractors excavating the rock with pick and shovel. The section of the dam called for the neat line of the excavation to be on the back line of the dam, and that the concrete skewback should butt up close against the rock. Drills were set about 2½ ft. back of this cutting line, and after the holes were fired the rock was picked off to a neat line. A trench about 2 ft. deep was thus dug out of the rock, care being taken to secure a good rock shoulder against which the concrete could butt. The excavated material was thrown outside of the coffer dam on the downstream side, and helped weight down the sheeting and keep it in place.

As the water was shallow for about 150 ft. out from the east shore, it was decided to build a puddled coffer dam on the upstream side. The coffer dam consisted of 8x8-in. timbers, 5 ft. apart horizontally and 2½ ft. apart vertically, separated by ½-in. round bars with square nuts. The truss was braced by 4x4-in. vertical posts 5 ft. apart, and 4x4-in. diagonals. Two rows of 1-in. plank were then placed on the inside of this coffer dam on each side. Sand bags were placed at the bottom and clay puddle was placed inside.

The material for the puddle was taken from the canal prism just north of the dam, and consisted of a clayey mixture, with considerable earth mixed in. The downstream side was treated by placing two rows of 1-in. sheeting against the stringers at the south end of the trestle timbers. Sand bags were then thrown on the bottom and clay dumped in until it was well up on the sides of the sheeting. One of the illustrations shows a section of the coffer dam, and the arrangement of the track overhead.

At Sta. 2+20 of the line of dam it was decided to substitute a crib coffer dam in place of the interior puddled dam. This was on account of the deeper section encountered, and it was also thought to be more economical.

The cribs consisted of rough hewn timbers, mostly maple and elm, which were all cut from the spoil banks further up the river. The cribs were framed on shore by placing one log upon another, log house fashion, and drift-bolting with ½-in. pieces of iron. One of the illustrations shows a section of these cribs. On the inside was nailed 2-in. plank to hold the stone with which they were sunk.

When a crib was framed on shore it was buoyed up by placing empty oil barrels in it and towed out to place. Guy ropes anchored to trees on shore assisted in letting it down to the proper location, when it was lined up and sunk. A large raft loaded with stone always accompanied the crib, and when it reached its anchorage the stones were thrown in. Owing to the swift current it was difficult to always hold the cribs in place, and considerable care and ingenuity had to be exercised to sink them at the proper place.

A large crib 50 ft. long was framed on shore to close the last gap between the rest of the cribs and the island, and was floated to place in the usual manner. Unfortunately, the water was too swift and the guy ropes broke, allowing the crib to float downstream. It was with difficulty recovered and brought back to place. At this latter place a depth of water of 28 ft. was found, and the crib had to be sunk here. This depth was not looked for, as the cross-sections did not extend upstream far enough to take in the hole. However, it was successfully done, and a small wing crib placed at an angle to deflect the strong current away from the deep hole.

Three separate coffer dams were used to cross the east spillway and as soon as enough cribs were in place 8 x 8-in. timbers were placed on the upstream side to connect them. These were securely fastened to the crib, and the sheeting was then run down to the bottom. Two rows were used, one-inch plank for the shallow water and two-inch plank for the deeper sections. These plank were nailed to the waling pieces connecting the cribs, and as soon as they were in place the maneuvering boat was placed close by, and sand bags were guided by two poles held by hand until they settled on the bottom. These were firmly rammed in place, and all large holes at the bottom chinked up.

Clay was next brought over from the prism excavation in 4-cu. yd. dump cars, three cars to a train load, and dumped on a platform. Shovelers then threw the dirt over the sides and it slid down the sheeting and settled at the bottom, closing all joints between the planks. The downstream side was made secure by placing sheeting against the two ends of the trestle timbers, and throwing in dirt until it almost reached to the top of the dam.

The first section of coffer dam, about 130 ft. long, was pumped out in 17 minutes, and no trouble at all was encountered by leakage. In fact, all the coffer dams were exceptionally well built, and very little leakage occurred in any of them.

The trestle was built as the coffer dam progressed, and consisted of upright posts 9 in. in diameter, spaced 12 ft. apart. Across the top of the posts were placed rough timbers smoothed on only two sides and projecting over the posts about 2 ft. These were fastened, both longitudinally and transversely, and were also braced against the rock-filled cribs. Ties were placed on top of the trestle, and a 3-ft. gauge track on the ties. When the concrete had hardened sufficiently and the forms removed, the vertical posts in the upstream side were taken out, and the transverse timbers allowed to rest directly on the dam. The track was then shifted on the dam.

The concrete was a 1:2½:5 mixture, and was conveyed from the mixer to the dam by an 18-ton Porter locomotive, drawing a four-yard concrete car. The method adopted was as follows: When a car was filled with concrete it was started by giving it a shove, which sent it on the track to Point A. The locomotive at this time was on the siding B with an empty car, which it brought up to the concrete mixer C, uncoupled and then went back and shoved the car of concrete at A over to the dam. The return trip was not started until the locomotive gave a warning blast, at which time the men at the mixer prepared to start the loaded car off again.

An actual timing between trips showed an interval of about seven minutes, and that two minutes was taken to dump the car. The length of time it took to dump was due to the fact that the car, being an ordinary dump car, was not suitable for this work, as the concrete could not slide out fast enough. The bottom was covered with a large sheet iron plate, and the corners plastered with sand, so that very little mortar could run out going from the mixer to the dam.

Points were given at intervals of about 20 ft. on the bottom of the large curve for setting the forms. A string was stretched between these points and the bottom of the curve brought to this line. Ribs were made out of 2-in. plank and spaced 5 ft. apart. These ribs were fastened by cleats to the trestle overhead and braced against the rock at the bottom, and the forms nailed on this curve. Ribs were also made for the small curve at the crest, and ¾ x 2-in. lagging nailed on. The line for the crest at the correct elevation was given, and the small ribs brought to this line after allowing for the lagging to be nailed on.

The slope below the larger curve was given by a template, and the tangent to the curve made by nailing pieces of 2-in. plank to the ribs and allowing them to rest against the rock at the bottom. The forms were then nailed to these straight ribs as far as the level of the rock.

The concrete was allowed to run out from inside the forms and fill the space between the rock and the bottom of the forms. This was the simplest and easiest way to construct the skewback, care being taken to see that the concrete had a close bond to the rock shoulder of the foundation.

Large stones about 1 cu. ft. in size were placed in the dam, spaced 12-in. apart. About ten per cent. of the dam consisted of these stones. On account of the flat curve of the dam it was difficult to ram the concrete against the forms, and only enough plank were placed to keep abreast of the concrete. By this method the men in the dam could use their forks to pry back the stones.

The abutment walls for the spillway were well bonded into the rock on each side, the elevation of the top being taken 2½ ft. above the maximum high-water stage. The core walls on the island and on the west mainland are of concrete, with an earthen embankment 16 ft. wide on top and covering the top of the wall to a depth of 2 ft.

The dam was started the latter part of May, and completed about Oct. 10, 1906. The total length of crest is 760 ft. The contractor was the Empire Engineering Corporation of New York.

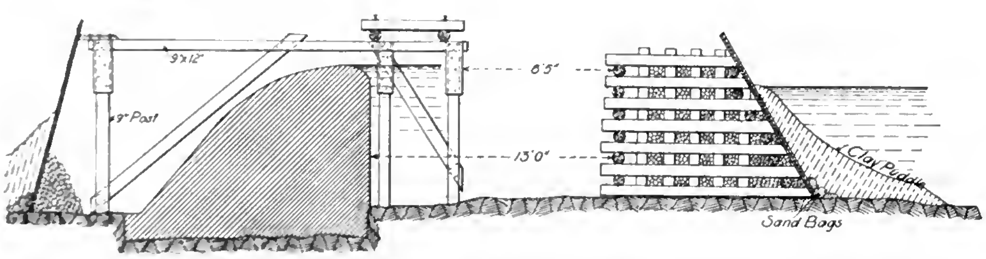
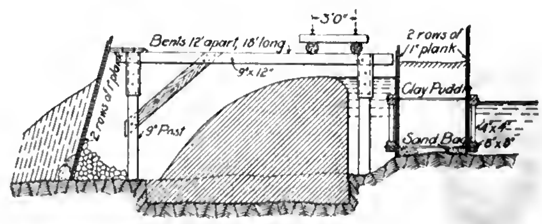
Location of Crocker's Reef Dam.



Arrangement of Crib and Trestle for Use in Deep Water.



Arrangement for Shallow Water.

Back-Filling Trenches.

A paper by George C. Warren, President of Warren Brothers Co., before the Detroit convention of the American Society of Municipal Improvements.

It is pleasing to note that recent issues of engineering periodicals have devoted prominent space to this matter, which is both one of the most important and one of the most generally neglected matters that municipal officials and contractors have to meet in connection with street work.

One of the articles referred to quotes from specifications of the West Park Commissioners, of Chicago, which are incorporated in permits granted for making excavations in streets to reach underground service pipes. From the quotation the following extract is of special interest:

"All material excavated from any trench under paved roadways must be removed from the boulevard; said trench being refilled with clean cinders, sand, gravel, or crushed stone, placed in layers not exceeding 6 in. in depth, thoroughly compacted with heavy hand rammers, using the necessary amount of water to complete perfect consolidation of the back filling."

This specification is certainly on the safe side, but for general use in many, if not most cases, it seems to the writer unnecessarily severe and expensive in the requirement that all material excavated from any trench must be removed from the street and replaced by cinders, sand, gravel, crushed stone, etc.

In the case of West Chicago Park Boulevards such a general stipulation may be justified by either:

(a) The importance of not littering the boulevards any more than absolutely necessary and of maintaining their fine appearance as constantly as possible, or

(b) The knowledge, if it is a fact, that the sub-soil underlying this section of Chicago is of a character which, after once being disturbed, is unsuitable for backfilling of trenches. Whatever may be the reason and justification for such a claim by the Chicago West Park Commission (and I assume it is justified there), this should not be set out as a generally suitable provision and for all cities and all classes of sub-soil. I do not want to be understood as advocating the withdrawal of one iota of the greatest precaution and care in this important matter of backfilling of trenches, carelessness in which is costing an aggregate of hundreds of thousands of dollars annually in damage to pavement and vehicles. On the contrary, my purpose is to endeavor to point out the importance of the matter and to suggest practicable, general requirements for overcoming the difficulty in the most economical way as to each particular case.

With a quarter of a century of experience in street paving throughout the United States and Canada, I believe I have met the matter of backfilling of trenches in about all of its possible phases, and I appreciate that it is a most difficult matter to draft a specification which will give (a) efficient results and (b) a basis of payment for the work which will insure the greatest practicable economy to the city and fairness to the contractor.

Completed Section of Crocker's Reef Dam with Work in Progress beyond It.

The greatest difficulty arises from the fact that the method of treatment and its cost vary very widely with the character of sub-soil, which often varies very greatly within the limits of one sewer or water or gas main trench; this often cannot be foreseen and often varies with the weather conditions (wet or dry) which happen to prevail.

Before attempting to offer a solution I will mention a few instances which have come to my notice. There is a popular notion that trenches should be allowed to settle for a year before paving and that then the work is safe. This is not only a fallacy which breeds carelessness in cases where it is thought no pavement will be laid in a year or more, but it is impracticable to defer paving until a year or more after all mains and house connections are made, and equally impracticable to avoid cutting into pavement for installation of and repairs to service pipes, although the latter can be guarded against by the exercise of reasonable precaution much more than is generally done.

We all know that by careless or indifferent backfilling of trenches unpaved streets are often rendered dangerous and nearly impassable for years. I remember about fifteen years ago an instance in one of our older cities, where an asphalt pavement was being laid, replacing an old cobble pavement. The cobbles and a few inches of the underlying earth necessary to provide the sub-grade were removed; the sub-grade rolled with a steam roller, and a concrete foundation laid. While the concrete was "setting" there had been a good deal of rain, and at one point in the street the concrete settled and developed a hole, into which a hoe handle was inserted the full length without finding the bottom of the hole. Investigation and subsequent examination developed a serious hollow, several feet deep, about 2 ft. below the surface and over 200 ft. long, over a sewer which had been laid twenty-five years before and doubtless backfilled in what is still the quite generally customary way of merely throwing the earth loosely back into the trench. In this case a crust or arch of solid earth had become formed, which did not develop the hollow below until the excavation for the new pavement removed a part of this crust, and the rains caused the balance of the crust in one spot to fall into the hole. In another instance no trouble developed in the construction of an asphalt pavement laid on concrete foundation, but three years later a horse's hoof broke through the surface of the pavement and he broke his leg. Here examination revealed a hole 6 ft. deep, which it took fifty loads of earth to fill, over a sewer trench ten years old.

It is very common for a pavement to settle a year or more after it is laid along the line of a sewer trench filled several years before the pavement, where no trouble developed during the rolling and laying of the pavement. It is still more common to find almost insurmountable difficulty from settlement of old trenches while the paving work is in progress.

So much for the theory that however carelessly a trench or other fill is made it will settle itself within a year. On the other hand, I have never known of a case where trouble has followed from the settlement of sewer or service pipe trenches made immediately before the laying of the pavement where I had supervision of the backfilling, even with very treacherous soil conditions. I would far rather take my chances on the guarantee of a pavement laid immediately after a sewer trench, the filling of which I could control, than five years after the laying of a sewer, the trench of which was filled with the generally customary carelessness and usual view to the least possible cost only.

About two years ago I was going over a street about two miles long in the Middle West, for the paving of which bids were about to be received. A sewer, the trench of which was from 15 to 20 ft. deep to a clay soil, was being built, using an excavating machine, which backfilled without tamping. On account of the looseness of the fill the level of the roadway over the trench was being raised about 18 in., sloping to nothing near the edge of the road. An inspector was standing over the work, and I asked him to show me the specifications. They clearly provided for "thorough tamping of the trench in courses, not more than 6 in." On calling the inspector's attention to the provision he first claimed that it only referred to paved streets. I showed clearly that this was not the case and explained that my interest in the matter was as a bidder and possible contractor for the pavement to follow, and received the following retort: "You don't shuppose Misther Murphy (naming the contractor) is going to fill the sewer for youse!" The outlet of the same sewer passed through a paved street, which I found was actually being filled, without any tamping whatever, with tipcarts loaded from the excavation by buckets and hoisting engines. An appeal to the engineer brought a promise to investigate any continuation of the trouble, and

further inquiry brought out the explanation that this provision of the specifications was not generally complied with: that contractors did not figure on doing so; that the price showed the contractor did not figure on doing so, and that it would be a hardship to force him to the expense, and that as the pavement would not be laid for a year, the trench would probably be settled by that time. This is only a somewhat aggravated case of what happens to-day, I believe, in fully three-fourths of the sewer trenches which are being built every year.

Now, for the remedy, which is more difficult than to call attention to the common faults.

In case of permits to public service corporations, plumbers and abutting owners to cut into the streets, whether paved or unpaved (the former is but little more important than the latter) it is only necessary to stipulate in the permit that "the trenches shall be backfilled by such means as the City Engineer may direct, depending on the character of the excavated material, in such a manner that all excavated material shall be replaced in the trench without raising the grade of the roadway. Flushing will only be permitted in cases where the sub-soil is sand or gravel or other material from which the surplus water will readily drain away."

In criticism of this proposed requirement reference may be made to the volume of the pipe. My reply is that except in trunk sewers (which do not apply to the permits referred to) the volume of the pipe is so little, in comparison to the volume of the trench, as to be insignificant, and it is well known that, in ordinary cases, more earth can be tamped into a trench than is removed from it. There is the familiar farmer's post hole, which will take the earth removed from the hole and the post besides. In my judgment the only case where the rule of "get back all the dirt" cannot apply is in rock excavation, in which case the breaking up of the rock nearly doubles its volume, and the pieces of rock are so large that they cannot be replaced to their original density.

In the case of contract work for sewers, etc., the case is more difficult, in view of the necessary uncertainty of conditions to be met under ground and consequent uncertainty of the most economical way to properly backfill the trench and consequent impracticability of the contractor accurately figuring in advance what the cost per linear foot will be. On this account some contractors are sure to bid far too low to permit proper work, and others figure "safe" with the probability that if they happen to receive the contract the price will be too much advance on the probable cost. In one case the city has the almost impossible task of forcing the contractor to do proper work when the price is too low to permit it without loss. In the other case the probability is that the city will pay too much for the work. An effort should be made to avoid both evils.

My suggestion is, divide prices in such a way that whatever material is encountered a fair price will be allowed the contractor, as follows:

(a) Setting pipes, per linear foot.

(b) Earth excavation, per cubic yard.

(c) Rock excavation, per cubic yard (if rock is likely to be encountered).

(d) Hauling excavated material to spoil bank (if unsuitable for backfilling, and its removal directed by the Engineer), per cubic yard.

(e) Lumber delivered on work (if any required for shoring), per M. B. M.

(f) Placing or replacing (if lumber reused) in sewer trench, per M. B. M.

(g) Refilling trench, if backfilled, by flushing earth excavated from trench, per cubic yard.

(h) Refilling trench, if backfilled, by tamping earth excavated from trench, per cubic yard.

(i) Refilling trench, if backfilled, by flushing suitable borrowed material (to replace unsuitable excavated material, drawn to spoil bank by order of Engineer), including furnishing the material, per cubic yard, measured in the wagons as material is delivered.

(j) Refilling trench, if backfilled, by tamping suitable borrowed material (conditions the same as item "i"), per cubic yard.

(k) Refilling trench with rock excavated from the trench, per cubic yard.

Corresponding with such a schedule of prices in proposal and contract, the specifications should provide as follows:

1. Material excavated from the trench, which, in the opinion of the Engineer, is unsuitable for backfilling, shall be hauled by the contractor to a spoil bank and shall be paid for at the price bid per cubic yard for "hauling excavation to spoil bank." Measurement to be made in the wagons at point where loaded.

2. Flushing in backfilling will be permitted only in case the material is sand or gravel or other material, from which, in the opinion of the engineer, the surplus water will readily drain away and leave the earth filled solid.

3. Except where flushing is directed by the enginer, the backfilling shall be done by thorough hand tamping in layers not exceeding 6 in. in depth.

4. Whether backfilling of earth is done by flushing or tamping the full amount of material excavated from the trench, less the volume of the sewer shall be refilled into the trench without raising the grade.

5. In case rock is excavated from the trench it shall be backfilled by carefully hand-placing the excavated rock in layers with succeeding layers of earth well filled into the voids between the pieces of hand-placed rock.

6. In case the excavated material is clay, which, in the opinion of the enginer, is too wet to enable solid backfilling by tamping, the excavated wet clay and reasonably dry "borrowed" earth shall be tamped into the trench in succeeding layers, using enough of the dry earth to overcome the excess of water in the clay and to provide a solidly filled trench, to the satisfaction of the engineer. The "borrowed" earth, including tamping, to be paid for per cubic yard of "borrowed material," tamped into the trench. Measurement to be made in the wagons as delivered on the work.

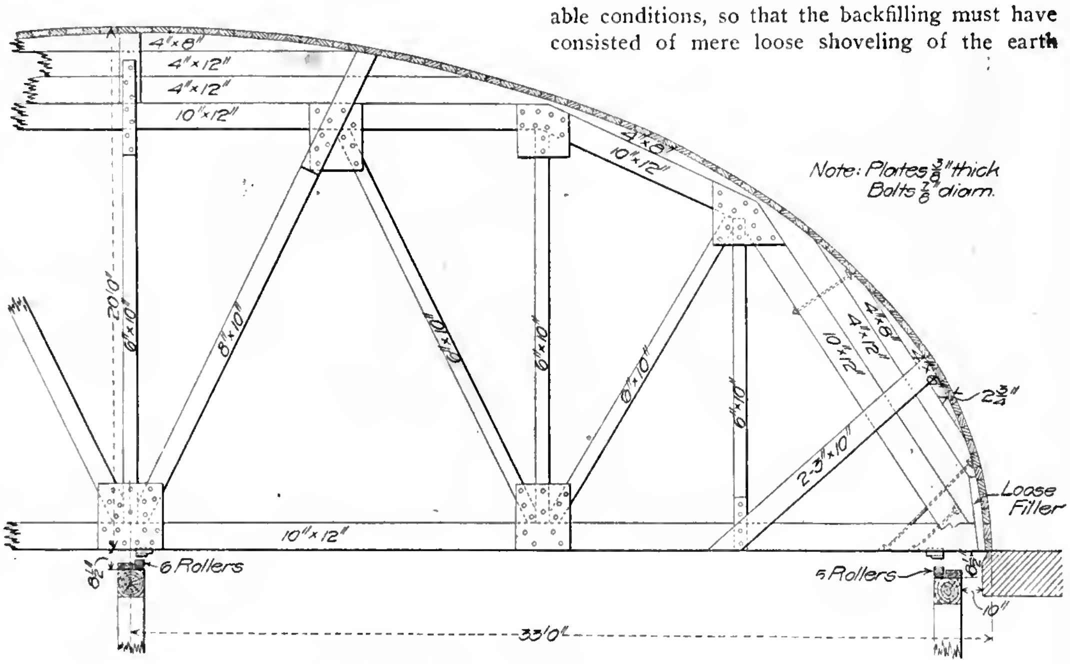
If this suggestion is criticised as being complicated the answer is: The conditions are necessarily complicated by practical inability to tell in advance the condition of material to be excavated and consequently the treatment it should receive in backfilling, and the simple but incomplete specifications and method of payment generally adopted in the past have resulted in quite general unsatisfactory results. Some condition should be provided which will correct the evil of poorly filled trenches, however complicated they may be.

Of course, it must be expected that the cost of efficient and proper backfilling of trenches will be much greater than the cost of the inefficient system at present generally in vogue, but the increased cost will be small, in comparison with the saving in repairs to road surfaces and vehicles.

A prominent engineering paper which makes a specialty of earth work in recent times published a series of interesting and complete cost data, evidently collected and tabulated with very great care. One report of twenty-six jobs on sewer sections in one city, aggregating 8,882 lin. ft., shows an average cost of backfilling the trenches of 7.22 cents per cubic yard. The soil is generally reported as good clay, and that backfilling was done by hand shovels. Now, it is well known that this is a very low average cost for the bare shoveling of earth under the most favorable conditions, so that the backfilling must have consisted of mere loose shoveling of the earth into the trench. What of the condition of the roadway, whether paved or unpaved, following this shoddy work, and what of the vehicles which have to pass over this nearly two miles of street during the next several years?

An important point not referred to above in connection with repaving over sewer trenches in unpaved streets is the matter of foundation. Even with the greatest care in backfilling the trench, it should be reinforced at the top by a solid Portland cement concrete foundation to the pavement, and the concrete should extend over the edges of the trench about 6 in. on each side.

One engineering journal recently suggested that tamping the earth in backfilling trenches be done with pneumatic or steam rammer, something on the order of pneumatic or steam riveting machines. This offers suggestive food for the mechanical inventor, but, as far as I am aware, nothing of the kind has yet been perfected. For the present tamping must be done by hand, and a good rule is two good men with heavy rammers in the trench to each shoveler outside, and of the three men, put the best two on the tampers. The common practice where there is even a pretence of tamping is, say, four to six shovelers to one tamper, with the poorest man in the trench, because his work doesn't count in the amount of trench backfilled.



Details of Centering for 175th Street Arch.

The Construction of the 175th Street Arch, New York City.

The Grand Boulevard and Concourse now under construction between 161st St. and Mosholu Parkway, in the Borough of the Bronx, New York City, is carried over 175th St. by an elliptical brick arch, of 66-ft. span and 20-ft. rise, built on a 9 deg. skew. This arch, which was described in detail in The Engineering Record of April 27, 1907, is approached from both directions over an earth fill contained between high, broken range, ashlar faced, rubble backed masonry walls 172 ft. apart, face to face under the coping. The spandrel walls over the arch and abutments are of the same class of masonry as the retaining walls except that the quoins are of Maine granite with 3-in. rock face and 1-in. chisel drafts on all exposed edges. The spandrel walls are 181 ft. 4 in. apart, face to face.

The abutments are of coursed granite backed with rubble, 20 ft. high from the top of the footings to the top of the coping courses or skewbacks which are 12 ft. 6 in. wide. The third course above the footings is a fine cut belt course and those above and below this are rock face, but the courses above have a 1-in. chiselled draft on all edges. The coping course is fine cut granite.

The arch ring is 40 and 48 in. thick at the crown and springing line, respectively, and is of hardburned brick except the soffit course which is buff vitrified brick. The ring is faced in the planes of the spandrel walls with fine cut granite voussoirs which extend into the ring parallel with the axis of the arch 3 ft. and 4 ft. alternately to bond securely with the brickwork. They are fine cut on the soffit and rock face on the vertical plane with a 1-in. chiselled draft on the radial and a 2-in. draft on all other edges. These voussoirs were cut on the work as required, the form of their soffit faces being laid off on the centering after the latter was in place.

The arch is being constructed in sections beginning at the west end and continuing eastward. The centering is supported on eleven wooden trusses placed in planes perpendicular to the axis of the arch and having the form and dimensions shown in an accompanying illustration. These trusses, which are placed 5 ft. on centers, are supported at their ends and middle points by three lines of 12x12-in. yellow-pine caps carried on 12x12-in. posts 5 ft. on centers resting on timber sills on concrete foundations. The upper and lower chord members of the trusses are of long-leaf yellow pine with the dimensions shown. Owing to the difficulty of securing yellow pine sticks 65 ft. long, the lower chord of each truss is made of two 32½-ft. timbers. The verticals and diagonals are short-leaf yellow pine and the lagging is 2¾x6-in. long-leaf yellow pine plank. Most of the connections are made with ⅜-in. steel plates on both sides of the members and ⅞-in. bolts, arranged as shown in the accompanying sketch. The trusses were built on a level spot near the work and, as it was absolutely necessary to have them all exactly alike so that when the centering was moved forward the lagging over the rear ribs would accurately fit the brickwork built over the front ribs, monuments were placed in the ground by the engineers in charge of the work to show the location of each panel point.

Building First Section of 175th Street Arch.

When it is necessary to shift the centering, which weighs about 105 tons, it is moved forward on a system of rollers under each bearing point. While this system is not new, it is believed that the arrangements in this particular case are in some respects superior to any which have been devised before for similar work. To the top of each cap is attached a 3x8-in. yellow pine bearing strip which carries the double oak wedges upon which the trusses rest. At one side of each 3x8-in. bearing plank and attached to the bottom sides of the lower chords of the trusses are 3x8-in. yellow pine roller plates carrying 1x8-in. oak shoes 20 in. long placed 5 ft. on centers. The 4-in. strip on top of each cap not covered by the bearing plate and immediately under the oak shoes is faced with a ¼x4-in. steel plate upon which the rollers bear. The latter are 4-in. sections of extra heavy 3-in. pipe. Five rollers are placed under each shoe at the ends of the trusses and six under each shoe at the middle point. When the centering is in place under the brickwork the clearance between the tops of the rollers and the under surfaces of the shoes is about 2¼ in.

Referring to the sketch it will be seen that it would be impossible for the centering to be lowered with all the lagging in place as the coping stones project slightly beyond the lagging strips immediately above them. To overcome this difficulty the lower ends of the upper chord of each truss were notched to receive filler strips about 4 in. deep and 3 ft. long. When the centering is to be lowered these filler strips are knocked out and the lagging planks supported by them are drawn out by hand.

The trusses were hoisted to place by two guyed derricks with 70-ft. booms, placed one on each side of the roadway near the west approach walls. Fish-plates about 8 ft. long were bolted to each side of the lower chord of each truss to prevent it from buckling while it was hoisted. The wedges were laid on the sills and the trusses placed directly on them so that when the lagging had been laid the centering was ready to carry the first section of brickwork.

The two derricks used in hoisting the trusses handled the facing stones and brick for the first section of the arch from the same position, but when this section had been completed before the centering was moved forward for the second section, they were mounted on top of the section just completed. The second section is now being constructed and when it is finished the derricks and their engines will be moved forward onto it. The earth fill will then be carried over the first section to form a roadway for the convenience of the contractor. These derricks are operated by Lidgerwood hoisting engines supplied with steam by a 40-h.p. boiler placed on the ground a little beyond the east end of the arch.

When the first section of the arch had been finished and the centering was to be moved forward, a bridle of steel cable was attached to the leading truss and a tackle of steel cable was attached to the bridle and to a deadman placed on the center line of the roadway some distance to the eastward. The free line of the tackle was carried to the drum of one of the hoisting engines placed on top of the completed section of the arch. The lagging over the coping stones was removed; the wedges were carefully driven out; and the centering was gradually lowered until the oak shoes took bearing on the rollers. Jackscrews were provided to assist in starting the centering but they were unnecessary as the engine started the load without difficulty. As the centering moved forward the rollers were shifted under each shoe by men who walked from one set of rollers to another on scaffolding hung from the trusses at the proper level. Twelve men were assigned to the work of shifting the rollers, four on each scaffolding; the actual time spent in moving the centering from the time it started till it came to rest was about three hours. The wedges were driven home to lift the centering by jackscrews placed between the ends of the upper wedges in successive sets, two wedges thus being driven at once. When the centering had been adjusted in its new position, with its west end lapping under the finished brickwork about 4 or 5 ft., the surfaces of the lagging and soffit course fitted perfectly. The settlement of the centering under its load has been found to be ¼ in., and the settlement of the arch ring after removal of the centering was ¼ in.

The 175th St. arch was designed and is being constructed under the direction of the engineering department of the Borough of the Bronx, Mr. Josiah A. Briggs, chief engineer, Mr. S. C. Thomson, engineer of highways, and Mr. Chas. Gartensteig, assistant engineer. The Uvalde Asphalt Paving Co. is the contractor. The centering and plan of work was devised by Mr. James H. Small, Jr., and Mr. Wm. Marshall, superintendent for the contractor, under whose personal direction the work has been carried forward since its beginning.

Triangulation and Traverse Work in The Bronx, New York City.

At the present time the City of New York is engaged in making complete topographical maps of all of the five boroughs in pursuance with one of the stipulations of the charter of Greater New York. The charter required that the triangulation system be in conformity with the methods used by the United States Coast and Geodetic Survey, and accordingly the city arranged to have the Survey take charge of the triangulation. In May, 1903, Mr. A. G. Mosman took charge of the triangulation as director, and in July, 1904, the President of the Borough of The Bronx started the field work by erecting the signal stations. An explanation of some of the methods followed in the work was given by Mr. Edward H. Holden, assistant engineer of the Bronx Topographical Bureau, in a paper recently read before the Municipal Engineers of the City of New York, from which these notes are taken.

The work of the Topographical Bureau called for the making of a topographical map on a scale embracing the entire district showing contours, rivers, roads, and such like topography; sectional sheets of the latter map on a larger scale showing more details; traverse sheets with range lines showing the traverse lines and stations with full dimensions; a general map of the entire section showing a plan of streets; sectional maps of the general map on a larger scale, showing contours, street lines, monumented lines with dimensions and grade elevations; and an accurate and complete record of all work done.

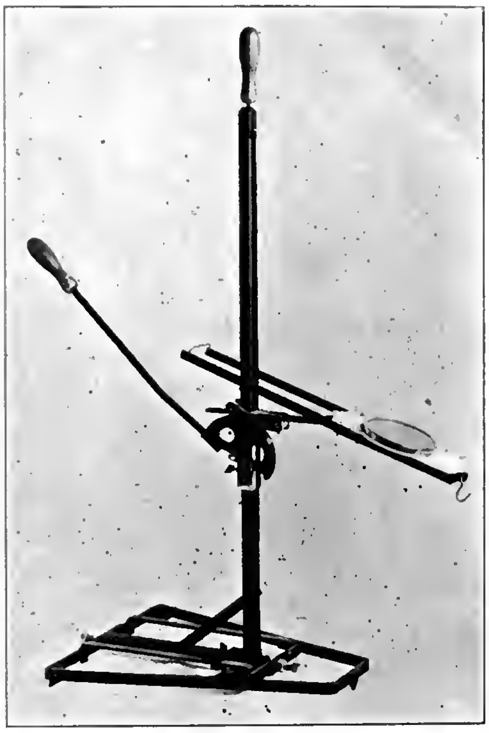
The first work was the selection of the triangulation stations. A reconnaissance survey was made showing the inter-visibility of the proposed stations and a plan of the same submitted to Mr. Mosman from which he laid out the base net and the general triangulation scheme. The base line selected was situated at Unionport and accordingly was so named, its length being approximately 1,200 ft.

Sixteen triangulation towers, ranging from 30 to 84 ft. in height were built, which together with eleven buildings and two poles constitute the twenty-nine stations for The Bronx. In the construction of these stations, high poles were used which materially lessened the time and expedited the work. These were set vertically in the vicinity of a proposed station to a height sufficient to get an unobstructed view of the surrounding stations. Without it one must occupy every station to find the inter-visibility of that station and the proposed one. With it you simply climb until you see the desired station and the height of the eye is the height of your station.

The high poles are 6 in. x 6 in. x 96 ft., consisting of 3 in. x 6 in. x 32 ft. timbers bolted together and breaking joints every 16 ft. The pieces are first laid out and marked on the ground, the holes for the bolts are bored and cleats nailed on one side of the pole, 1 ft. apart, on which the observer climbs. The lower section of the pole, consisting of a 6x6-in. section, 32 ft. long, and a half member section extending 16 ft. above the latter is raised by guide ropes, the half member forming the upper part breaking joint with its opposite half. Attached to the top is a pulley block by which the next member is hoisted into place. The poles were each laid out and raised in half a day, the horse used in hauling the lumber also raising the timbers. Five men constitute the necessary force. The poles were guyed all the way up.

Field work under the direction of Mr. Mosman was begun October 22, 1904, and finished in the Fall of 1905. The official report of the final results of the survey was received from Washington, December, 1905. It embodied the geographical positions of all the stations, the azimuths and back azimuths of the lines and the rectangular co-ordinates of the stations. Upon receipt of the report the Typographical Bureau began the work of connecting the traverses with the stations, and in many cases running new traverses connected directly with them. A comparison of the standard length of the Department of Public Works with that of the United States Coast and Geodetic Survey showed a difference of 0.01 ft. in 100 ft., so that in adjusting the traverses to the new survey, the lengths were first corrected for that difference, then started and closed on the triangulation line. The direction of many of the old fixtures laid down and monumented differed from the results of the Coast Survey, and as a result the directions and lengths as fixed by the triangulation in many cases played havoc with the final maps.

In general, traverses connecting the triangulation stations are called primary traverses. They



Forward Tape Stretcher.

are made with the utmost care, every precaution being taken to eliminate errors. The chaining is done in duplicate, the two results not differing more than 0.02 per thousand feet. Cloudy weather is used if possible. The apparatus used for primary traverses are the long tape, mechanical stretchers, and either sticks or tripods for supporting the tape. For secondary traverses the regular city engineers' 50-ft. spring-balance tapes are used with plumb bobs and tacks or marking pins.

The plumb bob, Mr. Holden thinks, has a proper place in the engineer's outfit. All plumb bobs used by the Topographical Bureau are tested to see that the line passing through the center of the chord suspending it shall when produced through the bob pass through the point. This secures the rejection of bobs which are not homogeneous, which are not properly bored to receive the string or have other imperfections. Every time a tape or chain is tested the plumb bobs used with it in the field are tested first.

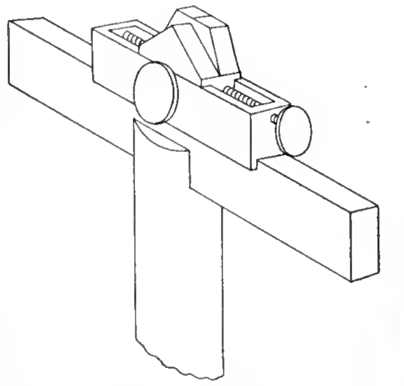
Equal care is taken with the measurement of angles on the traverses, at least two sets of six repetitions being taken and closing the horizon so that the closure shall be within 20 seconds. These limits have been easily maintained with normal conditions and reduce the traverse error to 1/4 in. per mile, which is the minimum distance between the triangulation stations.

As an example of the results of the work, the distance between Parkway and Baychester was measured with the primary apparatus, the distance being 6,347.356. The two measurements which were made differed by 0.01 ft. The line was divided into five sections and was defined by monuments set before the measurements were made. The first section was measured three times, and its length being 3,149.8185. The greatest range was 0.0044 ft. As an example of the rate at which the work was done about 2,400 ft. were measured in 45 min., an average of 100 ft. in 2 min.

On Tremont Ave., from Eastern Boulevard to Fort Schuyler Road, 8,000 ft. (over the line and back again) were measured in 5 hours and 55 min., a rate of 100 ft. in 4½ min. Many obstacles presented themselves, much clearing being necessary. The line crossed the salt meadows and the tide being up, the men had to pick their way over and around the streams. It was one of the worst places in The Bronx for this kind of work. The primary traverse apparatus was used.

In another traverse with a total length of 32,000 ft., the error of closure was 0.012 per 1,000 ft., and the six angles gave an angular error of 0.7 seconds per angle.

The line at Eastchester Meadows was measured with a 300-ft. tape, known as hoop-skirt wire tape, having a cross section of 1/50 in. by 3/32 in., and was supported every 50 ft. with a tension of 16 lb. The standardizing of this tape afforded an opportunity for studying the effects of temperature and forms of thermometers necessary with tapes of different cross sections.



Top of Portable Chaining Tripod.

A field comparator was established at Crotona Park and its length determined by the application six times of the Park Department 50-ft. standard length. This was done before sunrise to avoid the effects of the sun. The greatest range in these measurements was 0.003. The 300 ft. was measured twice in the morning and three times after sundown and again measured at an interval of two weeks and found by two measurements to be correct. The probable error of the standardizing was at least one in 600,000. The thermometers used were the chemical thermometers having no backing or support. They were graduated to single degrees, and estimated to 1/4 degree. Tests were continued from sunrise on and soon it was made certain that no reliable results could be obtained with the sun shining. Another fact made itself manifest that any kind of thermometer would not answer for all tapes, and also that certain thermometers would not answer at all. The thermometer of the so-called city engineers' tape is housed in a brass tube which stores heat and renders the readings misleading. Anything that stores heat is to be avoided.

The comparator was advantageously located in a place that was fairly shaded during the morning, and the air was influenced by the park, certain breezes causing alternately cool and warm currents of air about the tape. It was thus possible to learn if the tape and thermometers worked together. The tape was first watched and at a noted change the thermometer readings were

simultaneously called for and recorded. This was repeated several times and then the operation was reversed; that is, the thermometers were watched and the tape lengths recorded for the change noted in the thermometers. With the chemical thermometers the corresponding changes tallied exactly. With others this was not the case and their use was discontinued. The cross section of the tape regulates the sensitiveness required in the thermometer.

A most interesting fact has been observed in the 300-ft. tape in that it is constantly increasing in length. The cause, the engineers think, lies in the small cross section for the 16-lb. tension. The greatest care has been taken in reeling and unreeling the tape and no undue strain has been applied to it while so doing. A low-tension does not receive the endorsement of the United States Coast and Geodetic Survey, and the experience of the Topographical Bureau justifies the abandonment of small cross sections and low tensions.

About a year ago some steel tapes were received which had a cross section of 1/50 in. x 1/4 in., the outer surface being tinned to prevent rusting. It was found that they did not respond to temperature changes as do the ordinary steel tapes, the explanation being that the surface being bright reflects heat and does not therefore expand the same as the dull steel tape.

The tests made during the Summer of 1906 by the United States Coast and Geodetic Survey with four nickel steel (Invar) tapes show that they give results considerably more accurate and economical than steel tapes. [The tests were described in The Enginering Record of Feb. 9, 1907.] The topographical Bureau in December, 1906, ordered some of these tapes, but they have not yet been delivered. The same types of stretchers and portable supports will be used in connection with them as have been used with the steel tapes.

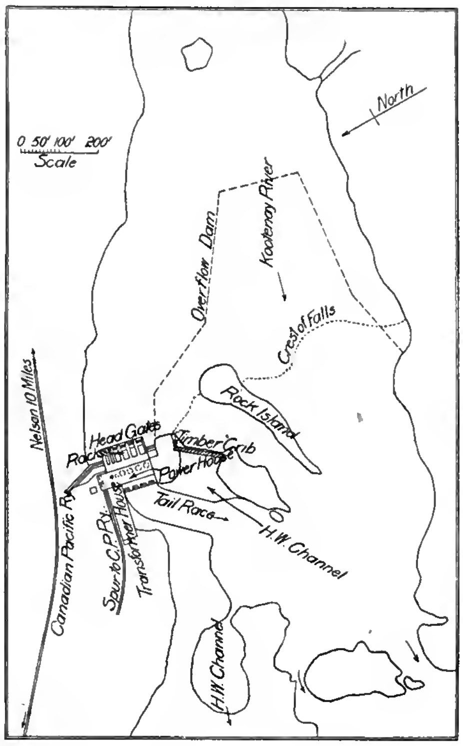
These stretchers and supports were designed by Mr. Holden. The front tape stretcher consists of an unright, hinging sideways at its lower end on its foot base, and terminating at the top in a handle. On this upright, traveling up and down, is a block, carrying the spring balance to regulate the tension. The tension is applied by a revolving half-wheel, centered in the block and working by a lever attached to its diameter. By means of the vertical motion of the block the balance at the front end of the tape is raised and lowered, while the motion on the upright gives lateral adjustment necessary for correct alignment. The rear stretcher is similar to the front one with the exception of the spring balance.

The advantages claimed for this stretcher are that it is manipulated with ease, and is instrumental in producing more accurate work because the tension can be maintained more easily for three minutes than in other forms for three seconds, the tape being absolutely under control for almost any length of time. With the tension released the stretcher is self-supporting, allowing one quickly to protect the tape from inadvertent injury, as from stray animals and from vehicles.

The portable supports are iron tripods with a round bar adjustable in height. The top of the bar terminates in a rectangular cross section forming a T-shape with the bar. This cross arm forms the track on which slides a block which forms a support for the tape, and adjacent to it, at a level with the tape, is the index mark which is brought to coincide with the tape graduations by means of a tangent screw. The block is set approximately near the tape graduation by sliding it along the bar and then clamping it. With the use of these tripods the driving of stakes is avoided, and time saved. Lines can also be measured over parks, lawns and pavements where stakes cannot be driven.

Both the stretchers and the supports are patented and are being put on the market.

The spring balance used with the city engineers' tape is faulty in respects other than that of the thermometer, and it has, in Mr. Holden's opinion, a wrong construction. The level tube is at the handle end, that is farthest away from the tape, working inside of the thermometer tube. The thermometer tube being attached away from the tape, takes a certain inclined position due to the catenary of the tape. This inclination must be secured every time the tape is used. For this position you rely on an inner tube which cannot be fitted close enough to secure parallelism without affecting the tension. The slightest movement out of parallelism gives a wrong level and a wrong length of the tape. Mr. Holden believes that the proper construction should be a reversion of the parts, that is, have the inner tube carrying the level immediately next to the tape with plenty of play between the inner and outer tubes. The level tube being absolutely free from friction would insure accuracy both of the levels and the tension. A further suggestion would be to have the end graduations on the tape and thus do away with the wear of the links which are interposed between the tape and the graduation on the handle.



Plan of Kootenay Power Development.

The Commissary Arrangements adopted by J. G. White & Co. in building railroads in the Philippines have resulted in securing at least 50 per cent. more work for the money paid to native laborers than was obtained on the highway construction in the Visayan Islands. Common labor is paid 50 centavos per day and subsistence. Food had to be provided as part of the wages, for if it was not some of the laborers would have gone hungry in order to use their money for other purposes, a habit observed among some of the negroes tried on the Panama Canal. A study of the subject showed that a diet consisting of six parts of rice, two parts of beef, one each of fish and vegetables, with condiments, was best adapted for natives engaged in hard physical labor. This food is prepared by a Chinese contractor, and while it costs 25 centavos per man daily, it has proved successful in attracting and keeping an excellent grade of men, who remain steadily at work.

The Hydro-Electric Plant of the West Kootenay Power & Light Co., Ltd.

The Upper Bonnington Falls power station of the West Kootenay Power & Light Co., Ltd., is located on the Kootenay River in British Columbia, 10 miles from Nelson, a town on the west arm of Kootenay Lake. The Kootenay River rises in British Columbia, a short distance east of the head waters of the Columbia River and flows southerly, approximately parallel to the north flowing waters of the Columbia for fifty miles and then crosses the international boundary into the United States. Here it continues to flow south then turns northwest and enters Canadian territory again, soon expanding into what is known as Kootenay Lake. The length of the river in the United States is about 120 miles. Kootenay Lake, which receives a small number of streams in its northern arm, discharges by way of the west arm, the river from this point keeping a southwesterly course to its junction with the Columbia River at Robson. The total length of the river is about 350 miles and the area drained by it and its tributaries above the power house site is about 9,800 sq. mi., of which 2,500 sq. mi. are in United States territory.

The development here described is owned by the company which has already developed the lower falls. The site of the plant was chosen on the north bank of the river, the channel between Rocky Island and that bank being used for the approach and the tailrace. The power house is built in the river and during its construction a cofferdam was built from the bank to the island, thus unwatering the whole site and diverting the flow to the south of the island. The installation is planned for 32,000 h.p., with a working head of 70 ft.

The minimum flow of the river was found to be 5,850 cu. ft. per second, the minimum occurring in January, 1905. The variations in the flow are very great, but no measurement of the maximum has been made as far as is known. The periods of high and low water differ from those of rivers not situated in mountainous country, and in the case of the Kootenay River, which depends largely for its supply on the melting snow on the mountains, the high water is comparatively late, in June and July. The variations between high and low water above and below the falls do not correspond, because the channel of the river below the falls is constricted by a number of rocky islands. These impede the flow of the stream, and it is intended to remove them in part so as to more nearly equalize the rise and fall on either side of the power station. Owing to these variations, which can never be entirely eliminated, except at a cost beyond commercial practicability, the vertical type of turbine was adopted, using all the head available at all stages of water, instead of adopting a head which would be nearly constant and which would involve a sacrifice of a large amount of power when low water prevailed. When the natural head is least, the volume of water used is not important, as the quantity available is more than ample, but at periods of low water the head is greatest and the vertical setting is an advantage since it permits the use of a higher head. Had a horizontal wheel been adopted, it would have been necessary to set the power house floor above high water, and, allowing the use of a draft tube of 24 ft., at this altitude, to maintain the tail water above low water, which would have involved a loss of head for a considerable period of each year, when water is low and consequently when head is most valuable.

It is the intention to increase the natural head by building a timber dam across the river to a height that will drown the rapids above the fall, thus affording an increase of head of 10 ft. It is

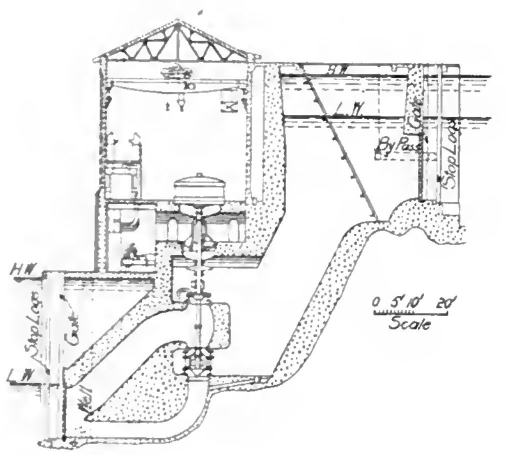
possible to construct work at the outlet of Kootenay Lake to maintain the lake level more nearly uniform and thus assist materially in reducing maximum discharge and increasing minimum discharge in the river. This will make the working conditions much better and increase the potentiality of the river considerably. The matter will be brought to the attention of the Government, for in addition to improving the power conditions of the river, it will afford a great advantage to navigation in the lake, which is now and will perhaps always be a part of the transportation system of this district, owing to the great difficulty of constructing a railway from Kootenay Landing to Proctor, 17 miles above Nelson.

The power house, measuring 40 x 140 ft., is built across the north channel of the river, and from the end of it the timber overflow dam continues to the south bank. Despite the material assistance of the natural channel, about 40,000 cu. yd. of rock had to be removed for the power house foundations and the tail race. The removal of this rock was somewhat difficult owing to the confined area in which the work had to be done, the difficulty of disposing of it, the nature of the rock, Nelson granite, and the irregularity in the direction of the seams. Some of the rock had to be excavated under water. As a large part of the concrete work admitted of the use of large stones, those most suitable for the work were piled up in convenient places, and a considerable quantity of the remainder were passed through crushers and the stone used in the concrete.

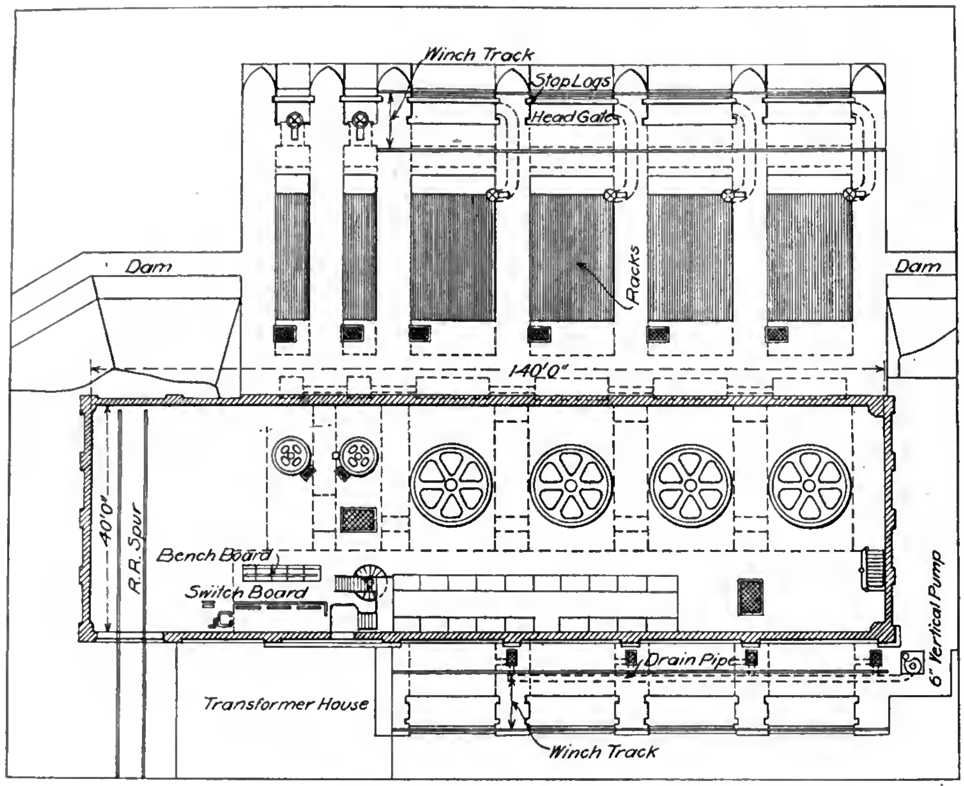
The power house building is entirely of monolithic concrete construction reinforced wherever necessary; the reinforcement consisting of round steel rods and in some places of steel rails, which were used in parts of the structure under severe strain. The four water wheels are placed in a row side by side and to the north of them are the two exciters. The switchboards are located on the down-stream side of the power house and beneath them runs a chamber in which the pressure pumps, governors and low tension tables are located. The only machinery on the floor are the generators, controlling board and the low tension switches. A spur railroad track connecting with the Canadian Pacific is run into the north end of the building so that the crane can lift machinery directly from the cars.

The water enters the intake through the submerged openings between the piers, and can be shut off by both gates and stop logs, the latter being provided so as to render the gates accessible in case of emergency. Behind the gates are the screens which are rendered accessible for repairs or cleaning. The intake and draft tubes and the turbine chamber are formed entirely of concrete, built integral with the structure, as cored openings in the monolith. Care was taken to secure very smooth surfaces on the inside of all passages, and their curves and cross sections were designed to offer as little resistance to the water as practicable. The exciter turbines are arranged similar to the main units but operate under a constant head by having the discharge at a higher head, which level is obtained by a weir. The tailrace openings are also provided with gates and stop logs, and any chamber can be emptied by a system of drains and valves, which lead the water to a well at the south end of the building, where a centrifugal pump throws it out into the tailrace. In laying out the station facility for inspection and the making of repairs were kept prominently in mind.

The floor of the power house is 24½ ft. below low water and 36½ ft. below high water, and since the building is located in the channel of the river and acts as a dam, special provision had to be made to care for whatever leakage should occur through the upstream wall of the building. The problem was solved by making the wall double as shown in the accompanying cross section and arranging for the drainage of the air space thus created.



Section through Main Unit.



Plan of Power House.

Each main unit operates at a speed of 180 r.p.m. under a head of 70 ft., and can deliver 8,000 mechanical horse power to its electrical generator. Each unit will require 1,260 cu. ft. per second, a volume equal to the flow of the river 100 ft. wide, 5 ft. deep, moving with a velocity of 151.2 ft. per minute. Each turbine consists of three inward flow Francis runners mounted on a vertical shaft, each runner being equipped with its own distributor and movable guide vanes. The top runner discharges downward and the middle runner upward into the same draft tube, and the bottom runner downward into a separate draft tube, which joins the former one just in front of the tailrace gates. The distributors are bolted to heavy cast-iron base rings secured to the concrete masonry, which forms the turbine wheel casings and the draft tubes for carrying the discharge water to the tailrace.

The runners are made of special turbine metal, approximately 88 parts copper, 10 parts tin, and 2 parts zinc. Each is built in one piece, cast in cores and bolted to the hub. The hubs are formed by enlarging the shaft at the points where the runners are attached, heavy flanges being turned on the shaft above the hubs, for attaching the runners.

In order to render the total resultant thrust on the shaft as small as possible, the chamber above the upper runner is by-passed to the draft tube, which relieves the pressure in the chamber, and thus eliminates the hydraulic thrust of this runner. Since the two other runners discharge in opposite directions, the total resultant thrust is theoretically zero. The thrust bearing, however, is designed to take care of a generous amount of thrust over and above the dead weights of the revolving parts. The latter consist of the rotor of the generator, the shaft, in three sections, three runners weighing 4,000 lb. each, couplings and bolts, making a total of 170,000 lb.

The thrust bearing consists of two specially close grained cast-iron discs. The lower disc is supported by a ball seat, while the upper is securely held in place by an adjusting nut upon the shaft. The discs have raised flanges on the outside and inside circumferences so as to form an annular pressure chamber into which the oil is forced under a pressure of 250 lb., thus lifting the revolving parts. When these parts are lifted the oil escapes between the surfaces of the discs, supporting the total weight on a film of oil.

The thrust bearing is fitted with a cover with glass peep holes. The oil is supplied to the bearing from a high pressure triplex pump, capable of working under a pressure of 500 lb. per square inch, and driven from the main turbine shaft, by bevel gearing and countershafting. Each turbine has its own pump, oil tank, piping, gauges, etc., making it independent and complete in itself. An extra motor-driven pump has been provided to act as a spare for any one of the main units or exciters and to supply oil to the turbines when starting up.

The main turbine shaft is kept in alignment by three guide bearings, the upper guide bearing being built in conjunction with the thrust bearing. It is lined with Parson's White Brass and is lubricated by oil provided under pressure. The intermediate and lower guide bearings, the former situated above the upper runner, and the latter between the intermediate and lower runners are of lignum vitae, made by driving the wood into dove-tail spaces in bronze boxes. As these bearings are submerged, they are well lubricated with water and require little or no attention.

The water is distributed to the runners through malleable iron, movable guide vanes, operated by means of links, which are connected to the vane

operating ring. The latter is operated by rods and levers from a vertical shaft which leads to the operating deck, where the governor is located. The governors are furnished with remote electrical control.

The two upper sections of the main turbine shaft are joined together by a cast steel coupling 4 ft. in diameter. The brake mechanism is fitted about the coupling, the outer edges forming the braking surface, against which the two shoes are applied, hand mechanism being provided to bring a force of 10,000 lb. on each shoe.

The turbines are guaranteed to give an efficiency of 80 per cent. when delivering 8,000 h.p. The hydraulic machinery was all designed and built by the I. P. Morris Co., of which Mr. W. M. White is the hydraulic engineer.

The generators each have a capacity of 4,500 kw. at 2,200 volts and 80 per cent. power factor, at a frequency of 60 cycles. They are of the umbrella type and directly connected to the water wheels. At the present time only two of the units have been installed. The exciters are two in number, each of a capacity sufficient to excite the entire equipment when finally installed. They are also of the umbrella type and directly connected to vertical wheels.

The current from the generators is carried to bus bars in compartments elevated above the station floor, and formed entirely of concrete. The top of the bus bar compartment, in which all the operating transformers are placed, forms the base of a platform on which are mounted nineteen 2,200 volt oil switches, all of which are motor operated by distant control from the benchboard. The latter which contains the control for the whole station, including switches for the 2,200, 22,000 and 60,000-volt switches, together with the speeders for the water wheels, is situated in front of the instrument panel at the end of the station, all connections thereto being reduced to a pressure of 110 volts. The general switching arrangement has been worked out on the basis of two separate and distinct plants, which may be coupled together or run separately on any transmission line or any bank of transformers.

The cables for connecting to the low voltage bus bars, and from them to the transformer station adjacent, are all rubber covered and drawn into bituminous fibre ducts, which are embedded in the concrete floors and partitions.

The transformer house, located at right angles to the power house and at the north end of the latter, is 36 ft. 1 in. wide, 136 ft. 6½ in. long, divided longitudinally into two sections, running the entire length of the building. The southern of these two divisions is devoted to the switches and lightning arrestors and is built in two stories. The north section is divided into five separate compartments, each of which contains three transformers, the barriers between the transformer banks and also the wall forming the main division of the building being of concrete.

The floor of the transformer room is 4 ft. 5½ in. above the top of rail of the Canadian Pacific spur, which runs along the north wall of the building. The latter consists of a series of doors, and the transformers being mounted on trucks, can be run from their positions directly onto flat cars with great ease.

Practically all of the power is transmitted at 60,000 volts, though the town of Rossland is supplied with 22,000 volt current over the existing lines of the old plant. The longest transmission at present is 83 miles, to Greenwood. All of the power so far sold is used in mining for large motor equipments and for the lighting and power of mines and mining towns within a radius of about 83 miles. It is expected that the company will at some future date sell power to the railways in the vicinity of Rossland for operating over the heavy grades. The haulage over these grades at the present time is done by steam locomotives of special type, some of them being geared. Switchbacks are necessary at a number of points. The heaviest grade is about 4½ per cent.

The plant was designed by Messrs. Ross & Holgate of Montreal, Canada, from whose paper before the Canadian Society of Civil Engineers, the data for this article were obtained.

The Cast-Iron Bridge erected by the Coalbrookdale foundry in 1797 at Stanford, Worcestershire, England, from the plans of John Nash, has been replaced by a Hennebique reinforced concrete structure of 96⅔ ft. span. It has three arched ribs; the center one is 20 in. wide at the springing line and 30 in. deep, and 20x22 in. at the crown, where the effective depth is increased 7 in. by the deck slab. The outer ribs are 14x30 in. and 14x22 in. at the springing and crown respectively. They are connected by transverse walls which are carried up to support the deck. Details of the old and new structures are given in "Engineering" of August 23.

An Umbrella Shed for Market Storage.

A 43x100-ft. umbrella shed has recently been built in front of pier 36 North River, New York, on part of an area secured by moving the bulkhead line out about 50 ft. farther into the river. It is used largely for temporary storage, especially of produce for city markets which is handled almost daily. In order to facilitate trucking and freight handling it was considered necessary to avoid to the utmost obstruction by columns along the sides, and the structure was designed with a light roof carried entirely by a single center longitudinal line of vertical columns 20 ft. apart on centers. The area covered by the shed was paved with asphalt pavement, in which six 4x4-in. pits were excavated to a depth of about 5 ft., and filled with concrete. Before they were concreted, 10x10-in. vertical posts 25 ft. long with 10x10-in. horizontal transverse sills 6 ft. long bolted to their lower ends were set in them and thoroughly bedded in the concrete. These posts were carefully plumbed and served to carry the entire superstructure. At their upper ends they are connected by a 3x10-in. mortised ribbed purlin and support the trussed rafters.

Umbrella Shed with Roof Frame Covered with Canvas.

Each truss is a triangular framework of 2½-in. screwed steel pipe, 2½ in. in diameter for the top chord and 3 in. in diameter for the bottom chord. The truss has a depth of 8 ft., and each side of the top chord, or each rafter, is a single length of pipe fitted at the upper end with an oblique screwed flange. The flanges of the two connected chord pieces are bolted together through the top of the post. The lower end of the top chord is screwed into a casting into which there is also screwed the end of the bottom chord pipe, which at the opposite end is also flange-connected to the vertical post through which it is bolted. The castings at the ends of the bottom chords also receive the screwed ends of horizontal eaves struts of 2½-in. pipe which support the intermediate rafters of 2x6-in. timbers 4 ft. apart with loop connection of flat iron engaging the struts. The upper ends of these rafters are mortised in the usual way into the ridge purlin. Half way between the ridge and eaves purlin there is a 2x6-in. intermediate purlin supported by a bent strap engaging the top chord of the roof truss.

The framework thus provided is covered with a continuous sheet of paraffined heavy canvas with transverse breadths sewed together sail fashion to make one large sheet or tarpaulin 100 ft. long and about 50 ft. wide, reaching continuously from the eaves on one side, up over the ridge purlin and down to the eaves on the other side where it is laced to the eaves strut. The side walls are formed of vertical curtains of the same material mounted on rollers at the eaves strut, which may be rolled up and give an entirely clear opening under the roof, or may be lowered and enclose the space to protect the goods within from rain or snow.

As the structure is very light and may be exposed to severe wind, extra bracing is provided by four inclined 4x5-in. struts, radiating from the intersection of the vertical post and its lower chord to the intermediate purlin, where they are kneebraced to secure stiffness and transmit the possible stresses to the main rafters. Additional stability is secured for the vertical posts by bolting to opposite sides of them pairs of 6x6-in. timbers 40 ft. long laid on top of the original asphalt pavements and serving as joists for the wooden floors, which is intermediately supported by 2x6-in. transverse joists also laid upon the pavement about 2 ft. apart.

Care is taken to leave 1-in. cracks between the outside longitudinal floor planks to provide for drainage. This construction is very simple and

proved easy to build and satisfactory in service. The estimated cost, including roof covering, end and side walls and floor, is only about $2,500, which compares very favorably with the cost of any other type of structure of equal strength and durability having the same cubical contents. It was erected in about two weeks actual working time by a small force of carpenters and pipe fitters. It was built for the Clyde Steamship Line by John Monk & Sons, contractors; Mr. J. W. Ripley, chief engineer, structural department.

Court Decision on Overflow of Land.

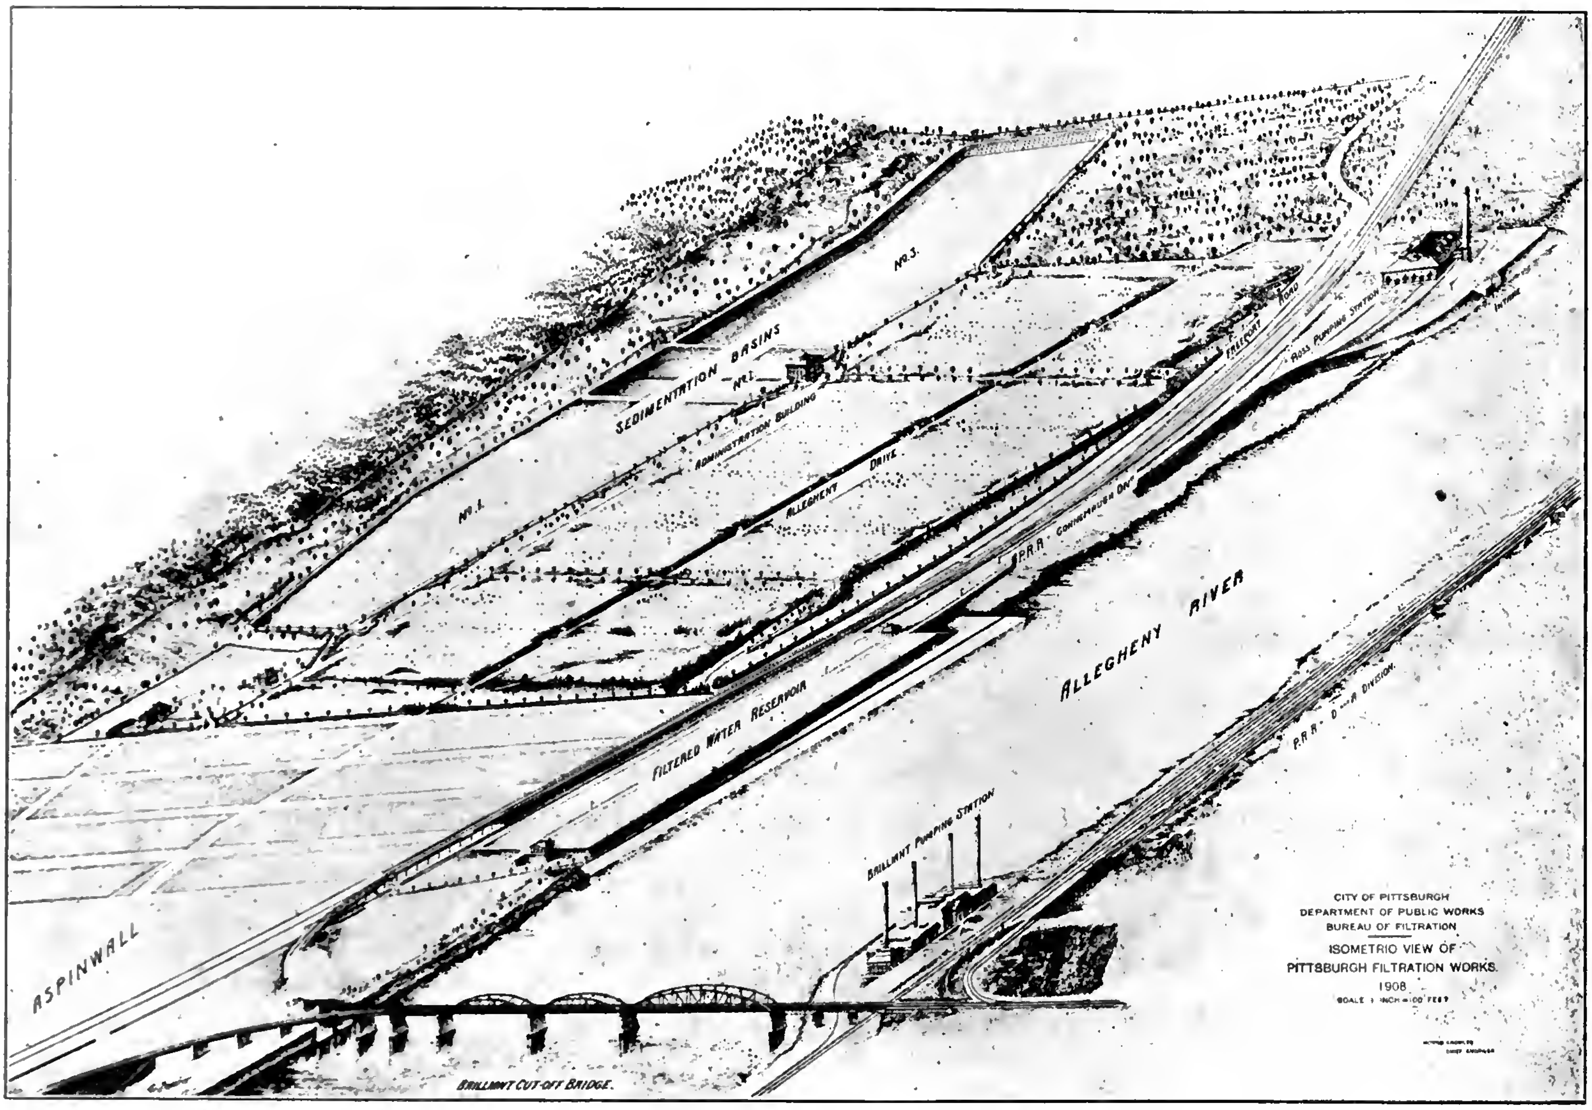
The overflow of land below a dam by the discharge of impounded water was recently before the Maine Supreme Court in Barker v. French, 67 Atl. Rep., 308. The laws of that State, unlike those of Massachusetts, do not authorize a complaint for overflowing lands below a dam, and consequently a case of this nature is necessarily an action at common law. Under this law, the court rules, a mill owner can only maintain a head of water for the use of his mill and only let it out at such times and in such quantities as are proper and reasonable for the use of his mill. He cannot hold water back when he has no use for it and there is no need of it. And if he has occasion to use his mill, he cannot turn out more water than is reasonably necessary and proper for the reasonable use of his mill. He must so far have regard for the rights and interests of those below him, although, within his rights to operate his mill, he can exercise these privileges, and if those below are injured, it is their misfortune in owning land below the mill. The case practically depends upon what constitutes reasonable use of water for power purposes.

The Pittsburg Filtration Works.

The design and construction of the water purification plant now being built at Pittsburg under the direction of Mr. Morris Knowles, was the subject of a series of articles printed in this journal during December of last year. The plant is of such an enormous size that those unacquainted with the details of filteration works will probably appreciate its magnitude better from the accompanying reproduction of a bird's-eye view of the plant as it will appear when completed, than from the more elaborate details of the design, which have already been published. It is located on the Allegheny River, from which the raw water is drawn, and considerable pains will be taken in the final finishing of the plant to give it an attractive appearance. The general idea that has been followed in developing the landscape plant has been to isolate the site from the surroundings by hedges and to plant hardy shrubs and trees of slow growth, which will require pruning only at considerable intervals. All attempts at elaborate decorations, such as flower gardens, set plants and fountains, have been avoided and the money will be spent on more permanent work. A growth of heavy timber on the hill back of the site will be retained. The entrances to the filter galleries from the drive over the Allegheny water main will be relieved by shrubbery. The entrances to the plant will be closed by iron gates carried by large stone piers. All overhead wires have been avoided by a system of underground ducts in which wires for all purposes will be carried.

The water is taken through an intake from the river into the low-lift Ross pumping station shown in the upper right-hand portion of the engraving. The pumps deliver it to the central sedimentation basin, marked No. 2 in the engraving. This has a capacity of 20,000,000 gal. and is flanked on either side by two much larger sedimentation basins, the three having a total capacity of about 150,000,000 gal. The water will pass from them to the filters, which are covered and lie on either side of Allegheny Drive, along which runs the Allegheny city water main. The filtered water flows into a covered reservoir built along the bank of the river, from which it passes through parallel twin steel conduits to the Brilliant pumping station of the Pittsburg waterworks. The plant will have a net capacity of approximately 100,000,000 gal. of water per day under normal operating conditions, with a maximum rate of 3,000,000 gal. per acre per day.

The filter beds are 46 in number, each with a net filtering area of 1 acre. Beds are arranged in eight rows transverse to the Allegheny Drive, with a covered pipe gallery 31 ft. wide in the clear between each alternate row of filters, or four galleries in all. These galleries are approximately 1,000 ft. long with the exception of the one at the end, and are divided in half transversely by the roadway over the 60-in. rising main of the Allegheny water works. The filters are entered from the galleries and all sand washing will be done in them, special appliances having been built to handle the sand economically between the filters and the washing apparatus. No storage for dirty sand is provided, for the system of operations will involve the continuous removal, washing and restoration of the sand. Provision has been made for warming these galleries so that all work connected with the maintenance of the plant can be done without interruption from the cold.



Isometric View of the Pittsburgh Water Purification Works Now Approaching Completion.

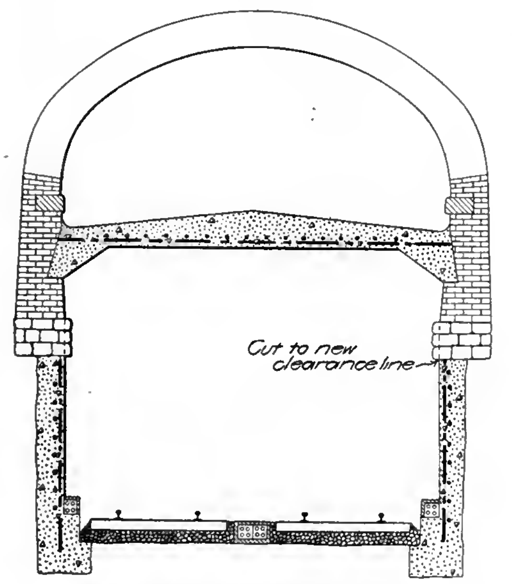
The Reconstruction of the Eighth Street Tunnel, Kansas City.

Upon the reorganization of the Metropolitan Street Railway Co. of Kansas City, Mo., in 1902 it was decided to secure better street car facilities between the Union Depot and the heart of the city. The depot is located in what is known as the "West Bottoms," of the Kaw River, at the foot of the bluff on the Missouri side. A number of street car lines reached the bottom lands, one of them the 12th St. cable line passing over a light viaduct on a 12 per cent. grade and another, the 9th St. cable line, being on a 27 per cent. grade.

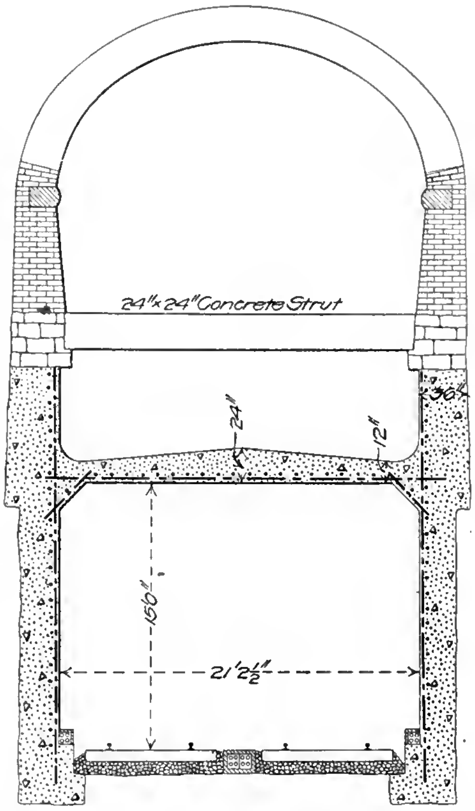
It was finally determined to make the improvements in the 8th St. tunnel which ran into the bluff close to the depot on an 8.648 per cent. grade. By this route the center of the city can be reached in about 8 min. The new schedule which was proposed called for two cars on each track in the tunnel at all busy hours, a condition too dangerous to be attempted on such a grade. The 8th St. line is the most direct between Kansas City, Mo., and Kansas City, Kan., and in the former city runs on the surface to Washington St., thence by the tunnel through the bluff directly onto the elevated structure, at a point about 500 ft. from the Union Depot, and continuing elevated to Kansas City, Kan. The plans for rebuilding called for changing the grade in the tunnel and strengthening and rebuilding the elevated to the depot, to accommodate the 80,000-lb. cars and thus make the line the main carrier to the different points in the cities, and building a return loop on the elevated at the passenger station.

The tunnel is in a thickly settled portion of the city and above its center line were a street lined with residences, a church and one house. The old tunnel was a 3-center brick arch, with 26-in. arch rings and 21 ft. 2½-in. span, the side walls battering below the springing line. Its length was 786.4 ft. The material in the bluff varied in character, limestone and a slippery shale being predominate. The shale was of a character to afford a good foundation and in general was a good material if protected from air and frost.

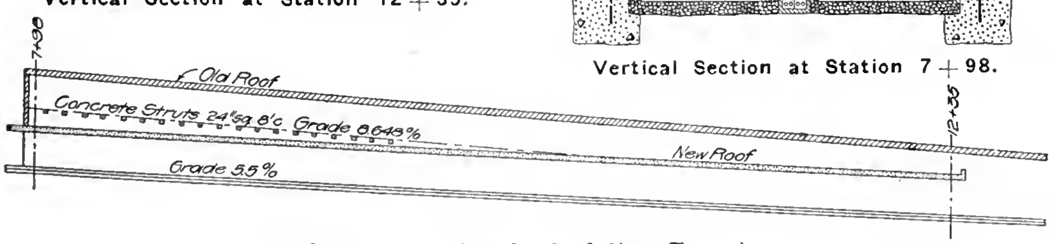
A study of all the conditions resulted in the selection of a reinforced concrete rectangular section for the tunnel, and a grade of 5.5 per cent., starting from the old elevated at the west end. The slope had to be extended 543 ft. beyond the old one to Broadway. This required the construction of 220 ft. of open cut retaining walls, 323 ft. of cut and cover section, including a 33-ft. arch and station at Washington St., and a new roof and side walls wherever necessary under the old tunnel. To provide for the new approach the street was widened for 20 ft. on each side for one block.



Vertical Section at Station 12 + 35.



Vertical Section at Station 7 + 98.



Section Showing Roof of New Tunnel.

The flood of June 1, 1903, carried away considerable of the elevated structure, and the tunnel work was to be carried on in connection with its reconstruction so that the entire line could be opened at the same time. The work was commenced in the latter part of August, 1903, the open cut work being the first part started. The first move in the latter work was to drive piling outside the proposed excavation, to be used later to hold the sheeting. The excavation east of Washington St. was handled entirely with wagons, and that portion of the open cut west of Washington St., and the tunnel itself was done with the aid of cars let down the grade on a 24-in. track by gravity and hauled back by a hoisting engine. This engine was installed at Washington St., and gradually lowered as the work progressed, being removed from the tunnel only when forced out by the track laying gang. All the excavated material west of Washington St. was wasted at the face of the bluff for the use of the park commission.

At the upper end the roof of the new tunnel structure was below the floor of the old one, but going down the new roof gradually cut into the old tunnel. This not only required a special design, but a careful method of procedure which would assure the safety of the older structure. The excavation under the old arch was handled by sinking a 12-ft. and in part a 13-ft. ditch the entire length down the sub-grade, and then gradually trimming the sides until only a 3-ft. or 4-ft. shoulder was left supporting the old footings. This shoulder support for the walls was divided into alternate 10-ft. and 12-ft. sections and excavation continued in the latter, going back 24 in. under the old wall and 18 in. below the new sub-grade. These sections were filled with reinforced concrete and allowed to set for 10 or 14 days, before the adjacent sections were excavated.

The shale and lime stone were found in nearly horizontal strata. A Fisher direct-connected gasoline air compressor and two air drills were installed and in addition to their work considerable drilling was done by hand with churn drills. After the first ditch was cut the use of the air drills was practically abandoned on account of the greater ease of placing a hole by hand in a difficult position. All of the holes were shallow and the shots light, the heaviest charge being 2½ sticks of 40 per cent. dynamite in a 4-ft. hole. For drilling into the shale an ordinary 1½-in. bridge auger, with the worm filed off, was used.

No trouble was experienced except at the east end of the old tunnel, where the excavation was deepest. Here the shale had vertical seams, and as it had been exposed to the air and frost for years, it was dried up into small cubes with almost no adhesion. The treacherous nature of the shale and the unevenness of the pile driving caused much more bracing to be used than would have been otherwise necessary. Upon this bracing the runways for the concrete barrows were afterwards placed. The braces were box struts of 2x8-in. stuff spiked together, and carried a house jack in one end. A test made of one of these struts resulted in breaking the jack without injury to the strut. Only one cave-in occurred, and that was outside of the old tunnel at the site of what was formerly a ravine.

The new tunnel has a flat roof of 21 ft. 2½ in. span, reinforced with 1¼ in. Johnson corrugated bars, 4 in. center to center across the span, and ¾-in. bars 12 in. center to center longitudinally, with 24-in. of concrete in the center and 13 in. at the haunches. The roof is carried on the side walls with the aid of an 18-in. 45-deg. continuous bracket. This roof extended 300 ft. into the old tunnel and was designed to act as a strut for the old side walls. Whenever no new side walls were built a groove was cut into the old brick walls and dowel pins put in before the roof was concreted. At the mouth of the old tunnel 24x24-in. concrete struts, 8 ft. center to center were put in between the foundations of the old walls. The height of the new tunnel above the top of the rail is 15 ft.

At the east end where the excavation was deepest and consequently the risk greatest, a complete 10-ft. section of the new side walls and roof was completed and allowed to set before undermining adjacent sections. The excavation for this section was made 12 ft. long and all longitudinal rods were cut in 12-ft. lengths, allowing 1 ft. to project through the forms to bond on to the next section.

At Washington St. a station was located and in order to provide the necessary platforms, the cross section was changed to a 33-ft. 3-center arch reinforced with two rows of ⅞-in. bent bars, 7 and 9 in. respectively center to center and ¾-in. longitudinal rods 12 in. center to center, the arch ring being 15 in. thick at the crown. The concreting of this arch was brought up to the springing line and allowed to set and the balance carried on continuously until the entire arch was completed.

East of the Washington St. station a poor foundation was encountered and reinforced concrete beams were placed below the sub-grade from one foundation to the other forming a sort of gridiron. This was done for about 60 ft., and then an old fill was encountered in which it was

almost impossible to get any foundation at all. It was, therefore, decided to make a complete concrete tube and a solid 18-in. floor was laid reinforced with old railroad iron every 12 in., this floor being necessary for about 200 ft. For the side walls of the open-cut approach 18-in. walls surmounted by a slightly ornamented coping were built.

The concrete used throughout was a 1:3:5 mixture with Lehigh and Atlas Portland cement, Missouri River sand and ¾-in. limestone. A No. 2 Smith mixer was used, and as high as 125 cu. yd. in 10 hr. was wheeled to the forms, 100 yd. being the usual day's work. Two inch planks were used exclusively for the concrete forms. The concrete was mixed on the surface for all parts of the work and run by means of wheelbarrows and spouts into place by gravity. Whenever possible the concrete under the old tunnel was wheeled in and dumped from the roof for the side walls. In other places it was dumped into a car and run down to the forms and shovelled into place, both sides being filled at once and kept at the same level. No attempt was made to get an exceptionally fine finish on the walls, as speed of construction consistent with strength and safety was the great object. Although the excavation was pushed both day and night, concrete work was carried on only during the day. The new tunnel was opened for traffic on April 14, 1904, 7 months and 14 days from the commencement of the work.

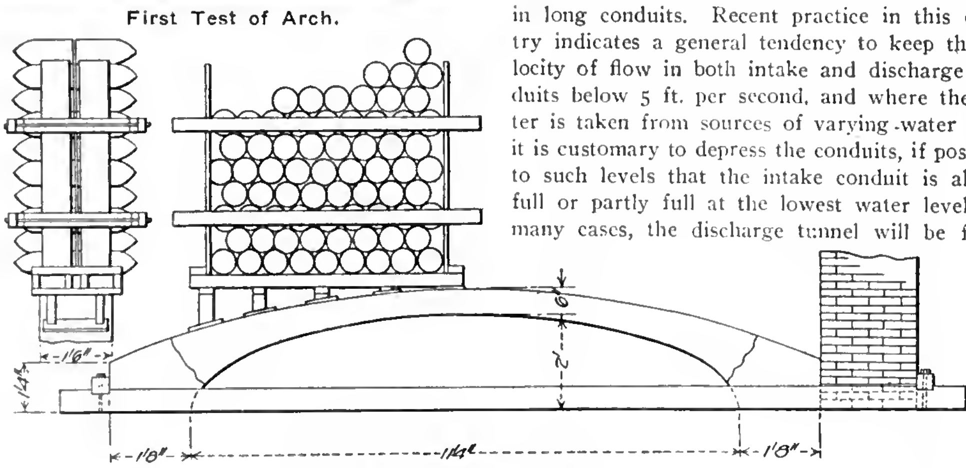
The work was done for the Metropolitan Street Railway Co., of Kansas City, under the supervision of Ford, Bacon & Davis, New York, Mr. C. M. Black being the engineer in charge of the Kansas City office. The contractors for the job were the General Construction Co., of Kansas City, under Mr. R. W. Waddell, the general manager. The contract was for the lump sum of $150,000. The work was described by Mr. W. M. Archibald in a paper before the Engineering Association of the South, from which the data for this article were taken.

Book Notes.

Considerable attention has been attracted to a series of articles on "Switches and Turnouts" contributed to the "Journal of the Worcester Polytechnic Institute" this year. The author, Professor Howard Chapin Ives, has developed the subject in a logical manner which should be particularly useful in the class-room. Special care has been devoted to the descriptions of the different forms of switches and to their effect on the lead; to the statement of practical conclusions at various places in the text and to the design of the slip switch, the mathematics of which have rarely been discussed. These papers have been reprinted by Mr. J. P. Williams, Worcester Polytechnic Institute, Worcester, Mass., who is selling them for 50 cents. As an explanation of the theory of switches and turnouts the pamphlet leaves nothing to be desired, and those engineers who are familiar only with the method used on one railroad system, and the tables for that method, will probably find the comprehensive discussion of the subject by Professor Ives an interesting and valuable review.

The fundamental factor in hydraulic power development, water supply and some other engineering works is the amount of available water. Although the importance of this factor is self-evident, it has long been a matter of surprise that so little information concerning the methods of gauging the flow of water is readily available. Most textbooks on hydraulics and surveying devote a few pages to these considerations, but the treatment is necessarily very sketchy. For this reason a small book on "River Discharge," recently written by Messrs. John C. Hoyt and Nathan C. Grover, is likely to find a wide circle of appreciative readers. There are few things offering a bigger chance of reward to the engineer who keeps his eyes open than the small undeveloped water powers throughout the country. Before their value can be properly determined, however, it is necessary to make a series of stream gaugings and to determine the amount of pondage that can be provided readily. Probably there is no other book which furnishes so much information on hydrographic work of this sort as this volume by two of the leading members of the engineering staff of the United States Geological Survey. It explains the conditions affecting stream flow, describes the methods, instruments and equipments used in making gaugings, outlines the best practice in selecting stations for making such measurements, describes the construction of weir stations, and gives a full discussion of the methods of analyzing and using the data accumulated in this manner. The book is to be highly recommended from both theoretical and practical points of view. (New York, John Wiley & Sons; $2.00.)

First Test of Arch.



Load Distributed Over Half of Arch.

Letters to the Editor.

Test of Arch for Filter.

Sir: With the idea that the result may interest your readers, there is sent you herewith a print showing the details of a recent test of a concrete arch. A timber framework made the abutments of the arch practically unyielding.

The first test is shown in the accompanying photograph, the load being 1,464 lb. per square foot. In the second test, the load was confined to about half of the arch, 9 square feet. The load over this portion of the arch was nearly uniform and aggregated 2,847 lb. per square foot; the arch cracked at the haunches. The shock or jar incident to this cracking was sufficient to scatter the projectiles. The arch itself did not collapse and was still apparently strong enough to bear the load for which it was designed, that is, 300 lb. per square foot.

The concrete was thoroughly mixed in the proportion of 1 bbl. of cement, 11 cu. ft. of sand and 19 cu. ft. of broken stone, and was carefully placed, but there was no steel reinforcement. The arch was built Feb. 25 and broken Aug. 15.

Yours very truly,

Charles W. Kutz,
Captain, Corps of Engineers.

West Point, Sept. 24.

Condenser Intake and Discharge Conduits.

Sir: What is the usual method of figuring the cross section of intake and discharge conduits for supplying condensing water to power station equipment, same to be based on the amount of water used and the distance traversed? Is there any standard work giving rules relating to this subject?

Pawtucket, R. I. Benjamin Gridley.

[In the absence of published information on the design of conduits for condenser circulation water supply, it may be stated that as conduits for this purpose are rarely more than a few hundred feet in length, the problem usually resolves itself into the use of good judgment in selecting ample sections for low velocities of flow and to provide for future extensions of plant rather than a study of the conditions that govern the flow of water in long conduits. Recent practice in this country indicates a general tendency to keep the velocity of flow in both intake and discharge conduits below 5 ft. per second, and where the water is taken from sources of varying water level, it is customary to depress the conduits, if possible, to such levels that the intake conduit is always full or partly full at the lowest water level. In many cases, the discharge tunnel will be found placed at a higher level than that for the intake, since, if it is desired to operate the pumps on the closed circulation system, this may always be accomplished by damming the conduit near its discharge outlet in order to maintain the water level at such height as to always cover the ends of the condenser discharge pipes. An important feature of the intake conduit is the provision of screens or trash racks, which precaution must be taken in practically all locations. These screening devices are, however, of widely varying design, but are all located in enlargements of the conduits in order to secure the necessary reduction of flow velocity, and in most cases there are two sets of racks provided so that one may be removed for cleaning, leaving the other still in service. The relative proportions of the intake and discharge conduits also vary considerably with differing conditions, many preferring a smaller section in the discharge conduit with consequent higher velocity of outflow. But in all cases, the preference has been shown by recent practice for intake conduit sections that will give flow velocities not to exceed 5 ft. per second, and as much larger sections as limits of cost will permit.]

THE ENGINEERING RECORD

PUBLISHED WEEKLY BY THE

McGraw Publishing Company

James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.

MAIN OFFICES:

239 WEST 39TH STREET, NEW YORK.

BRANCH OFFICES:

SUBSCRIPTION RATES.

United States, Cuba and Mexico............$3.00 a year
Canada ....$4.50 a year
Foreign subscription.......................$6.00 a year
25 shillings. 25 marks. 31 francs.

Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of THE ENGINEERING RECORD on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

REMITTANCES.—Remittances should be made by check, New York draft, or money order, in favor of THE ENGINEERING RECORD.

CHANGES OF ADDRESS.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

BACK COPIES.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.

DATE ON WRAPPER indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

CLUB RATE.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. The rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 14,500 copies are printed. Total circulation for 1907 to date, 597,000 copies, an average of 14,561 copies per week.

TABLE OF LEADING ARTICLES.

Small Producer Gas Plants.

It is only recently that producer gas as a source of power has obtained a firm foothold in this country. Even now, with a considerable amount of effort on the part of the manufacturers, comparatively slow headway is being made. Big gas engines are coming to be fairly well known, but the logical step of feeding them from cheap producer gas is rather seldom taken as yet. The philosophy of the matter is very simple. It costs heavily to produce gas of high thermal value and particularly of high luminous value. On the other hand, low-grade gas, from the mere fact that it is of small calorific value, has per unit of energy a heavy distribution charge against it if furnished by a supply company. Hence fuel gas of a thermal value such as to give minimum cost per heat unit has not become at all a familiar thing, and the ordinary man, when invited to make gas of 100 to 150 B. t. u., gets suspicious and sheers off. Yet the practical question in gas production for power purposes is not how to make a gas of maximum thermal value, but of maximum thermal value for the money, which is a very different thing. It has been shown over and over again that coal can be used to make gas for an engine much more efficiently than it can be used under a boiler, and it is pertinent to inquire why it is not more frequently thus utilized.

Probably the chief reason lies in human inertia which resists attempts to force the mind out of the line in which it has been traveling. A secondary one of considerable importance is fear of the apparent complication which the mind associates with gas making. Now, in point of fact, it is really simpler to make gas in a modern producer than to make steam under the pressure necessary for a steam engine. The producer has been made nearly automatic in its action and can certainly be run successfully by anyone who has ability enough to run an ordinary domestic furnace, when once he learns the trick. Whether a comparatively inexperienced man can operate it in such wise as to reach the best economy is another matter. The simpler producers are fairly fool-proof as regards producing gas, but it is more than likely that inability to produce good and uniform gas in unskilled hands has been one of the obstacles in the way of working the apparatus at its proper economy. Several makers are willing to guarantee the production of a brake-horse-power-hour on the consumption of 1 to 1.25 lb. of coal in the producer, and this even in units as small as 50 h.-p. How nearly these figures can be regularly reached with ordinary labor and with output rigorously measured is an open question, but there seems to be no doubt that under favorable conditions the guarantee can be made good. It must be remembered that the engine in such plants involves extra expenditure on account of having to utilize a large volume of lean gas, and that the depreciation of the producer is a somewhat uncertain quantity. Here again it is likely that the system may suffer on account of its claims to automatism. All in all, however, producer gas can be made a very cheap and convenient source of power, particularly on a moderate scale, and considerable further progress is likely. The system seems certain to find more and more applications every year.

The National Hydraulic Interests.

The statements made by President Roosevelt at Memphis on Oct. 4 deserve more thoughtful consideration than they seem to have received. Those portions of them reprinted elsewhere in this issue form a most comprehensive outline of the important and varied relations of the various national hydraulic interests. The development of navigation on inland water-ways has frequently been discussed in state papers but there has always been a tendency to consider that the subject ended there. It is true that in the West the value of water for irrigation has been recognized and during recent years our chief magistrates have dwelt from time to time on this subject. President Roosevelt seems to be the first, however, to recognize the intimate relations which all branches of hydraulic engineering bear to each other and to the national welfare. In fact, few engineers have probably stopped to consider the closeness of these relations, and anyone termed a hydraulic engineer in this country was generally considered, even among his associates, to confine his attentions to power developments. This narrow view is unlike that which prevails in Germany, for instance, where a recognition of the many directions in which water is employed has given to the term of hydraulic engineer a far wider significance than it has on this side of the Atlantic. It is particularly gratifying to notice that this comprehensive understanding of the importance of our national water resources was emphasized by the President at a gathering primarily called for the purpose of discussing only the improvement of internal navigation. The President did well to point out clearly that while navigation is important there are many other uses to which rivers and lakes are put, and anything which is done for one interest must be executed in a spirit of fairness to all other interests which are likely to be affected by it.

A great deal has been printed recently concerning some statements by Mr. James J. Hill, who has taken a decidedly pessimistic view of the ability of railways to keep pace with the demands for transportation which the development of the country will produce. It is probable that some of these statements by the eminent railway builder and operator are to be taken with a large grain of salt, but it is nevertheless noteworthy that a number of men engaged in the higher walks of railway affairs look with favor upon the improvement of internal water-ways. The congestion of tracks by bulk freight paying low rates and interfering with the operation of trains from which a much larger revenue can be obtained has been altogether too frequently observed in too many sections of the country during recent years. It is unquestionably true that there is no problem to-day which is full of greater complications, of more factors of debatable importance, than railway transportation, and when it is still further complicated by considerations of competing water transportation, the problem is one which may well stagger a master intellect. Yet it is one which must be faced and solved, and the fact that our President has so fully recognized its importance as to approve a special gathering for its consideration is a gratifying indication that he, at least, appreciates its many aspects and proposes to be guided in his recommendations concerning it by the advice of specialists who have first conferred together regarding the scope of each aspect of the problem and the relations of the various factors. The interests which are affected are so important and diverse that any other method of seeking the truth is certain to produce results based upon an imperfect, disjointed appreciation of the whole vast problem.

This is well indicated by the attempt to force the national government into undertaking prematurely the construction of a deep water-way from the Great Lakes to the Mississippi River by way of the Illinois River. The arguments so far advanced for such a water-way are partly good and partly bad, and are manifestly based on incomplete data. The Engineering Record cannot reconcile the enormous expenditure for constructing a ship canal from the Great Lakes to the Mississippi and then canalizing that stream to the Gulf for sea-going vessels, with any economical results which now seem likely to follow from the completion of a water-way of such magnitude. The effect of the diversion of an enormous amount of water from the Great Lakes to feed the upper portion of such a canal is a subject so vitally important to the existing lake commerce of the United States, to say nothing of the

Dominion of Canada, that the suggestion seems impracticable of fulfillment. Moreover, there is always the latent distrust of all arguments of this sort in the nominal interest of navigation on account of the manifest desire of a part of the people of Chicago to have the nation construct an enormous ditch carrying so much water to the Mississippi that the sewage of the city can be turned into it forevermore. Nevertheless, the complications and simplifications which mark this interesting subject as it passes from one stage to another may ultimately give it an entirely different appearance from what it now presents, and it is certainly the part of wisdom to maintain a mind open to conviction on all these great problems until the commission which is now studying them is able to make a report of the comprehensive nature which is essential for the basis of any satisfactory study.

The statements made by President Roosevelt concerning the value of water for irrigation, water supply and other purposes, deserves far more attention than they are likely to receive. At the present time very few citizens of the United States, other than those who have lived abroad and become familiar with public works there, have any idea of the value of pure water. Even to-day in a good many of our large cities it is a pretty expensive article. It is bound to become far more expensive, as the filtration of the supplies becomes more generally practiced and it is necessary to go farther for them. For this reason some measure of national supervision over the quality of water is highly desirable, for most of our large streams are of an interstate character and the control of their flow and the purity of their water rests with the people of no one state. The United States Supreme Court has decided, in the recent suit of Kansas against Colorado, that the national government cannot intervene to protect such streams under any authority now given to it by the Constitution, but this does not mean that government supervision cannot be arranged by the mutual consent of States or by some other indirect method which Congress may devise. The same consideration makes the pollution of water supplies of an interstate nature a problem of much complexity, the importance of which is hardly recognized at the present time. The President also points out the great value of many of our streams from a power development standpoint, something that has just begun to receive the consideration it deserves. All these hydraulic and sanitary aspects of our internal water-ways must be considered along with those of navigation, and the President has done well to call the attention of the nation to this inter-relation and its deep signficance to the country as a whole.

The Congestion of the Elevated Railroad Loop in Chicago.

The downtown union terminal loop of the four elevated railroads in Chicago has become so completely congested that it is entirely impossible to operate any of these roads satisfactorily during the rush hours. This congestion has been serious for several years and has been growing worse apace with the natural increase in traffic due to the rapid growth in the population of the districts served by the four lines. The recent opening of several new branches of the latter, which tap very populous districts, has required numerous additional trains to be passed around the already overcrowded downtown loop, with the result that long, tedious delays to traffic are occasioned for at least an hour and a half each morning and night. Under the existing conditions it is generally conceded by engineers familiar with the circumstances that no appreciable relief can be afforded to this situation which so seriously affects daily such a large population. As might be expected, however, a great volume of suggested solutions of the difficulty have been variously promoted through the local daily press, rivaling, indeed, in number and range of feasibility the methods which have been proposed to enable the Manhattan terminal of the Brooklyn Bridge to handle the traffic that has overwhelmed it for years during rush hours.

Several principal conditions, which it is apparently practicable to change, combine to limit the capacity of the loop to about half that which should be available immediately, to say nothing of provisions for the future. First of all, the trackage of the loop is totally inadequate to handle the trains from all four of the lines tributary to it. In the second place, the short platforms at the stations on the loop limit the capacity of the latter probably as much as any one condition. The arrangement of the connections between the tracks on the loop and the different roads is a feature that adds another great limit to capacity for handling trains. The present separation of the traffic of all four lines, thus preventing any possibility of routing trains through from one road to another, also precludes an increase in capacity that might be obtained otherwise.

The two tracks on the loop are each a trifle over two miles in length, the loop being five city blocks one way by seven the other, so the total trackage is close to four miles. The inadequacy of this amount of trackage to provide proper terminal facilities for the four roads using it may be indicated by the fact that during a period of one hour each day over 150 five-car trains are scheduled to enter and leave the loop. Each of these trains is required to discharge and receive passengers at ten different stations in the two-mile circuit of the loop. The result is that at the most crucial periods of the day both tracks of the loop are filled with trains spaced a few feet apart, and long lines of trains are held up on each of the four roads waiting to obtain an entrance. The most feasible method of providing greater trackage facilities for this great number of trains is generally believed to be the removal of the south end of the loop several blocks from the present location, as it is impracticable to move the other sides. At the same time, the right-of-way in the city streets for such a change could scarcely be acquired without a considerable outlay for damages to the abutting property, although the district through which the extension would pass has actually been greatly retarded by the fact that it is outside of the present loop. Various other means of securing additional trackage have been suggested by engineers familiar with the circumstances, most of which changes contemplate the construction of tracks within the loop, but such extensions are completely forestalled by local conditions.

The two platforms at each station on the loop are just long enough to serve simultaneously two five-car trains on each of the two tracks. Careful investigations have shown that if these platforms could be lengthened so two six-car trains might be accommodated the capacity of the loop would be increased at least 10 per cent. When an attempt was made some time ago to carry out this improvement, however, the property owners adjacent to the stations secured a permanent injunction which prevents any such additions, so advantage cannot be taken of this means of relief.

The necessary arrangement of the connections between the different roads and the tracks on the loop causes each train of the two roads which use each loop track to cross the other loop track either in entering or in leaving. The entrance and exit for two of the roads are at the same corner of the loop, while the other two roads each enter and leave at separate corners. Consequently, when the trains of one road are entering or leaving the loop they not only interfere with the trains of the two roads on the other track, but also hold up the trains of the other road which uses the same loop track. The switches at these connections are equipped with the most perfect apparatus available and the operators handling them are unusually proficient in their manipulation, so no further improvement in the present arrangement can be expected at these points. The separation of grades where a train on one loop track is required to cross the other track at the corners of the loop has been suggested, but the practicability of obtaining a clearance of at least 14 ft. in 400 or 500 ft. by inclines on an elevated structure over which such a large number of trains must be operated has been questioned. The through routing of the trains from one road to another would overcome a large part of the difficulty at these crossings, but as the four roads are separately owned such an arrangement is hardly feasible.

Three of the four roads using the loop, the Metropolitan West Side Elevated R. R., the Chicago & Oak Park Elevated R. R., and the South Side Elevated R. R., each have a stub terminal adjacent to the loop, and an ordinance was recently presented to the city council to permit the Northwestern Elevated R. R. to build such a terminal just across the Chicago River from the loop. The stub terminals of the first three roads have been built for some years, although none of them, except the one used by the Metropolitan, have been employed to any extent until recently. Notwithstanding this fact, all of these terminals are situated so passengers bound for certain parts of the loop district could save time by taking and leaving trains at them, and it may be expected that with the regular increase in traffic on the elevated lines that occurs in the Fall the congestion of the loop will become so acute as to cause the patrons of the different roads to appreciate the advantage of the stub terminals.

The only permanent relief of the elevated loop appears to be a system of subways in the downtown districts, such as has been proposed by Mr. Bion J. Arnold. The difficulties that will be encountered in building such subways, however, will unquestionably greatly postpone the time when they are placed under construction. The extensive changes that will have to be made in the public service mains and conduits that completely occupy the streets in the downtown district, and the handling of traffic on these streets during construction are simple matters, as compared with the shoring of the buildings adjacent to the excavations required for the subways. The soft blue clay that extends to a depth of 40 to 60 ft. from the surface over the whole area in which the most necessary subways will have to be constructed is an exceedingly treacherous material to handle. In fact, recent experiences in deep excavations for the sub-basements of tall buildings have shown that this clay will flow under any form of sheeting that can be devised unless this sheeting is carried down to the firm underlying strata before excavation is started. Since the freight tunnels of the Chicago Subway Co. occupy every downtown street at an average depth of 40 ft. below the surface, it is evident that subways for passenger service will have to be built above them in this soft, blue clay. At the same time, such subways are the only permanent means of relieving the present elevated loop, and as the capacity of the latter has long since been exceeded further extension of the various elevated lines tributary to it is useless. The utilization for residence purposes of the great undeveloped outlying districts within the city is limited largely therefore by the relief that can be afforded to the downtown terminals of the elevated railroads.

Coal Selection for Power Plants.

Possibly in no branch of power plant operation are there greater variations in the practice of owners and managers than in the selection of coal for steaming purposes. It is not surprising that this should be so, considering the differences in coal quality found in the open markets and in the mining regions, the discrepancies in freight rates, cost of handling, uncertain effect of storage, and variations in adaptability of fuels to specific boiler-room services. Within the last few years the determination of the heating power of coals by calorimeter and chemical tests has grown much in favor among large consumers, and there is no question that when such work is properly handled the results are of high significance and value, both to the engineer and the technical chemist. But when these tests are made by unskilled hands or with inferior apparatus, and unless the typical samples from barge and car are selected with experienced judgment, the work may be worse than futile, tending to produce warped judgments and decisions unjust alike to the producer and the consumer. These points were emphasized for the special benefit of engineers and public service corporations in a talk on coal economy given by Mr. E. G. Bailey, of the Little Laboratory, in Boston, before the Society of Chemical Industry on Oct. 4.

Emphasis from a chemist on the importance of coal tests by specialists may be *ex parte* judgment, but it hits close to the work when one considers the present uncertain status of the whole problem of fuel combustion. Reduction of fuel bills is one of the perpetual ends which power plant managers are striving to attain, and it is decidedly in fashion nowadays to carry on experiments in the fire room leading toward the use of less fuel by varying the conditions in the furnaces and flues. In some quarters, certainly, the great and encompassing difficulties of the problem do not seem to be realized, and hasty methods, careless observations and inaccurate generalizations have failed to bring the economies expected. It ought to be clear by this time that in the selection of coal for a given service, chemical tests should supplement the experience gained in the fire room, except in special cases where it would be simply out of the question to select other than a certain kind, as in the vicinity of particular mines. Even here much improvement in the situation may spring from a careful series of laboratory tests, particularly with reference to the betterment of firing conditions and furnace structures, draft adjustments and the like. The work may be done by the operating company itself if the organization can afford the quality of apparatus and the technical skill essential, otherwise, it had better be handled by a competent consulting chemist with special knowledge of fuels. To assume that any ordinary assistant steam engineer or electrician in a power plant is competent to sample coal in a representative way and accurately test its calorific power by the calorimeter or by proximate analysis is to invite conclusions that are void of scientific usefulness and are misleading as bases for the settlement of contracts and guidance in future purchases.

Almost any coal will produce steam, but economy in selection starts at the mine, makes certain that the handling is somewhere near right, and figures the transportation charges separately from the net cost of the fuel. Bad results often come from breaking the coal up more than is necessary, and it is not always the coal of highest calorific power which gives the best results in a given shipment. Variations in shipments make it most desirable for the purchaser to know exactly what he is getting. It is sometimes claimed that daily records of coal burned per kilowatt-hour are a sufficient check upon the quality of the fuel, but while such data are useful in running down both sweeping and gradual changes in station performance, they may easily come too late to give the necessary impetus to the required fuel changes. Undue reliance is frequently placed upon the weighing of ashes as a check upon coal quality, in view of the fact that the remaining unburned carbon and also the ashes carried up the stack by a strong draft are neglected. In a carefully made ash test cited by Mr. Bailey, the weight of ashes came short 5 to 10 per cent. of the total ash in the coal, after the unburned carbon was taken out. Under ordinary circumstances, where the carbon is not deducted, the ash frequently runs 25 per cent. higher than the coal analysis shows. As for the ability of the evaporative boiler test to throw a side light upon coal quality, there is no escaping the difficulty which attends the duplication of conditions in regard to firing while the variation of a single condition with the other factors constant is perhaps even more troublesome. Upon the calorimeter and the balances of the laboratory rest the ultimate determination of coal quality.

The diverse factors entering the problem of coal selection render the task a hard one for the layman. The interpretation of the analysis and British thermal unit record remains after the precise methods of the chemist have been applied. There is no question that the higher a coal shows in heat units, the more steam it will generate, other things being equal. It may not, however, be the best fuel for the particular plant in hand. The purchaser naturally desires to get as many heat units per dollar as possible, but there are other points to be considered in the selection of coal. A coal high in sulphur or a fine wet coal tends more readily toward spontaneous combustion and requires more careful watching. In the selection of coal it should be borne in mind that all coal will oxidize more or less, and that so long as the generation of heat can be kept from becoming cumulative, fire will not occur; but if the heat becomes sufficient to drive off the moisture, the danger point has been reached. A closer knowledge of the conditions which lead to spontaneous combustion in coal is much needed at the present time.

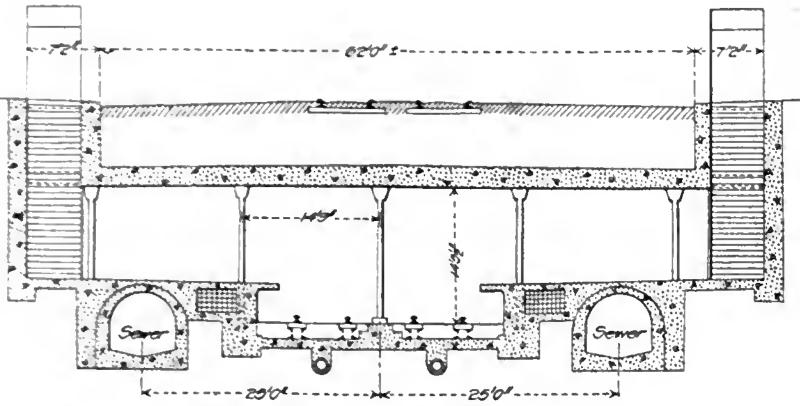
The problems of the boiler-room cannot be divorced from the questions of coal selection in finding out the fitness of a given fuel of known characteristic for a given plant. It is becoming clearer every year that the work of the chemist is but half done when the typical samples are tested. The boiler furnace, tubes, passes and flues are all parts of a laboratory on a large scale and to ignore this is to lose the vital conditions of a particular fuel problem. The cost of handling the coal from the barge to the grates is frequently under-figured. The interest of the fireman is often difficult to arouse unless it is backed up by a bonus for good records and assisted by good scales, a common-sense system of keeping consumption figures, and possibly by the pyrometer and CO_2 recorder. These points must be considered in testing the adaptability of a given coal in actual practice.

The only reason for buying coal on a B. t. u. basis is to make certain that a fair money value is secured on both sides. Coal specifications often set very high limits in calorific power, say, 14,000 B. t. u. as a minimum, and if a great variety of bids are desired this debars fuels which might be excellent for the purpose if investigated, or it possibly admits them under a penalty which artificially raises the price to a point high enough to give the coal dealer a good profit on top of the penalty. If coal of a certain known grade is desired, the limit in B. t. u. need not be as elastic. In cases of large consumption where a wide choice exists, the specification problem demands experience for its proper economical solution. Scientific methods of purchasing fuel do not cost much money in terms of their possible savings, but they must be carried out with skill and with first-class apparatus to be worth anything to the consumer.

Notes and Comment.

Specifications for Incandescent Lamps recently issued by one of the federal departments are interesting as being among the first, if not the first, to employ mean spherical candle power as a basis of comparison. The rating of the lamps called for remains on the mean horizontal candle-power basis, as is customary, but the initial specific consumption called for is 3.76 watts per mean spherical candle, corresponding to 3.1 watts per mean horizontal candle, when the spherical reduction factor is 82.5 per cent. There are many conditions in which increased candle-power in some particular direction is preferable to a nearly uniform distribution, as, for example, the case of a single incandescent lamp, without globe or reflector, suspended above a reading desk. In this case a type of lamp with powerful end-on candle-power with weakened horizontal intensity is preferable to a lamp of the usual type. No proper comparison of the two types of lamp would be possible on the basis either of end-on candle-power or of mean horizontal candle-power. The specification is an important recognition of improvements in lamps and the methods of using lamps, which is particularly significant as the result of long consideration of the subject by the government's staff.

A Contractor's Right to recover for work done under a contract subsequently taken from him has been before the federal courts for some time in an action by the Jonathan Clark & Sons Co. against the city of Pittsburgh. This company undertook to build the Highland Park reservoir in that city, but after carrying on the work for about three years was ordered by the Director of Public Works to discontinue any further construction under the contract. This order was issued in accordance with a contract provision giving the Director the right to stop the work if it was unnecessarily delayed or the contractor was wilfully violating any of the conditions. After the completion of the construction by other parties the contractor sued the city for retained percentages on what it had done and for extras. The city's defense was that no final estimate had been given the contractor by the Director and consequently nothing was due and that the contract specifically provided that the Director should act as an arbitrator in all disputes between the parties to the contract. The U. S. Circuit Court of Appeals has just upheld, 154 Fed. Rep. 464, a decision of the District Court in favor of the contractor. The items claimed by the contractor were sufficiently proved, it is stated, during the trial, and the provision for a final estimate did not apply when the contractor was put off the work. The arbitration clause is also held to be inapplicable in such a case. The city's action under the clause authorizing the Director to order the contractor to leave the work is held to provide impliedly for a determination of the rights of the parties by regular judicial proceedings. The case seems to be a rather unusual one, as shown by the fact that the editors of the "Reporter" could refer to nothing like it in the decisions of any court of final jurisdiction.



Second Street Station of the Market Street Subway.

THE MARKET STREET SUBWAY, PHILADELPHIA.

The Market St. Subway, about 2¼ miles long, is a very important portion of the system of the Market St. Elevated Passenger Ry. Co., the Philadelphia Rapid Transit Co. lessee. This system, as so far planned and authorized, includes about 7½ miles of two and four-track construction, equivalent to about 17 miles of single track. The main line follows Market St. about 6 miles from the Delaware River to 63d St., and east of 24th St., at the east end of the company's bridge over the Schuylkill River, being constructed in subways through the most congested part of the city. That portion of the subway extending from 24th St. to 15th St., together with about 4 miles of the elevated structure west of the Schuylkill River, has already been constructed and trains have been in service since March of the current year, though street cars from West Philadelphia have been running to 15th St. since December, 1905.

The remainder of the structure will consist of both elevated and subway construction, differing somewhat from that already completed, and is now under construction from 15th St., down Market St., to Front St., near the Delaware River, thence on property purchased by the company between Front and Water Sts. to Arch St. and thence along Delaware Ave. about 4,100 ft. to a terminal at the ferries at the foot of South St. Of this portion of the work that which is on Market St., about 1⅛ miles in length, is a two-track subway structure. That portion between Market and Arch Sts., comprising an incline to connect the subway and elevated railway, is partly a reinforced-concrete viaduct, the remainder on Arch St and Delaware Ave. being double-track elevated steel viaduct structure.

The subway between 15th St. and the Delaware River differs from that on the opposite side of 15th St., chiefly in that it is two-track instead of four-track, in the roof construction and in the methods employed in building it. Between 15th St. and 22d St. the subway, which was illustrated in The Engineering Record of February 25th, 1905, has a standard cross-section 48 ft. 6 in. wide inside and 14 ft. high above tops of rails, and is made with massive concrete side walls and inverts, the former reinforced with vertical and horizontal rods near the inner surface. The roof is made with transverse 5-ft. concrete arches reinforced over the tops of the beams only with wire cloth to prevent temperature and shrinkage of cracks, and supported on 20-in. I-beams carried by the sidewalls and by three intermediate rows of riveted columns. The structure was built in three successive longitudinal sections, the first two being made in open trench and including the side walls and part of the inverts to include the outside tracks. The excavation for the middle section of the structure was made by drifting and tunneling under the two surface tracks.

At its intersection with Broad St., between 13th and 15th St., the continuity of Market St. is interrupted by the City Hall, which occupies an area about 450 ft. square and approximately on its center line. It is an extremely heavy stone building, six stories high, with a tower about 538 ft. high, imposing very heavy loads on its foundations, on account of which, and the character of the soil, it was determined not to attempt to carry the subway underneath the structure, as is the rational alignment, but to diverge on both sides of it, thus forming a rectangular belt enclosing the City Hall, with substantially the same location as that of the present surface tracks. Provision is also made with this belt for connection with lines north and south on Broad St., and as the location was limited by the boundaries of City Hall Square, nearly all of the tracks are on curves with short tangents, which together with the cross-over switches and connections for future branches and provision for passing and connecting the express and local service, has made a very complicated construction which is too elaborate for other than a very general description in this article.

By "express" service is meant that of the trains which pass to and on the elevated railway, and "local" service includes that furnished by the street cars which enter the subway from the surface tracks in West Philadelphia.

Between 15th and Broad Sts., the subway is about 70 ft. wide between outside passenger platforms and about 90 ft. wide between the main walls of the passenger station located there. The center tracks are used for express service and the outside tracks for local service, and both of them make a complete loop around City Hall Square, thus avoiding stub ends and providing for the continuous operation of trains in both directions from the 13th and 15th St. stations, respectively, to the terminals, and for looping the local cars about the City Hall, and as no provision is made in the subway for the local cars east of City Hall Square.

On the 13th St. side of City Hall Square the tracks for trains converge by curves through 90 deg. to meet the two tracks in the subway on east Market St., with switches and connecting track to allow the looping of trains from and to the tracks west of the City Hall. The tracks for the local cars on the east side of the City Hall run under the express tracks where the latter swing into the Market St. line. This arrangement provides for the express service to be continued on Market St., the east and westbound trains passing around City Hall Square, to the south and north, respectively. At both intersections with Broad St. there are two curved connections with the local tracks for future double-track subways in Broad St. The elevation of the express track varies from + 11 to + 17, that of the curb varying from about 34 to 41. The lowest elevation, about 0, is where the local tracks pass under the express tracks at Juniper St.

The subway has everywhere reinforced-concrete side walls and roof, the invert being reinforced below the ground water level, and is built with one row of columns where there are two tracks, the columns being omitted at the cross-overs. At the curved sections at the northeast and southwest corners of the City Hall Square, where the express and local tracks are at different elevations, there are no columns, and the roof is supported entirely by concrete wall S. The cross-section is everywhere rectangular and is a continuous integral structure whether the tracks are at the same or different elevations or in case of a cross-over or two-story track, and where there is a passenger subway underneath the track. Be-

tween the curved lines of Market and Broad Sts., at their intersection with City Hall Square, the walls of the subway form very large triangles and the roof is supported by a number of extra interior columns.

Besides the 15th St. station there are five others located at 13th and 11th, 8th, 5th and 2d Sts., all of them of the same general type with platforms having an effective length of 350 ft. on opposite sides of the two-track section and entrances on both sides of Market St. The station at 15th St. has four passages from the express platform to the street above the level tracks and below the street surface. It also has a direct entrance through the basement of the Broad St. station of the Pennsylvania Railroad. The 8th St. station, at the center of the retail drygoods district, is 400 ft. long over extreme end structures and is made with spacious platforms extending laterally to include the vaults under the sidewalks, thus increasing the width to 100 ft. The platforms are connected by two passageways over the tracks and below the street surface. The 5th St. station is about 80 ft. wide, and is of simple construction, with one row of columns between the tracks and two rows on each side of them, and has a large main sewer adjacent to each of the outside walls. The 2d St. station is about 80 ft. wide and is also made with five longitudinal rows of columns and has a 7½-ft. main sewer under each of the passenger platforms, manholes being provided for them at each end of the station.

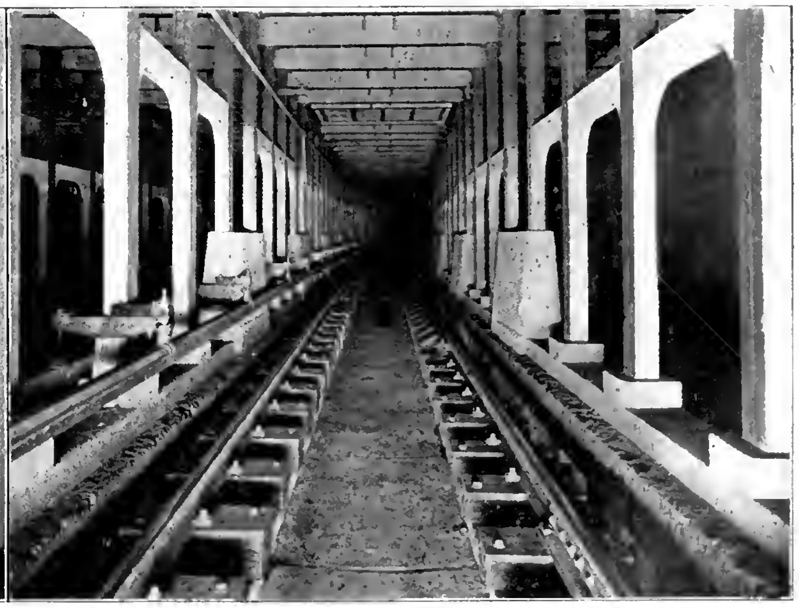
The standard double-track subway between 13th and 2d Sts. has a rectangular cross-section 30 ft. 6 in. out to out of walls and about 37 ft. wide over the duct construction, which varies in height above the floor and is 20 ft. deep over all with a flat concrete invert and reinforced-concrete vertical sidewalls and flat roof with a center row of riveted steel H-shaped columns 6 ft. apart on centers. The subway is 26 ft. 6 in. wide and about 15 ft. high inside with a longitudinal tile drain bedded in the concrete under the center of one track. Except under column footings, the invert is 11 in. thick, without reinforcement where above the ground water level. Below the ground water level the floor is thickened and reinforced to resist hydrostatic pressure.

The sidewalls are 2 ft. thick, except when they are enlarged, and have hollow spaces for the reception of the ducts, with vertical bars 12 in. apart and with horizontal bars 12 in. apart in two staggered rows near the inner and outer surfaces of the wall. The roof is reinforced with one tier of horizontal transversed rods 6 in. apart on centers extending the full width from sidewall to sidewall, 3 in. above the lower surface of the concrete. There are also horizontal longitudinal rods 12 in. apart in each of two staggered tiers, which are made in 30-ft. lengths overlapping 2 ft. at each end. Additional transverse bars, 12 ft. long, are placed over the tops of the columns, and six lines of bars are placed in the longitudinal concrete girder which forms an integral part of the roof in the planes of the columns. In each sidewall a rectangular space, the maximum size of which is 2 ft. 10 in. wide and 8 ft. high, is occupied by 96 electric ducts, the size of the space and the number of ducts varying along the line.

The corners between the roof and sidewall concrete have a concrete cove or fillet with a 2-ft. radius, and sockets are built in the roof to provide for the support of a possible future trolley wire. The columns are made with four 5x3-in. angles, and have four 6x⅜-in. tie plates besides the top and bottom web plates connected with the caps and bases, and are embedded in solid 10½x 14-in. concrete jackets. The concrete protection is reinforced and secured to the columns by ¼-in. bent rods like cotters through the column webs and by curved sheets of 3-in. mesh expanded metal wired on as indicated in the detail, and serves in place of usual web plates or latticing. The design of the track conforms to that installed in the subway on West Market Street, each rail being supported on 6x6-in. ties 2 ft. long and 2 ft. apart on centers, which rest on the tops of a pair of 12-in. channels 15 in. apart back to back bedded in 12-in. concrete laid over the top of the invert.

On curves and at crossovers pairs of columns are protected against collision and derailed trains

Local Track Section near West Portal.



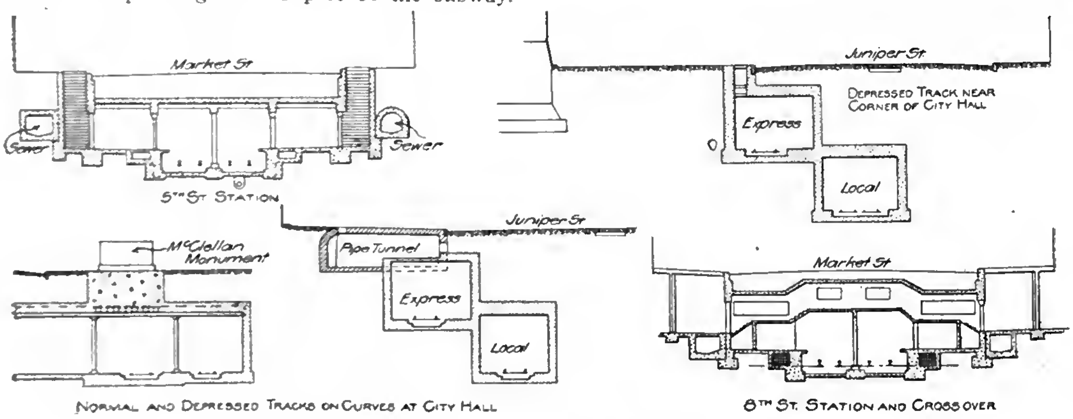
Express Track Section near West Portal.

by concrete piers enclosing them to a height of 4 ft. above the rail base and having a thickness of 18 in. at the top and 24 in. at the bottom. They are made with rounded corners and are reinforced with a pair of ⅜-in. horizontal rods forming a complete loop enclosing the columns.

On the curved portion of the subway about the City Hall the collision piers are 18 ft. apart on centers and the two unprotected columns between them, together with the adjacent end columns of each pier, are connected by a line of three continuous horizontal longitudinal concrete struts, about 6 in wide and 8 in. deep, engaging the webs of the columns at a height of about 8 ft. above the rail bed. Above these struts the columns are not concreted.

At cross-overs the center columns are omitted to clear the tracks, and the thickness of the roof slab is 3 ft. 1½ in., which is increased to 3 ft. 6½ in. by 1 in. of waterproofing and 3 in. of concrete protection over the waterproofing, for a clear span of 26½ ft. The span, however, is practically reduced by the deep covers at each wall, which act as continuous corbels. The reinforcement consists of two tiers of transverse rods, each tier 3 in. inside of the top and bottom of the main concrete, respectively, and three tiers of longitudinal rods, one in the center and one near each surface, inside of the transverse rods. The lower main rods are bent up at their ends, the spacing being 4 in. for the transverse rods.

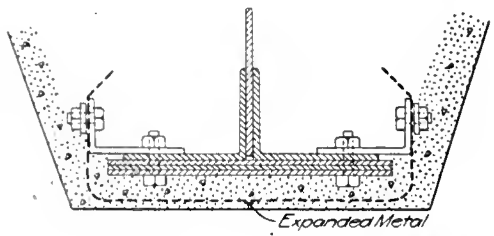
The shallow roof construction differs from the standard construction in that it is only 24½ in. thick and in that the tier of 12-ft. transverse rods is replaced by a tier of full-length transverse rods. The lower tier of transverse rods in the roof over the cross-overs has one 1.56 sq. in. cross-section, all other main transverse rods have 1 sq. in. cross-sections and all are of the twisted type. A layer of asphalted mastic waterproofing 1 in. thick is placed on the roof and is covered by a layer of concrete 3 in. thick. There is no other waterproofing in this part of the subway.



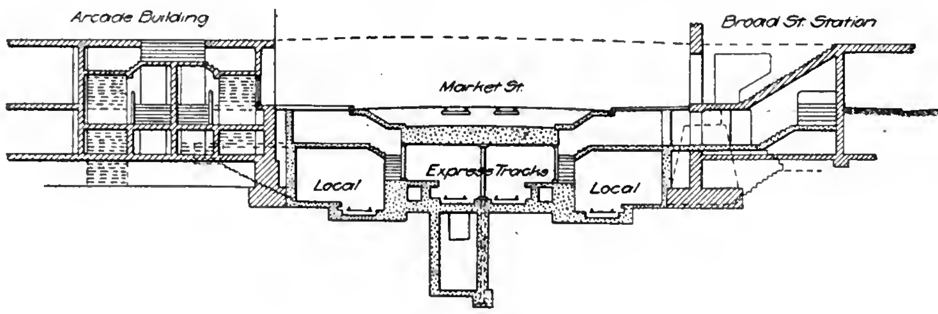
Subway Construction at Stations and on Curves.

The surface of the roof slopes 2 in. in 12 ft. from the center to each side.

The quantities involved per lineal foot in the construction of the standard two-track subway are as follows: About 38.1 cu. yd. of excavation, 7.8 cu. yd. of concrete, and 574 lb. of steel reinforcement, and 206 lb. of structural steel. The structure was designed by the Engineering Department of the Philadelphia Rapid Transit Co., Mr. Wm. S. Twining, chief engineer; Mr. C. M. Mills, principal assistant engineer. The contractors are the E. E. Smith Contracting Co. for the City Hall section, and the Millard Construction Co. for the section from the City Hall eastward toward the Delaware River.



Girder Flange Protection in Subway.



Four-Track Subway Station near City Hall.

A Diamond Drill Bore-Hole 6,700 ft. deep was put down in Upper Silesia in 1900, according to a note in The Engineering and Mining Journal. Another deep hole was put down on the Rand, South Africa, in 1905, the depth being 6,304 ft.

The Garbage Reduction Process at Toledo.

The garbage of Toledo, Ohio, is treated by the Edson reduction process, which furnishes two commercial products, grease and tankage. The garbage tankage is used by manufacturers of commercial fertilizers, and is sold at an average price of $9 per ton at the plant. The garbage grease is sold to soapmakers and brings about $80 per ton f. o. b. cars at the plant. The works have been under the charge of Mr. Thomas R. Cook as receiver during the past year, and at the recent meeting of the Central States Water-Works Association he read a paper concerning them, from which the following notes are taken. The fact that the company had to go into the hands of a receiver is a pretty strong commentary on the commercial aspect of garbage reduction under the existing local conditions.

The apparatus used in the process consists of hermetically sealed digesters, dryers and grease extractors. Two digesters and one dryer constitute what is known as a unit and are supposed to be capable of treating 20 tons of raw garbage every 24 hours. There are three units at Toledo, and consequently a total capacity of 60 tons in 24 hours. The delivery of garbage to the plant during summer months averages about 45 tons daily, and during the winter months about 30 tons daily, and consequently the plant has never been forced to its full capacity.

The raw garbage is delivered in steel wagon boxes, so constructed that a box can be picked up with an electric crane, hoisted to the fourth, or charging, floor, and there dumped into bins of concrete. The box is then thoroughly cleansed and cleaned by hot steam and returned to the wagon, the whole operation consuming less than five minutes.

The next step is to charge the digesters with this raw material, which is done through galvanized iron pipes running from the charging floor into the digesters on the floor below. When the digesters are filled they are sealed up, the steam is turned on, and the mass of garbage undergoes sterilization and disintegration for a period of about 9 hours. During this time the heat is regulated by air pressure upon the surface of the material, and no boiling occurs within. A valve is now opened and the mass is dropped through a sleeve into the dryer waiting to receive it. It is dried by external steam heat and the maintenance internally of a vacuum during the drying process, which lasts about 12 hours. The original mass of material is now dry and is discharged automatically from the dryer in the form of unpercolated tankage, or, in other words, tankage from which the grease has not been extracted.

During the entire process up to this stage this material has been under steam pressure and not once exposed to the air. All foul gases that arise during the operation are passed through a deodorizer for that purpose, and thence into the combustion chambers under the boilers. The unpercolated tankage is now conveyed by means of elevators and conveyors to the third floor of the grease extracting department, where it is ready to be put through the percolating process, which consists of cold filtration, using naphtha as a solvent. The material is fed through a galvanized iron pipe into the percolators, of which there are two, each having a capacity of about 5 tons of unpercolated material every 12 hours. The percolator being filled, it is then sealed, and naphtha pumped into it until the material is entirely flooded. It is allowed to stand for a certain length of time, and the naphtha and grease together are pumped out and into separating tanks, which are provided with mushrooms heated enough to vaporize the naphtha, which is conducted through vapor lines to the condensing tank, changed into liquid form and used again. The grease is then pumped into storage tanks. This process is repeated until the whole mass of material in the percolater is thoroughly percolated and the grease entirely removed.

The material is now ready to dry, which is accomplished in the same receptacle by external steam heat, thorough agitation and the maintenance of a vacuum. The dry tankage is now discharged automatically from the percolater and taken by means of an elevator and conveyors to the storage room, where it is ready to be shipped out for use in the manufacture of fertilizers. The percolating process consumes from 6 to 7 hours and the drying from 4 to 5 hours.

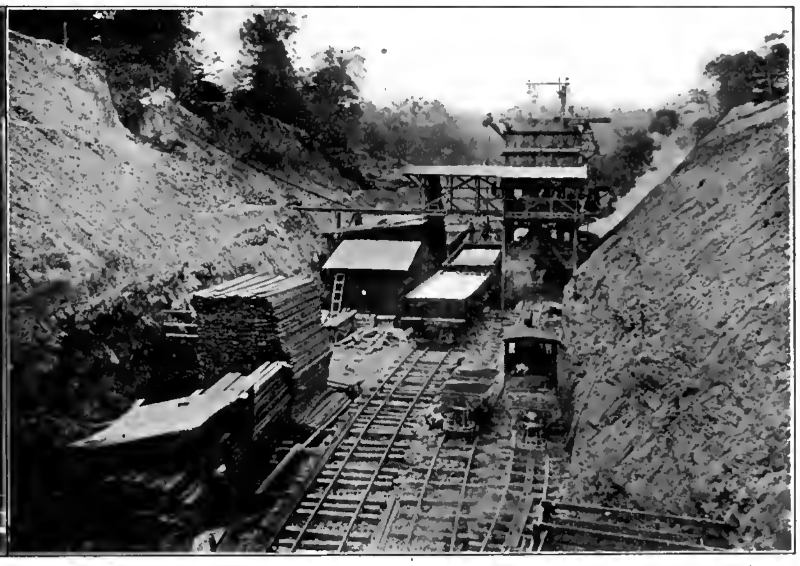
Using as a basis the class of garbage received in Toledo, which is not of the best, the amount of finished tankage from raw garbage is about 17 per cent. and of grease is about 3 per cent. This system will handle dead animals, bones and anything in the way of organic matter, in addition to garbage.

Lining a Tunnel With Concrete.

The Jasper-French Lick extension of the Southern Ry. in the southern part of Indiana includes a single-track tunnel, 2,200 ft. long, at a point about 4 miles from French Lick. The tunnel is on a 4-degree and 30-minute curve for 300 ft. at one end, with the remaining 1,900 ft. on tangent. It was driven through slate and soapstone rock, which had to be closely timbered throughout as the headings advanced from both ends. The timbering used in the tunnel consisted of local beech, the intention being at the time it was finished, about a year ago, to line the tunnel from end to end with concrete. The placing of this concrete lining was started in June of this year, and from the results that have thus far been attained, it is reasonable to expect that it will be completed by October 31, although the work had to be shut down for a month, and the slow delivery of concrete materials occasioned considerable delay while it was in progress.

The dimensions of the tunnel and the details of the lining are shown in the accompanying cross section. The tunnel was driven to a clear width of 21 ft., and a height of 26 ft. 3 in. at the center line, both measured to the outside limits of the timbering. Inside the latter the clear height at the center line was 24 ft. above the sub-grade, and the clear width 18 ft. After the concrete lining is placed, the clear width is 16 ft. and the clear height above the rail is 22 ft. at the center line, the arch being semi-circular, with a rise of 8 ft. The timbering consists of 10x12-in. uprights, spaced 3 ft. apart on centers, and carrying 10x12-in. horizontal wall-plate timbers, on which are placed 10x12-in. arch ribs, also set 3 ft. apart on centers. The upright timbers are on 3x12-in. sills, and are lagged with 3x6-in. plank, while the arch ribs are lagged with 4x6-in. plank.

Looking toward Tunnel Portal from Mixing Plant.



Looking toward Mixing Plant from Tunnel Portal.

The concrete lining has a floor approximately 14 in. thick, that is laid on the sub-grade of the tunnel. The track ballast is confined between two concrete curbs, 12 in. high. These curbs are built as a part of the floor, and are 1 ft. 10 in. from the side walls, thus forming a drain, 1 ft. x 1 ft. 10 in. in cross section, at each side of the tunnel. Weep holes, consisting of 3-in. vitrified tiling, spaced 20 ft. apart in the base of the side walls, open into these side drains. The side walls of the lining are 2 ft. thick, the arch decreasing from 2 ft. in thickness at the springing lines to 18 in. at the crown. The side walls and arch are reinforced, 3 in. from each face, with a row of 3/4-in. Johnson corrugated bars, spaced as shown in the cross section. The timbering is enclosed in the concrete lining, the reinforcement bars being arranged to avoid it. The lining requires 4.132 cu. yd. of concrete and 181.45 lb. of Johnson bars per linear foot of tunnel. The concrete was made in the proportions of 1 of Lehigh cement, 2 1/2 of sand and 5 of crushed stone. Screened crushed stone, all of which would pass a 2-in. ring and be retained on a screen with 1/2-in. meshes, was used.

The concrete lining was all carried forward from one portal of the tunnel. A complete plant for handling and mixing the concrete materials was erected near that portal, and a very satisfactory arrangement for delivering the concrete from this plant into the forms for the lining was developed. The concrete materials and other supplies were brought to the tunnel in standard-gauge cars, operating over the track that had been laid to French Lick.

The plant for handling and mixing the concrete materials was about 200 ft. from the adjacent portal of the tunnel. A low, temporary trestle, 500 ft. long and carrying an 18-ft. gauge track, was placed back of the mixing plant, in the cut which forms the approach to that portal. This trestle was 20 ft. to one side of the standard-gauge track laid in the cut, the space between it and the track being floored over, so sand and stone could be stored on it. A stiff-leg derrick and a hoisting engine were mounted on a platform traveling on four double-flanged wheels on the wide-gauge track on the trestle. This derrick has a 65-ft. boom carrying a 1-yd. orange-peel, or a 1 1/2-yd. clam-shell Hayward bucket. This boom, with the travel of the platform, gave the derrick a range for unloading sand and stone from gondola cars on the track to the storage piles, or directly to two 20-yd. supply hoppers at the foot of two inclined bucket elevators, which raised the materials to storage hoppers of the mixing plant. The sand and stone stored in the piles at the side of the trestle were loaded into 2-yd. dump cars on a narrow-gauge track at the same level as the trestle track, with the orange-peel bucket, and were delivered to the supply hoppers of the elevators by these small cars. During most of the time that work was in progress, however, crushed stone could not be obtained fast enough to permit any accumulation in storage piles, so most of the stone was unloaded from the cars directly into the supply hoppers of the elevators by the derrick.

The concrete mixing plant was erected on the same side of the track as the trestle carrying the traveling derrick. Two storage bins, with a capacity of 85 cu. yd., one of which was for sand and the other for stone, were placed on a timber tower, with their bottoms 25 ft. above the grade of the track. One of the bucket elevators delivered sand to one of these bins, and the other carried stone to the second bin. A working platform on which the concrete materials were measured in a charging hopper, was built directly under the storage bins. A shed for storing cement was erected on the opposite side of the track from the mixing plant, because no other space was available. The cement was raised from this shed to a bridge over the main-line track by a bag elevator, the bridge extending to the charging platform under the storage bins. The bags of cement were delivered on a flat car by the elevator, and were carried to the charging hopper on this car, which ran on a track on the bridge.

A 1 1/2-yd. cubical concrete mixer was placed directly under the hopper in the charging platform, the mixer engine being at the level of the track. The mixer was set high enough so 1 1/2-yd. Koppel dump cars could be run under it on a 3-ft. gauge track. This track was extended through the tunnel, to facilitate the delivery of the concrete.

The floor of the tunnel lining was laid first, the work being started at the portal farthest from the mixing plant. The concrete was delivered to place in the 1 1/2-yd. dump cars, which were handled by a light locomotive. As the floor was carried toward the portal at the mixing plant, the 3-ft. gauge track that had been laid in the tunnel was raised and suspended from timbers placed across the latter until the concrete had set. When the floor had been finished, a standard-gauge track was laid on it, with a third rail for the narrow-gauge track, and work was started on the side walls.

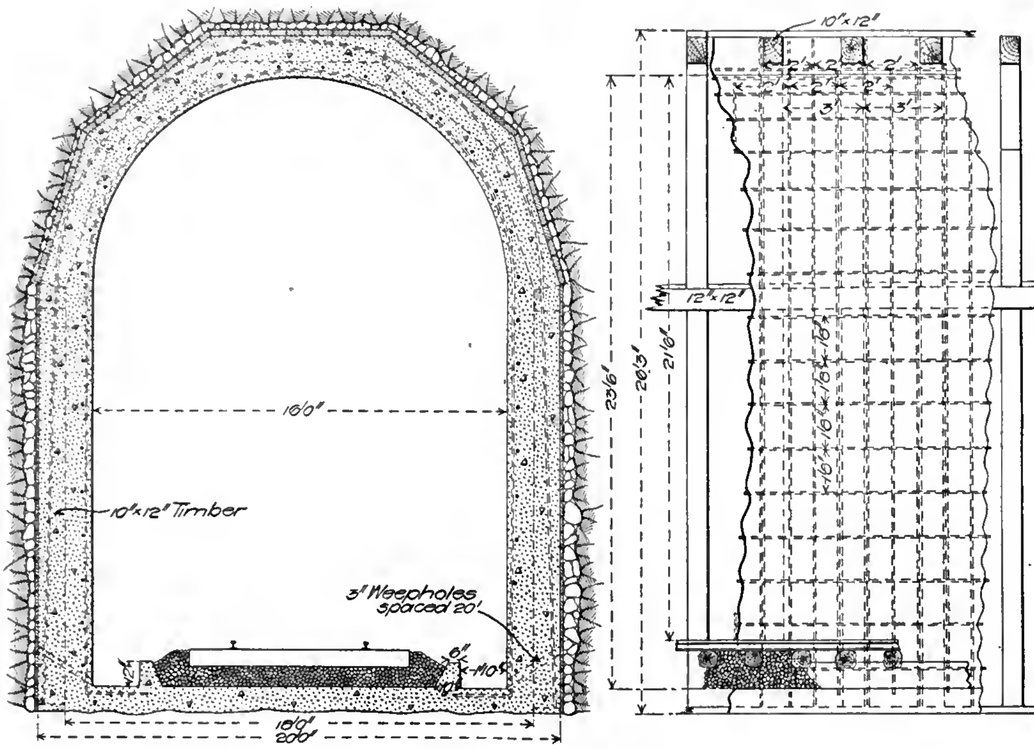
A special arrangement for handling the construction of the side walls and arch, which proved specially advantageous, was adopted. Two standard-gauge flat cars were attached together, end to end, and far enough apart so a working platform about 100 ft. long could be erected on them. This platform was made just wide enough so it would comfortably clear the forms for the side walls of the tunnel, and was placed at such height that concrete could be shoveled from it directly into the wall forms, up to the springing lines of the arch. An incline, about 60 ft. long, extending from the level of the standard-gauge track to the platform on these cars, carried a 3-ft. gauge track, which was continued the full length of the platform. This incline was built with a trussed under-frame, carried, independently of the cars, by two pairs of wheels. It was attached to the platform at the upper end by heavy hooks, and was arranged with a de-

tachable section at the lower end. The loaded 1½-yd. Koppel cars were brought to the foot of the incline from the mixing plant by the light locomotive, which also pulled them up the incline by means of a cable rove through a block anchored on the working platform. The concrete was dumped on the platform from the cars, and was then shoveled down into the wall forms, the tops of the forms being at about the same level as the working platform. The walls were finished for about 100 ft. to the full height in this manner while the cars were in one position. The portable section of the incline was then removed, and the incline and platform cars were moved along to the next length of the wall by the light locomotive. As the cars were merely blocked in position while concrete was being placed, they could be moved ahead without interrupting the progress of the work more than a few minutes.

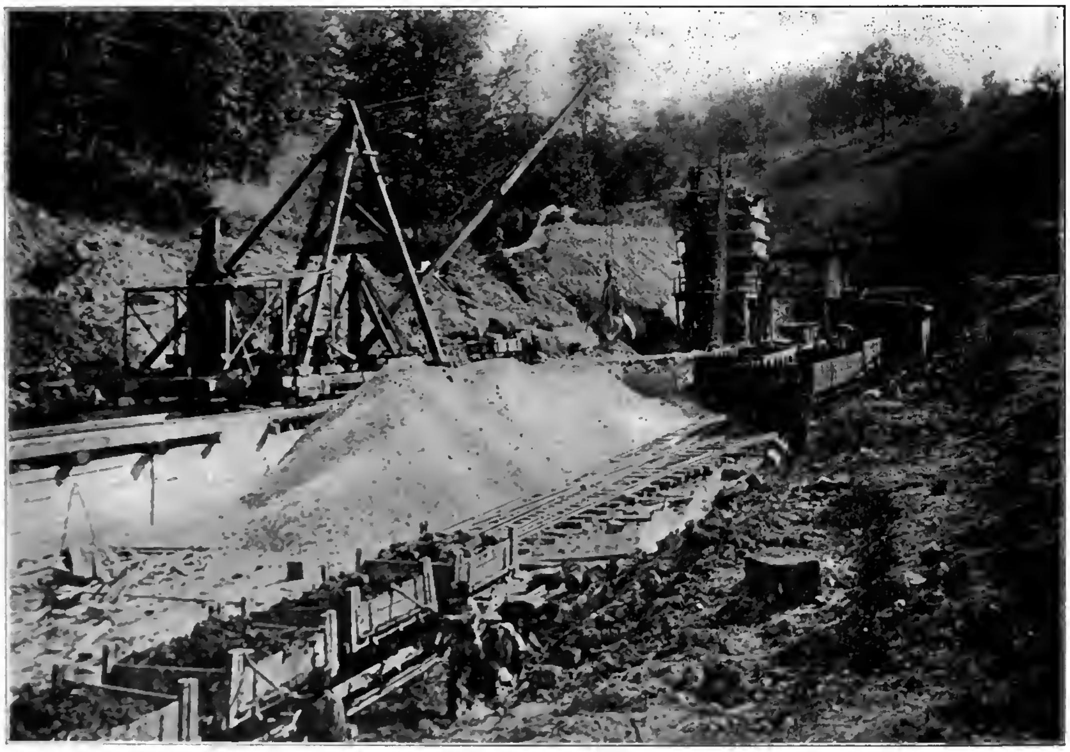
The forms for the side walls had 4x6-in. uprights, spaced 3 ft. apart on centers. These uprights were reinforced at the center by a 6x6-in. waling, which was attached to the plumb posts of the timber lining with lag bolts extending through the concrete wall; they were also attached to the timbering at the top by short pieces of plank, and were lagged with 2x12-in. plank, dressed on one side. The wall forms were allowed to remain in place at least 48 hr., after which they were carried ahead to be used again.

After the side walls had been completed, the platform on the two flat cars was raised until the 1½-yd. dump cars, when in a dumping position, would just comfortably clear the forms for the arch. Concrete work on the latter was then started at the portal distant from the mixing plant and was carried forward toward the other portal. The forms for the arch had 6x12-in. ribs, cut to conform with the curve of the arch intrados. These ribs were carried at each end on a horizontal 6x12-in. timber resting on 6x6-in. posts erected against the side walls already completed. A 6x6-in. waling timber was also placed along the foot of the ribs on each side of the arch, and was anchored to the timber lining by lag bolts, so the ribs were sustained without cross braces in the tunnel. The lagging of the arch ribs consisted of 2x6-in. plank in 6-ft. lengths. These plank were carried up on the sides of the arch just ahead of the concrete, until a space 18 in. wide was left at the crown of the arch. Lagging in 3-ft. lengths was then used to finish out the forms at this opening, the closing section of concrete being shoveled from the platform into place from the end of each 3-ft. section. Work on the arch was carried on day and night, in order that the closing section could always be placed before the concrete in the balance of the arch had set. An electric lighting plant was installed to expedite the night work, and also the work in the interior of the tunnel. The ease with which the working platform could be moved, the opportunity to handle the concrete work rapidly and the absence of any cross braces in the tunnel greatly reduced the number of men required and facilitated the progress of the work.

The general contract for the construction of the Jasper-French Lick extension of the Southern Ry. was awarded to MacArthur Bros. Co., of Chicago, which company built the tunnel and erected the timber lining. The concrete lining is being placed, under a sub-contract, by the Cullen-Friestedt Co., of Chicago, the plant and methods described herewith having been developed by the latter company. Mr. J. B. Anderson was engineer in charge for the railway company.



Cross Sections of Concrete-Lined Tunnel on Southern Railway.



Traveling Derrick for Handling Concrete Materials from the Cars.

Economy Tests of a 7500-Kw. Westinghouse-Parsons Turbine.

The following data comprise the principal results obtained on Sept. 1, 1907, during an 8-hour economy test upon turbine No. 253, installed earlier in the year, at Waterside Station No. 2 of the New York Edison Co. This test was conducted entirely by the New York Edison Co., under the direction of Mr. J. P. Sparrow, chief engineer. The various arrangements therefor were carried out in accordance with a mutual agreement between builder and operator, entered into previous to the test, and the results, as herein given, were obtained by independent computation.

The turbine unit tested is of standard Westinghouse construction throughout. It has a maximum rated capacity of 11,250 kw., and was built to operate on 175-lb. steam pressure, 28 in. vacuum and 100° superheat. Under these conditions, the turbine unit was guaranteed to have a minimum steam consumption of 15.9 lb. per kilowatt hour at the generator terminals with a normal speed of 750 r. p. m. Incidentally, the electrical efficiency of the generator was guaranteed to be 97.8 per cent., exclusive of friction and windage, at a load corresponding to that sustained during the test. The results of the test detailed below show an economy about 7.5 per cent. better than the guarantee.

During the test period, No. 2 Waterside Station sustained practically all of the 25-cycle load on the system, of which the unit under test carried practically 70 per cent., the remainder being taken by the other turbine units in the station. This load was maintained as constant as possible by remote control of the turbine governor by the switchboard operator. Between the first and the last hours of the test, the maximum variation in load was held within 4 per cent. above and below mean. During the last hour, however, the load decreased somewhat. Previous to the test, this turbine unit had been running on a load of 7,000 kw., which was increased to its test load ten minutes before the start of the test.

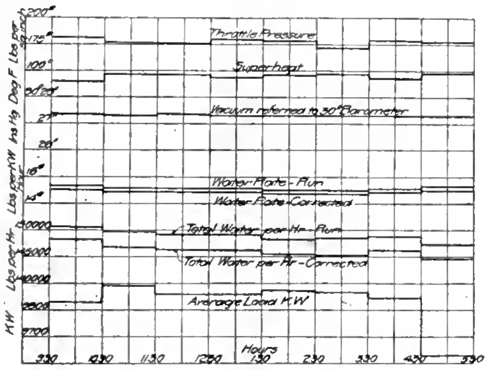
Three-phase electrical load was measured by the two-wattmeter method, using two Weston indicating wattmeters of the standard laboratory type. These instruments were calibrated at the

New York Electrical Testing Laboratories immediately before and after the test. Power factor was maintained substantially at unity, and all electrical readings were taken at one-minute intervals.

As a surface condenser was used in connection with this turbine unit, the water rate was determined by weighing the condensed steam delivered from the condenser hot well. This condensation was weighed in a tank mounted upon platform scales, with a reservoir above large enough to hold the condensation accumulating between each weighing, the arrangement being shown in the accompanying sketch. These weighings of 12,000 to 13,000 lb. each were made at intervals of five minutes.

By the loop method of connecting the gland water supply, shown in the attached sketch, the necessity for correcting condensation by an amount equivalent to the weight of the gland water used is avoided. It will be noted that a continuous gland water circuit is used entirely outside of the weighing apparatus, and that all overflow from the standpipe returns to the hot well delivery.

As the circulating water is quite salt, any condenser leakage may immediately be detected by the salinity of the condensed steam, which



Log of Turbine Test.

should be pure distilled water. On this account, condenser leakage was determined entirely by chemical analysis, employing the silver-nitrate test with a suitable color indicator. This method proved extremely sensitive, and possessed a decided advantage over the ordinary method of weighing the leakage accumulating during a definite period when the condenser is idle and under full vacuum. As samples of circulating water and condensed steam could be taken at the same time, this method made it possible to discover any change in the rate of condenser leakage taking place during the test, while the method of weighing above described provides only an average result during the period.

In this condensing plant, the delivery of the hot-well pump is automatically controlled by a float valve in the interior of the hot well. This maintains the water level therein at a practically constant point, and hence no correction had to be made for difference in level of water in the hot well before and after the test.

Steam pressures and temperatures were determined close to the turbine throttle. As usual, the degree of superheat was obtained by subtracting from the actual steam temperature the temperature of saturated steam at the corresponding pressure carried at the time. All gauges and themometers were calibrated previous to the test at the U. S. Testing Bureau. It will be noted that both pressure and superheat were somewhat below the guarantee.

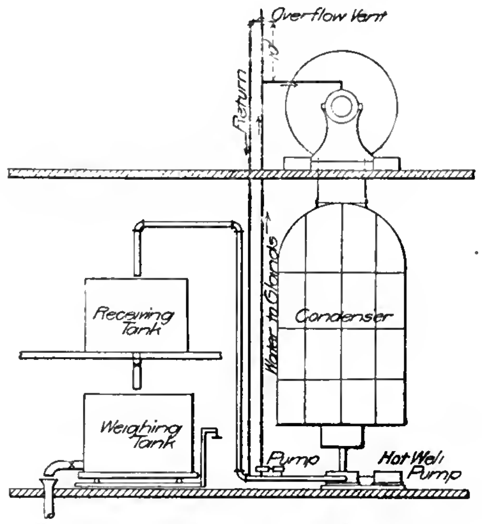
Vacuum was measured directly at the turbine exhaust by means of a mercury column with a barometer alongside for reducing to standard barometer, 30 in. This also obviated the necessity for temperature correction between the two mercury columns. During the test the vacuum was not maintained quite up to normal.

The following data represents the average results of the tests, calculated for the conditions as actually run; i. e., for instrument errors only: Duration of test, 9.30 a. m. to 5.30 p. m.; steam pressure at throttle, pounds per square inch gauge, 177.5; superheat at throttle, deg. F., 95.74; vacuum (referred to 30" barom.) in mercury, 27.31; load on generator, kw., 9830.48; steam consumption, as tested, pounds per kw. hour, 15.15.

Owing to the departure, during the test, from specific operating conditions upon which guarantees were based, it was necessary to correct the observed results by the following amounts:

Pressure (2.5 lb. high) correction, 0.25; vacuum (0.69 in. low) correction, 1.84 per cent.; superheat (4.26° low) correction, 0.29 per cent.

These corrections were mutually agreed upon previous to the test as representative of this type of turbine. When applied to the observed steam consumption given above, the following results, representing contract conditions, are obtained:



Method of Weighing Condensation.

Average corrected water rate during 8-hour test, 14.85 lb. per kw. hr.; guaranteed water rate, 15.9 lb. per kw. hr.

Referring now to the accompanying log, it is interesting as a check upon the average figures above presented, to observe the results segregated into hourly periods, as shown. Here it will be noted that the load was considerably lower during the first and last hour than during the main part of the test. Neglecting, therefore, these two hours and considering only the six hours period from 10.30 a. m. to 4.30 p. m., the results are as follows: Average corrected water rate, 14.8 lb. per kw. hr.; equivalent water rate, 10.65 lb. per bhp. hr., or 9.8 lb. per ihp. hr. The two latter quantities are determined by applying conversion factors for generator efficiency and for internal losses.

In connection with these tests, a noteworthy agreement exists between the results noted and those previously obtained from tests of machines of similar design installed in the Manhattan Station of the Interborough Rapid Transit Co., New York, and the Long Island City Station of the Pennsylvania R. R. At the same loads and with equivalent operating conditions, the performance of the machines is almost identical. These economic results, while not exceeding in actual steam consumption the best records of European practice, yet are extremely good in view of the moderate operating conditions under which the test was conducted. In fact they are considered by the builders to represent the best results that have yet been obtained by any turbine under the conditions named.

The Government of Formosa is organizing an irrigation bureau and has sent an engineer to study methods of the U. S. Reclamation Service.

Concrete Work at Charles River Locks.

The locks in the Charles River dam at Boston are being constructed by the Holbrook, Cabot & Rollins Corporation, and in the last report of Mr. Hiram A. Miller, chief engineer of the commission in charge of the work, there are some notes concerning the manner in which the concrete was handled. Gravel from the harbor and Shirley Gut was brought by scows and dumped in the river bed at one end of the coffer-dam surrounding the site of the locks. From there it was raised by an orange peel bucket to a 16 x 14-ft. hopper, with its top about 70 ft. above the bottom of the lock. From this hopper the material passed over four screens set at an angle of 1 to 12, which separated it into sand and stones which were deposited in bins of 120 and 200 cu. yd. capacity. Below the bins were the measuring hoppers for getting the proper quantity of sand and gravel. After leaving the hoppers, the sand and gravel passed to a 24-in. belt conveyor about 90 ft. long, which carried the mixture, together with the proper amount of cement, to a hopper over a cubical mixer holding a little over 2 cu. yd. From the mixer the concrete was dumped into bottom-dumping boxes holding about 2 cu. yd., mounted on trucks running on a track and operated by an endless cable.

The boxes were handled by a bull-wheel derrick on a platform at the elevation of the top of the lock walls, and carried on wheels running on rails laid on heavy timbers on each side of the bottom of the lock. The forms for the side walls of the lock were 40 ft. long and about 30 ft. high, and were built of 3-in. plank planed one side to even thicknesses. These forms were hung from a traveler 30 ft. high and 40 ft. long, running in advance of the movable derrick on the same rails.

The specifications provided that the lock should be built in sections not exceeding 40 ft. in length, and the ends of the sections were to have an offset or projection 6 in. in width, to form a water-stop. The ends of these sections were covered with two layers of tar paper applied with a hot mixture of coal-tar pitch, which was first spread over the surface of the concrete, then between the layers of tar paper, and finally over the entire surface of the tar paper joint.

The proper mixture and thickness to use for facing the side walls required considerable attention, and experiments were made to determine what proportions made the most impermeable concrete. From their results and from information obtained elsewhere, it was decided to use a 6-in. layer of 1 : 1 : 2 concrete for the facing. This was changed to a 1 : 3 mortar, after the results of further experiments were known. This facing was carried up with the other concrete for the side walls, the 6-in. space being maintained by a steel diaphragm 12 in. high and about 10 ft. long, with spacers 6 in. long at each end and one in the middle to keep a uniform distance from the forms. As soon as the facing was placed, the diaphragm was removed and the mortar and backing spaded together to make sure of a good bond, and strips of No. 16 gauge, 3-in. mesh, expanded metal, 12 in. wide, were placed horizontally in the soft concrete 1 to 2 ft. apart, in order to prevent the facing from separating from the main portion of the wall.

A Private Car Service for disposing of ashes and for hauling coal from Lake Michigan to its plant at West Allis, Wis., has been undertaken by the Allis-Chalmers Co. All-steel bottom-dumping coal cars and side-dumping ash cars of 50 tons capacity have been placed in service on the company's private tracks. The coal cars are loaded direct from vessels at the docks on Lake Michigan, and the ashes are used for filling and ballast.

The President's Message on Hydraulic Engineering Works.

In his speech at Memphis on Oct. 4. President Roosevelt took occasion to state the views of the administration concerning the improvement of the hydraulic resources of the country. On that day the National Waterways Convention, attended by the governors of sixteen States and by many men prominent in public affairs, held its first session. In his introductory remarks the President asserted that the Mississippi Valley is better adapted to the development of inland navigation than any other valley in either hemisphere, for there are 12,000 miles of waterway now more or less fully navigable, and the conditions are so favorable that it will be easy to increase the extent of navigable waterways to almost any required degree by canalization. Early in our industrial history this valley was the seat of the largest development of inland navigation in the United States, and the President stated that the first steamboat west of the Alleghenies was built by a Roosevelt, his great-grandfather's brother, in 1811, for the New Orleans trade, and in that year made the trip from Pittsburg to New Orleans. But from various causes river and canal transportation declined all over the United States as the railroad systems came to their full development. It is our business to see that the decline is not permanent, and it is of interest to remember that nearly a century ago President Madison advocated the canalization of the Mississippi.

The great variety of natural resources and the extent of the manufacturing interests in the Valley render its welfare a matter of national concern, and the Mississippi River and its tributaries ought therefore to be utilized to their utmost. Facility of cheap transportation is an essential in our modern civilization, and we cannot afford any longer to neglect the great highways which nature has provided for us. These natural highways, the waterways, can never be monopolized by any corporation. They belong to all the people, and it is in the power of no one to take them away. Wherever a navigable river runs beside railroads the problem of regulating the rates on the railroads becomes far easier, because river regulation is rate regulation. When the water rate sinks, the land rate cannot be kept at an excessive height. Therefore, it is of national importance to develop these streams as highways to the fullest extent which is genuinely profitable. Year by year transportation problems become more acute, and the time has come when the rivers really fit to serve as arteries of trade should be provided with channels deep enough and wide enough to make the investment of the necessary money profitable to the public. The national government should undertake this work. Where the immediately abutting land is markedly benefited, and this benefit can be definitely localized, the President hoped that there will be careful investigation to see whether some way can be devised by which the immediate beneficiaries may pay a portion of the expenses—as is now the custom as regards certain classes of improvements in our municipalities; and measures should be taken to secure from the localities specially benefited proper terminal facilities.

We should act on the same principle in improving our rivers that we should follow in improving our harbors. The great harbors are of consequence not merely to the immediate localities, but to immense stretches of country, and the same is true of the great rivers. It is these great rivers and great harbors the improvement of which is of primary national interest. The main streams should be improved to the highest practical degree of efficiency before improvements are attempted on the branches, and work should be undertaken only when completion is in sight within a reasonable time, so that assured results may be gained and the communities affected depend upon the improvements. Moreover, as an incident in caring for the river so that it may become an efficient channel of transportation, the United States government should do its full part in levee building, which, in the lower reaches of the river, will not only give a channel for commerce, but will also give protection to the adjacent bottom lands.

Immense sums have already been spent upon the Mississippi by the states and the nation, yet much of it remains practically unusued for commerce. The reasons for this fact are many. One is that the work done by the national government at least has not been based upon a definite and continuous plan. Appropriations by Congress, instead of assuring the steady progress and timely completion of each piece of work, as it was undertaken, have been irregular and uncertain. As a direct consequence, far-reaching plans have been discouraged and continuity in execution has been made impossible. It is altogether unlikely that better results will be obtained so long as the method is followed of making partial appropriations at irregular intervals for works, which should never be undertaken until it is certain that they can be carried to completion within a definite and reasonable time. Planned and orderly development is essential to the best use of every natural resource, and to none more than to the best use of our inland waterways. In the case of the waterways it has been conspicuously absent. Because such foresight was lacking the interests of our rivers have been in fact overlooked, in spite of the immense sums spent upon them. It is evident that their most urgent need is a far-sighted and comprehensive plan, dealing not with navigation alone, nor with irrigation alone, but considering our inland waterways as a whole, and with reference to every use to which they can be put. The central motive of such a plan should be to get from the streams of the United States not only the fullest but also the most permanent service they are capable of rendering to the nation as a whole.

The industries developed under the stimulus of the railroads are for the most part permanent industries, and therefore they form the basis of future development. But the railroads have shown that they alone cannot meet the demands of the country for transportation, and where this is true the rivers should begin to supplement the railroads, to the benefit of both, by relieving them of certain of the less profitable classes of freight. The more farseeing railroad men realize this fact, and many of them have become earnest advocates of the improvement of the Mississippi, so that it may become a sort of inland seaboard, extending from the Gulf far into the interior, and the President hopes ultimately to the Great Lakes. An investigation of the proposed Lakes-to-the-Gulf deep waterway is now in progress under an appropriation of the last Congress. We shall await its results with the keenest interest. The decision is obviously of capital importance to our internal development and scarcely less so in relation to external commerce.

This is but one of the many projects which it is time to consider, although a most important one. Plans for the improvement of our inland navigation may fairly begin with our greatest river and its chief tributaries, but they cannot end there. The lands which the Columbia drains include a vast area of rich grain fields and fruit lands, much of which is not easily reached by railways. The removal of obstructions in the Columbia and its chief tributaries would open to navigation and inexpensive freight transportation fully two thousand miles of channel. The Sacramento and San Joaquin rivers with their tidal openings into San Francisco Bay are partly navigable now. Their navigation should be maintained and improved, so as to open the marvelously rich valley of California to inexpensive traffic, in order to facilitate both rate regulation and the control of the waters for other purposes. And many other rivers of the United States demand improvement, so as better to meet the requirements of increasing production from the soil, increasing manufacture, and a rapidly growing population.

While thus the improvement of inland navigation is a vital problem, there are other questions of no less consequence connected with our waterways. One of these relates to the purity of waters used for the supply of towns and cities, to the prevention of pollution by manufacturing and other industries, and to the protection of drainage areas from soil wash through forest covering or judicious cultivation. With our constantly increasing population this question becomes more and more pressing, because the health and safety of great bodies of citizens are directly involved.

Another important group of questions concerns the irrigation of arid lands, the prevention of floods and the reclamation of swamps. Already many thousands of homes have been established on the arid regions, and the population and wealth of seventeen states and territories have been largely increased through irrigation. Yet this means of national development is still in its infancy, and it will doubtless long continue to multiply homes and increase the productiveness and power of the nation. The reclamation of overflow lands and marshes, both in the interior and along the coasts, has already been carried on with admirable results, but in this field, too, scarcely more than a good beginning has yet been made. Still another fundamentally important question is that of water power. Its significance in the future development of our whole country, and especially of the West, is only just beginning to be understood. The plan of the city of Los Angeles, for example, to bring water for its use a distance of nearly 250 miles—perhaps the boldest project of the kind in modern times—promises not only to achieve its purpose, but in addition to produce a water power sufficiently valuable to pay large interest on the investment of over $23,000,000.

Hitherto such opportunities for using water to double purpose have not always been seized. Thus it has recently been shown that water enough is flowing unused over government dams, built to improve navigation, to produce many hundreds of thousands of horsepower. It is computed that the annual value of the available but unused water power in the United States exceeds the annual value of the products of all our mines. Furthermore, it is calculated that under judicious handling the power of our streams may be made to pay for all the works required for the complete development and control of our inland waterways.

Forests are the most effective preventers of floods, especially when they grow on the higher mountain slopes. The national forest policy, inaugurated primarily to avert or mitigate the timber famine which is now beginning to be felt, has been effective also in securing partial control of floods by retarding the run-off and checking the erosion of the higher slopes within the national forests. Still the loss from soil wash is enormous. It is computed that one-fifth of a cubic mile in volume, or one billion tons in weight, of the richest soil matter of the United States, is annually gathered in storm rivulets, washed into the rivers and borne into the sea. The loss to the farmer is in effect a tax greater

than all other land taxes combined, and one yielding absolutely no return. The Department of Agriculture is now devising and testing means to check this enormous waste through improved methods of agriculture and forest management.

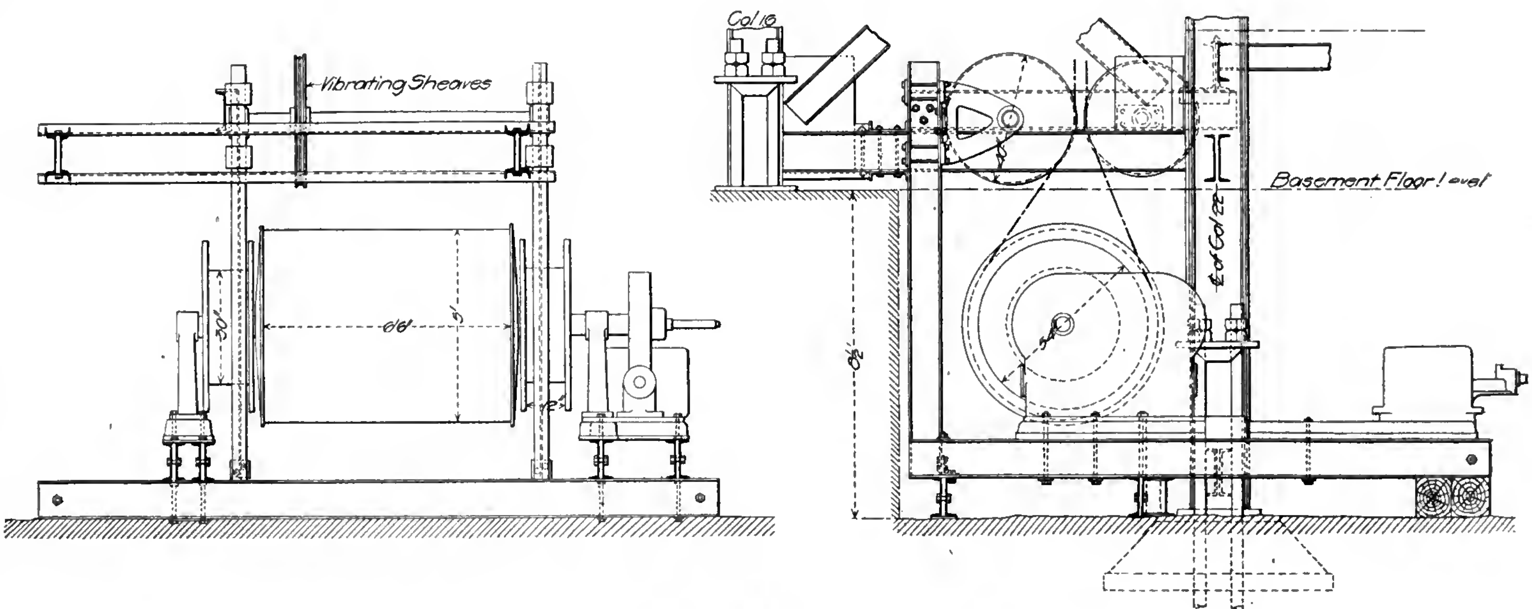
Citizens of all portions of the country are coming to realize that, however important the improvement of navigation may be, it is only one of many ends to be kept in view. The demand for navigation is hardly more pressing than the demands for reclaiming lands by irrigation in the arid regions and by drainage in the humid lowlands or for utilizing the water power now running to waste or for purifying the waters so as to reduce or remove the tax of soil waste, to promote manufactures and safeguard life. It is the part of wisdom to adopt not a jumble of unrelated plans, but a single comprehensive scheme for meeting all the demands so far as possible at the same time and by the same means. This is the reason why the Inland Waterways Commission was created in March last, largely in response to petitions from citizens of the interior, including many of the members of this congress. Broad instructions were given to the commission in accordance with this general policy that no plan should be prepared for the use of any stream for a single purpose without carefully considering, and so far as practicable actually providing for, the use of that stream for every other purpose. Plans for navigation and power should provide with special care for sites and terminals not only for the immediate present but also for the future.

The conservation of natural resources is the fundamental problem. Unless we solve that problem it will avail us little to solve all others. To solve it the whole nation must undertake the task through their organizations and associations, through the men whom they have made specially responsible for the welfare of the several States, and finally through Congress and the Executive. As a preliminary step the Inland Waterways Commission has decided, with the President's full approval, to call a conference on the conservation of natural resources, including, of course, the streams, to meet in Washington during the coming winter. This conference ought to be among the most important gatherings in our history, for none have had a more vital question to consider.

Steel Shot for Drill Points is now being made by spraying molten steel into cold water. The shot is extremely hard and in some formations can be used instead of diamonds.

Temporary Elevators for the Erection of the Singer Building Tower.

An unusual temporary elevator installation is in use during the erection of the 42-story tower of the new Singer Building at Broadway and Liberty street, New York City, as a precautionary measure for the safety of the workmen. Owing to the height of the structure and the incentive that usually exists in the construction of tall steel buildings to operate the material hoists at very high speed, it was here thought desirable to provide independent means of transportation for the workmen to and from the upper floor levels and thus free the material hoists from passenger duty. Accordingly a special elevator equipment has been installed by Mr. Ernest E. Flagg, the architect. It is of the electrically operated drum type, with provisions for raising the head-works from time to time and increasing the height of rise as the height of the structure increases. The equipment is, however, complete in every particular, with all the governing and safety appliances used in the best electric elevator installations, and is unique as one of the most effective measures taken for the safety of workmen in tall building construction, being the first installation of a complete elevator equipment solely for this purpose. The details of this tower extension of the Singer Building, and the many interesting features in its construction, have been described in a number of recent articles in this journal.



Details of Temporary Elevator Machine in the Singer Building.

One of the factors that has favored the use of the material hoist for the accommodation of laborers traveling to and from upper floors of buildings during construction is the facility with which the head-works may be raised from floor to floor as the structure increases in height. The upper works generally consist of nothing more than a sheave, supported upon a temporary framework, which may be raised from floor to floor as required, while the necessary additional cable is merely paid out from the drum of the hoisting engine. It is rightly considered as a temporary feature of the construction equipment and is used for passenger travel, with no further precautions for safety than increased vigilance on the part of the engineer operating the hoist, no safety appliances being generally used, as is required on approved elevator installations. In the Singer Building, however, the great height of rise, nearly 550 ft., rendered this mode of travel more than ordinarily hazardous, as there exists a strong tendency to operate the hoisting cars at too high rates of speed on the long descents, and accordingly it was the desire of the owners and architects to provide something better.

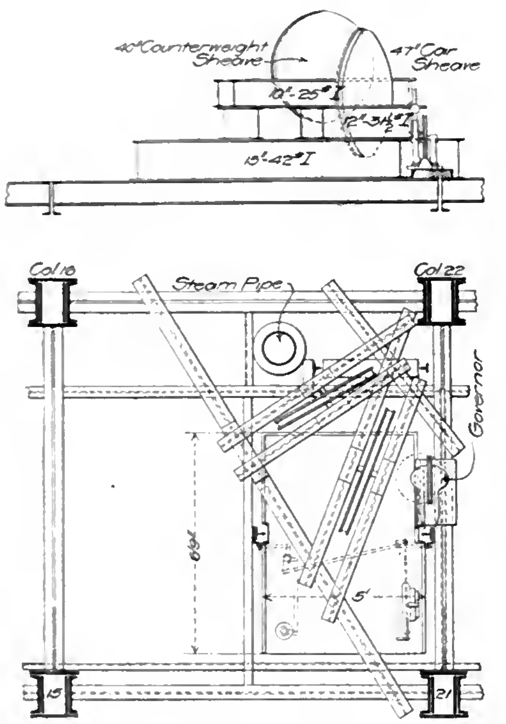
In a study of these conditions by the Otis Elevator Co., of New York, a modification of the standard drum electric elevator equipment, which meets with all the requirements of a temporary installation and in addition offers the advantages of the safety of the approved electric elevator apparatus, was suggested, and a contract was awarded to this company to install such an equipment for use during the construction of the building. It was required to be adjustable for seven different heights of rise as the erection of the structure proceeds, top landings to be made at the 10th, 15th, 20th, 25th, 30th, 35th and 40th floors, respectively, while the equipment must be removed entirely upon completion of the building construction, and the installation of the final traction type of elevator equipment which will be used there.

The electric drum type was selected as the most convenient, with respect to motive power, electric current for its operation being available from the 220-volt Edison street mains, which had been brought into the building for lighting and hoisting purposes, and as the maximum height of rise required, 546 ft. 9 in., is attainable by the use of a large drum. The special features necessary in the installation were, therefore, an extra size of drum to provide for the high rise, some means of storing the surplus cable while operating initially with the shorter distances of travel, and a means of readily transferring the headworks and the top limit mechanisms to the upper levels as it becomes necessary to increase the height of rise. A drum 5 ft. in diameter by 6½ ft. in length was chosen, with special mountings, providing for 12-in. reels between either end of the drum and the drum bearings, which served to carry the surplus cable for both car and counterweight before it was paid out for increased height of rise. The mountings are otherwise of the usual type of the Otis electric drum machine, consisting of the usual double worm-gear drive at one end, to which the driving motor is directly attached, but, owing to the temporary character of the installation, no permanent sub-base was used, the whole machine being mounted on 12-in. channels, rigidly bolted together, as shown in the accompanying details of the machine as installed.

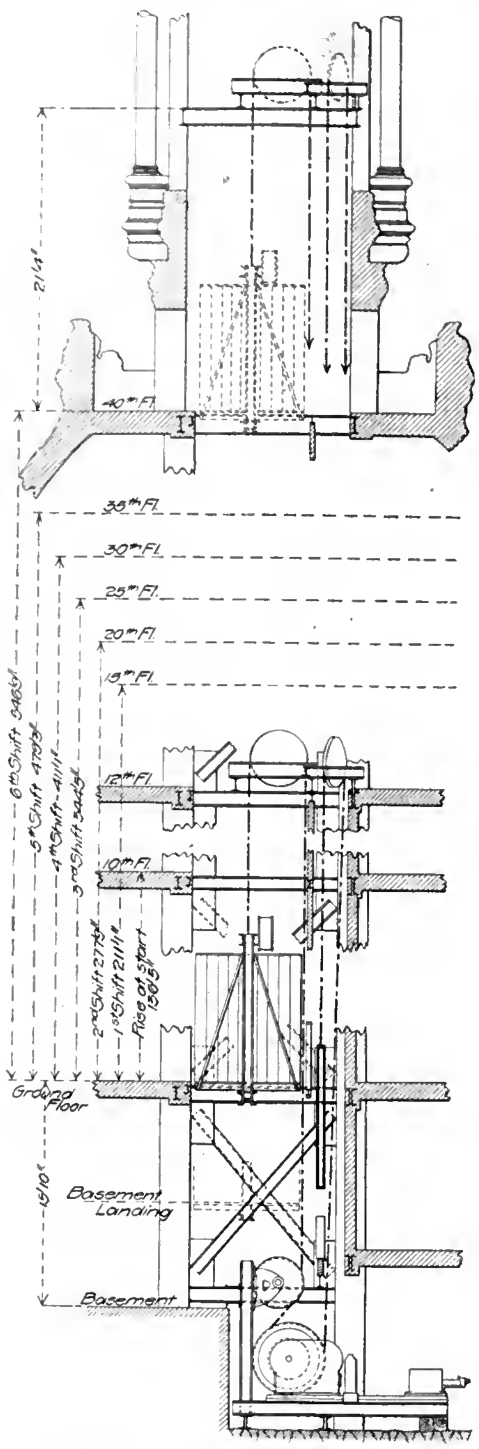
The frame carrying the machine consists of two pairs of longitudinal channels for foundation beams, which are, to withstand the lifting effort of the car and counterweight, shored down from the wind-bracing members of the tower frame-

work immediately above. Supported upon these beams are cross members, consisting of two pairs of channels for both the drum bearing and the worm-gear drive, and, at a distance of about 8 ft. above, a lighter auxiliary framework, which carries the shafts for the vibrating sheaves which guide the counterweight and car cables on and off the drum. The upper frame construction was simplified somewhat by attaching the members to the framework of the building, but the entire framework is firmly anchored to the foundation beams throughout. Considerable difficulty was experienced in locating the machine in the space at the foot of the elevator shaft, owing to limited room between a retaining wall and the adjacent building columns; it was, however, thought advisable to utilize one of the permanent elevator hatches for the temporary car, and this was accomplished by locating the drum in the 7-ft. space available between the columns and the retaining wall, allowing the motor and driving gear to project beyond the columns at one end.

The overhead gear was rendered easily removable by a special design of supporting beams for the car and counterweight sheaves, which are bolted together and so arranged as to be very



Details of Temporary Overhead Work.

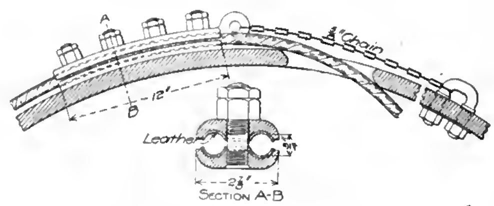


Rises of the Temporary Elevator.

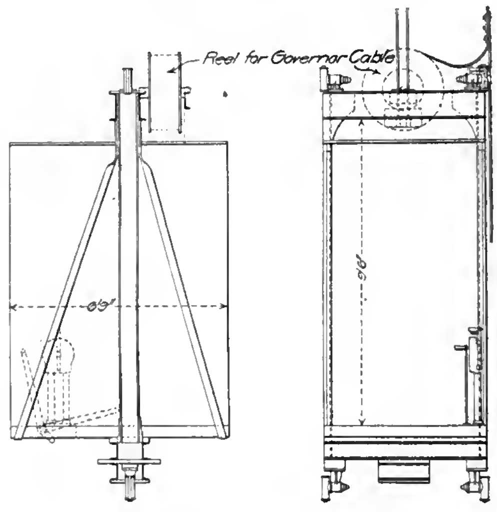
easily detached when it is necessary to remove them. This construction consists of two 15-in. I-beams, arranged diagonally across the hatch for foundation members, upon which are two 12-in. I-beams, so placed as to locate the car sheaves properly. Upon one of the latter beams and a block on the outer 15-in. beam two short 10-in. I-beams are placed to carry the counterweight sheave. Owing to the use of one of the permanent elevator hatches, it was arranged to make use of car and counterweight guides available for the future permanent elevator installation. Two complete sets of this overhead framework were provided to facilitate the work of changing the car travel to a higher rise, enabling one set to be erected without sheaves in the desired new position, and the other set to be removed after the cables and sheaves have been raised to the upper set of beams. Special clamps were devised for bolting the beams firmly in position, which can also be readily released for their removal. Other features due to the removal of the overhead gear are the governor and the upper limit stops of the control system; these are in both cases mounted on special frames, which are merely bolted in position at each of the top landings, and thence removed simultaneously with the overhead gear. For the governor rope not paid out a 12-in. reel, 2½ ft. in diameter, is mounted on top of the car adjacent to the governor rope fastening, so that when increased car travel is desired the rope is unclamped at this fastening and paid out to the new length desired.

The arrangement for storing the surplus rope until paid out for the higher distances of travel is, as above stated, narrow wooden reels mounted on the drum shaft between either end of the drum and the bearings, one of which is for the ropes leading to the car and the other for those to the counterweight. The reels are 12 in. in width and 4½ ft. in extreme diameter, or considerably less than that of the main drum, and the cables are fed out from them to the space inside the drum, and thence through a hole in the outer face to a special rope grip, by means of which it is anchored to the face of the drum. The rope grip is a forged clamp, with longitudinal leather-faced openings for the cables, and grips the two for a length of about 12 in., as shown in the accompanying detail, just after they pass through the hole in the face of the drum. Thus, in lengthening the rope for an increased car travel it is only necessary to loosen the bolts of the clamp, and after unfastening the reels pay through the required amount of additional cable, which is then clamped in the new position. The rope grips are fastened to the face of the drum in either case by a ⅝-in. chain about 20 in. in length, which extends from an eye in one end of the clamp to a U-bolt chain connection bolted to the drum.

The driving mechanism of the elevator machine is the gear of a standard No. 5 Otis double-screw drum machine, direct-connected to a No. 6½ Otis bipolar motor, which is wound for 220-volt direct current, so as to be operated from the Edison street service. The gear is designed for a regular operating speed of 400 ft. per minute, at which the car has a capacity of 2,000 lb., but for the purpose of lifting very heavy weights a back gear attachment has been added to the regular gear, which is readily thrown in by disconnecting a flange and shifting a pair of gears. This back gear has a ratio of 9 to 1 and facilitates raising the parts of the new traction elevator equipments which are to be installed in this building, an arrangement having been made by the Otis Co. in installing this temporary elevator to utilize it for this purpose. The machine is, for simplicity,



Rope Fastening on Drum.



Details of Elevator Car.

operated with two ¾-in. ropes for both car and counterweight, instead of a larger number of smaller ropes, these sizes offering sufficient capacity for the service to be carried. The machine is controlled through one of the Otis magnetic controllers similar to those used with the traction machines.

A 150-Ton Crane of unusual construction has been installed at Birkenhead, opposite Liverpool, England, for the handling of great weights into vessels alongside the wharf. It consists of a special 3-footed supporting framework, which rises about 60 ft. above the dock level and is enlarged at the top to carry a revolving derrick structure with an overhanging jib. The latter is pivoted on a step bearing within the lower part of the suporting frame, and bears at the top against a pressure ring that withstands the thrust of the overhang. The jib has an extreme overhang of 88 ft. 8 in., and at the end carries an auxiliary hoisting gear of 50 tons capacity. The main gear, of 150 tons capacity, has a radius of action of 28 ft. A peculiar feature of the derrick is the use of continuous current power for the operation of the hoisting motors.

Single-Phase Electric Motive Power on the Rochester Division of the Erie Railroad.

By W. N. Smith.

One of the most important electric railway developments of the present year is the change from steam to electric motive power on a portion of the Rochester Division of the Erie Railroad, which took place on June 18, 1907. This is the first installation of a single-phase alternating system of electrical motive power upon a steam railroad, to go into commercial operation.

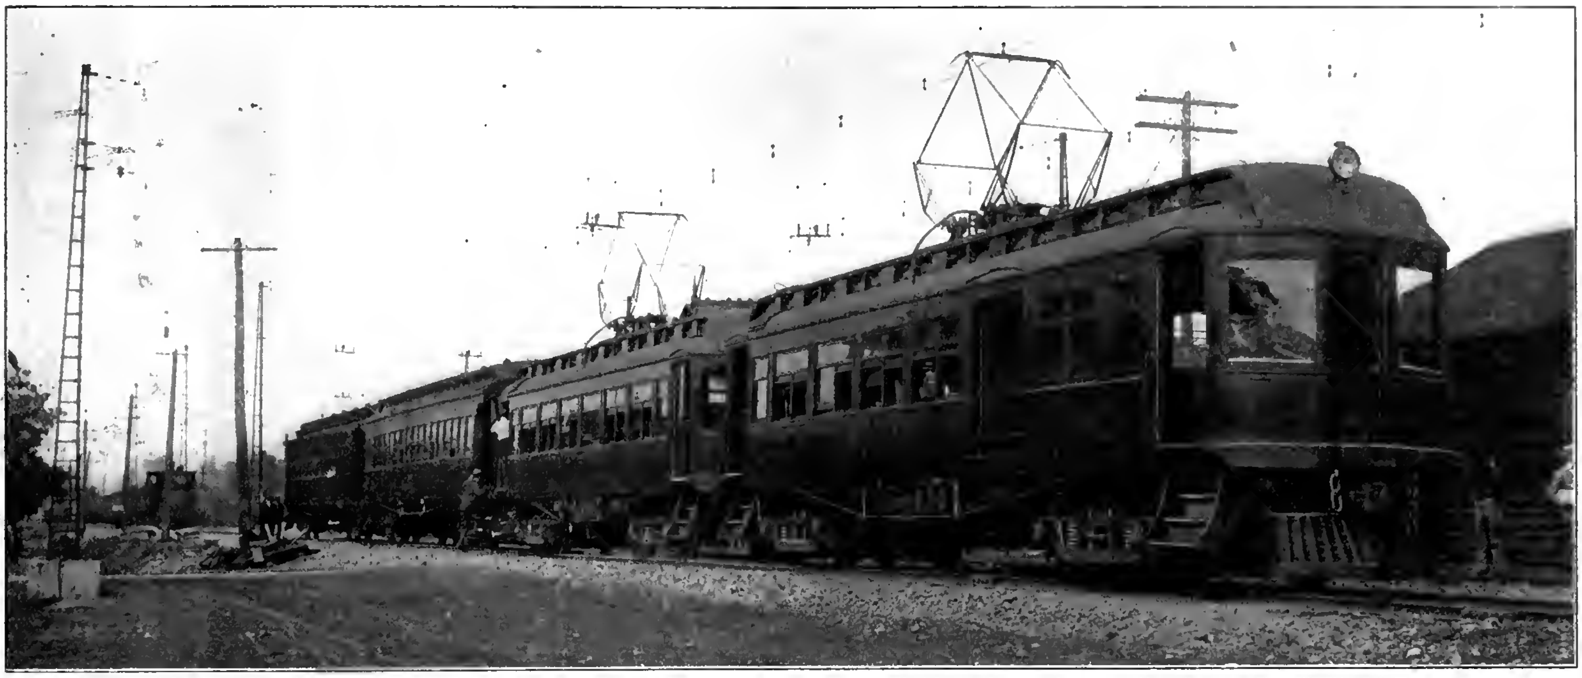
The Erie electrification can justly claim the priority of application of several important features which are of interest in connection with the discussion now prevailing upon systems best suited for steam railroad electrification. This line was the first in this country to operate electric cars on the single-phase system over the tracks of an operating steam railroad; the first in this country to use 11,000 volts working pressure commercially on a trolley, and the first instance of a single-phase traction system receiving power from a 60,000-volt transmission line. All of the construction described below, except that of the 60,000-volt power transmission line and the car bodies and trucks, was designed, executed and placed in operative condition by Westinghouse, Church, Kerr & Co., engineers.

The section of track equipped is 34 miles long, extending from Rochester, over the main line of the Rochester Division, to Avon, a distance of about 19 miles, thence 15 miles over the Mt. Morris Branch. The railroad is entirely single-track, with sidings at way stations, averaging 3 to 4 miles apart. The grades are light, and the curvature for the most part quite easy, the line being relatively quite straight.

The track was originally laid with 68-lb. rails, but was relaid with 80-lb. rail, taken from another division just prior to electrification. The roadbed is ballasted with gravel, and the joints are of the Weber type. A single No. 00 protected rail bond is applied to each rail joint under the plate, one of the advantages of the high-tension single-phase system being that the relatively small current combined with the high impedance of the main circuit renders it unnecessary to resort to heavy bonding.

The line crosses a number of bridges, the longest one, that over the Genesee River, about 1½ miles south of Rochester, being 780 ft. long and comprising seven spans. There are also through truss bridges at Rush, and at Canaseraga Creek, near Mt. Morris, and a stone arch bridge over Conesus Creek, a short distance south of Avon.

The electric service is devoted solely to passenger traffic, which is of the local interurban type. The freight service is handled exclusively by steam as heretofore, as are also the through trains operating between Rochester and Corning over the main line of the Rochester Division, a distance of about 94 miles. The steam service between Rochester and Mt. Morris originally comprised three round trips daily. The principal villages served are Avon, Geneseo and Mt. Morris the other regular way stations being little else than cross-road stops. The population is entirely agricultural, and the Genesee Valley traversed by this line is probably one of the most beautiful and prosperous farming regions of New York State. Instead of three round trips per day, the electric service has introduced six complete round trips between Rochester and Mt. Morris, and three more between Avon and Mt. Morris.



Four-Car Electric Train on the Rochester Division of the Erie Railroad.

Power Supply.—The power is generated at Niagara Falls, in the plant of the Ontario Power Co., and is transmitted at 60,000 volts, three-phase, over the lines of the Niagara, Lockport & Ontario Power Co. The Iroquois Construction Co. built a branch line from Mortimer, a little over 4 miles south of Rochester, to Avon, locating it upon the Erie R. R. right of way for nearly the whole distance. The pole construction used upon this branch transmission line is of the A-frame type, using two 40-ft. cypress poles, set abreast of each other, and inclined so that their tops are framed together, the butts being joined by horizontal plank braces underground. The cross-arms consist of two 3½ x 6-in. timbers, 8 ft. long. The insular pins are of cast steel, one being placed at the apex of the A-frame, and the other two bolted near the extremities of the cross-arms, so that there is an equilateral spacing of 7 ft. between each of the three wires. The insulator pins are grounded by copper wire. The neutral of the transmission system is grounded at the power station through a resistance. Lightning protection of the horn arrester type has been installed at every fifth pole. The conductors are of No. 4, hard-drawn, stranded copper cable. The standard length of span between poles is 220 ft., which is shortened at curves where necessary. When crossing over the tracks of the Erie, or other railroads, recourse is had to a special construction of No. 0 copper cables carried on steel towers, so reinforced by guys that it is impossible for a failure of the line to result in dropping the conductors across railroad tracks.

Sub-Station Building.—The sub-station building is located in the Y formed by the railroad tracks at Avon, and together with the car shed, is adjacent to the roundhouse and division repair shop. The walls of the building are of brick, resting upon solid concrete foundations, the roof and floors being of reinforced concrete. The floors are supported upon steel beams, but the roof beams are of reinforced concrete, like the slabs which they support.

In the basement of the building are located one of the transformer oil tanks and the oil pump. The main floor is divided into three rooms, the main transformer room being 43 x 17 ft., and extending the full height of the structure to allow room for the high-tension bus-bars, which are carried over the transformers. The remaining space on the main floor is divided into a high-tension room (through which the 60,000-volt wires enter, and which is the location of the high-tension circuit breakers, 16 ft. 8 in. by 19 ft. 8 in.) and the operating room, which is 19 ft. 8 in. by 24 ft., where are located all the 11,000-volt switching apparatus and the measuring instruments. Directly over the operating room is a mezzanine floor, reached by an iron staircase, in which are located the 11,000-volt lightning arresters, the 60,000-volt choke coils, and the 60,000-volt series coils. The high-tension connections enter through the high-tension room, which runs from floor to floor, and pass through the choke coils and series coil, on the mezzanine floor, and then turn through a wide opening in the wall to the 60,000-volt bus-bars, which are located in the upper portion of the transformer room.

There is space in the transformer room for another transformer of the same size and there is also space in the high-tension room for an oil-insulated circuit breaker should it ever be decided necessary. The interior is painted with cold-water paint of the same light green shade that is commonly used by the Erie R. R. for interior finish.

The interior lighting equipment consists of 47 16-c.-p. incandescent lamps. Heat is supplied by a simple system of Colonial wall-type steam radiators, supplied by steam from the locomotive roundhouse.

Sub-Station Equipment.—The transmission line terminates at the lightning arrester yard in the

rear of the sub-station. The arrangement of the 60,000-volt lightning arresters consists of three horn gaps, arranged one behind the other, on each of the three conductors, the first gap being 4¾ in. across, the second 5, and the third 6 in. A concrete column is in series with the first gap, an electrolytic arrester in series with the second and a 5-ft. fuse of No. 18 copper wire in series with the third, that is to say, between one horn and the ground. Both horns of each gap are of ½-in. round iron. Between the line and the first arrester there is a hook-type knife switch, and between the last arrester and the lead into the sub-station, there is a No. 18 copper wire fuse, in each conductor, placed horizontally upon a structure especially devised for it on top of a pole. These fuses are enclosed in wooden tubes about 5 ft. long, wrapped with torpedo twine. The entire arrangement of lightning arrester gaps, fuses and switches is mounted upon eighteen chestnut poles; and a suitable elevated platform, railed off and fitted with a gate to keep out trespassers, affords means of access to the apparatus when attention is required.

The three high-tension conductors enter the sub-station through glass disks held in 36-in. tile, set in the upper portion of the rear wall of the sub-station.

Within the sub-station, the wires first pass through three 60,000-volt stick-type circuit breakers, mounted directly inside of the rear wall. Thence, over bare copper conductors to the three oil-insulated choke coils, situated on the mezzanine floor, thence to three oil-insulated series transformers, also on the mezzanine floor, from which connections are taken to the power-measuring instruments in the operating room. The main connections finally terminate upon a set of copper bus-bars in the transformer room, which are run upon porcelain insulators mounted on wooden cross-arms and placed at a convenient height directly over the line of transformers.

The 60,000-volt three-phase current is rendered available for single-phase distribution by means of three transformers of the Westinghouse oil-insulated water-cooled type, each of 750 kw. capacity. For the present installation, two transformers only are used at one time, the third being a spare. The high-tension connections are such that in case of one transformer failing while in service, its connections can quickly be taken off the bus-bars, and put on the spare transformers. The transformer windings are fitted with taps enabling the three-phase to two-phase "Scott connection" to be used. The low-tension windings can be so connected that either 11,000 or 22,000 volts can be obtained, so that in case it should ever be desired to transmit railway current for an extension of 40 or 50 miles to another sub-station it could readily be done without adding transformers to this equipment. The low-tension windings also have six taps, enabling relatively small variations to be made in the secondary voltage, if they should be necessary to suit operating conditions in the trolley line.

One end of each low-tension winding is directly grounded to the boiler iron case, which in turn is, by means of a No. 0000 stranded copper cable, directly connected to the track return circuit.

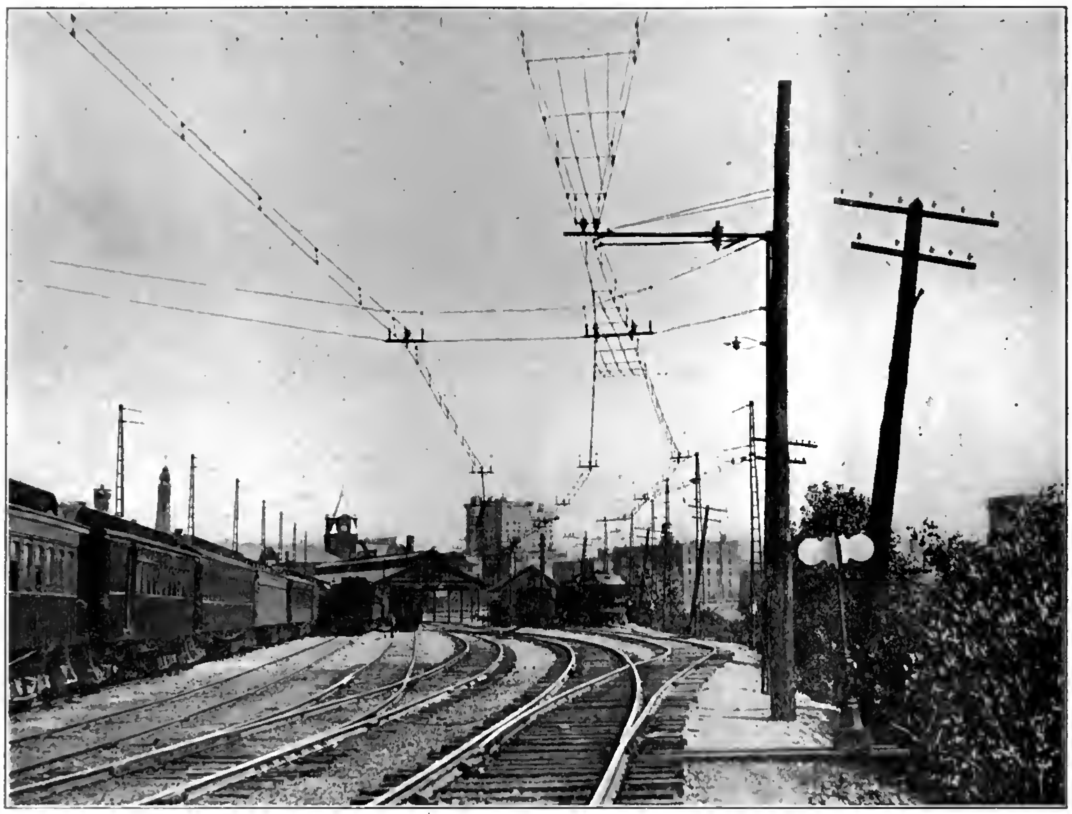
The transformer cases are made of boiler iron, and set on a square cast-iron base, which is in turn mounted on three pairs of wheels running upon an iron sub-base set in the concrete floor of the room. A track runs lengthwise of the room directly in front of the transformers, a transfer truck running upon it, upon the top of which there is another set of little wheels or rollers, which line up with those upon which the transformer cases are set. When it is desired to remove the windings from the transformer case, it is only necessary to disconnect the electrical, water and oil connections, roll the transformer off its sub-base and onto the track, which is then pushed to the rear of the transformer room, where it comes directly under a 10-ton hand hoist, which is able to lift any part of the transformer that repairs make it necessary to handle.

Two cylindrical boiler-iron oil tanks are provided, each of slightly greater capacity than a single transformer. One is located in the basement directly under the transformer room, so that the oil from the transformer can readily be drained into it. The other is suspended from the concrete roof beams at the top of the transformer room, close to the side wall of the building, this being intended to act as a reservoir for distributing oil back into the transformer. The oil is pumped from the lower to the upper tank by means of a steam pump supplied from the boiler room in the adjacent division roundhouse, where steam is always available. From the upper tank oil is fed by gravity into either transformer. It is thus a simple matter to draw the oil from any transformer if its insulating qualities are found to have depreciated, and the rehydrating, filtering or purifying apparatus can readily be employed with the aid of the pump, and the supply returned again to storage. The oil piping is of iron throughout.

The water circulation is by gravity, the supply coming from the railroad company's water tank system, at the adjacent roundhouse, being pumped originally from the Genesee River about a mile distant. An artesian well had been opened on the premises, but the water was so strongly impregnated with sulphur and other impurities that it was thought best not to introduce it into the copper piping in the transformers, although the cost of such a supply would have been practically nothing.

There are three separate water-cooled coils in each transformer case, each controlled by its own valve, so that the amount of water may be controlled as found necessary under various conditions of load.

The necessary transformation from three-phase to two-phase fits in very well with the natural subdivision of the electrified line into two sections, one of which is about 19 miles in length, north of Avon, the other about 15 miles in length,



Overhead Construction in the Rochester Yard.

being to the south of Avon. The connections were therefore laid out to operate such sections upon separate phases of the two-phase secondary system. Either the T or V connection can be used, the latter method being employed at present. Each one of the active transformers therefore feeds a separate section.

As mentioned above, one terminal of each single-phase, 11,000-volt transformer is grounded. The middle transformer of the three is ordinarily used as a spare, and the other low-tension lead from this transformer runs to the center of a double-throw switch, whose outside poles connect separately to two low-tension bus-bars. The ungrounded low-tension terminals of the other two transformers connect through single-pole switches, one to each of these bus-bars.

The low-tension bus-bars run along the wall of the operating room, and directly beneath them are three type-E Westinghouse automatic oil circuit-breakers, one on each of the two trolley feeders, the third breaker which is situated between the other two, being a spare. One pole of each of the three oil breakers is connected to the center pole of a double-throw hoop-type knife-switch, by means of which it is thrown upon either bus-bar. The other pole of the oil breaker runs directly to the feeder. The outgoing lead from the middle or spare circuit-breaker runs to the center pole of the double-throw hook-type switch, so that it can instantly be thrown upon either one of the feeders, should the breaker usually confronting that feeder be temporarily disabled. This system of connections is simple, compact and flexible, and has admirably fulfilled the conditions for which it is intended.

The outgoing 11,000-volt feeders run up to the mezzanine floor directly over the operating room, where they emerge from the building through perforated glass disks, set in 18-inch round tiles. Before emerging there are tapped to them two Westinghouse low-equivalent lightning arresters, set in brick compartments and reinforced by two electrolytic lightning arresters of the 11,000-volt type. A set of call bells is provided so that when the automatic breakers open, a bell is rung in the adjoining car-inspection shed. Also, if the temperature of any transformer runs above normal, a bell circuit connected

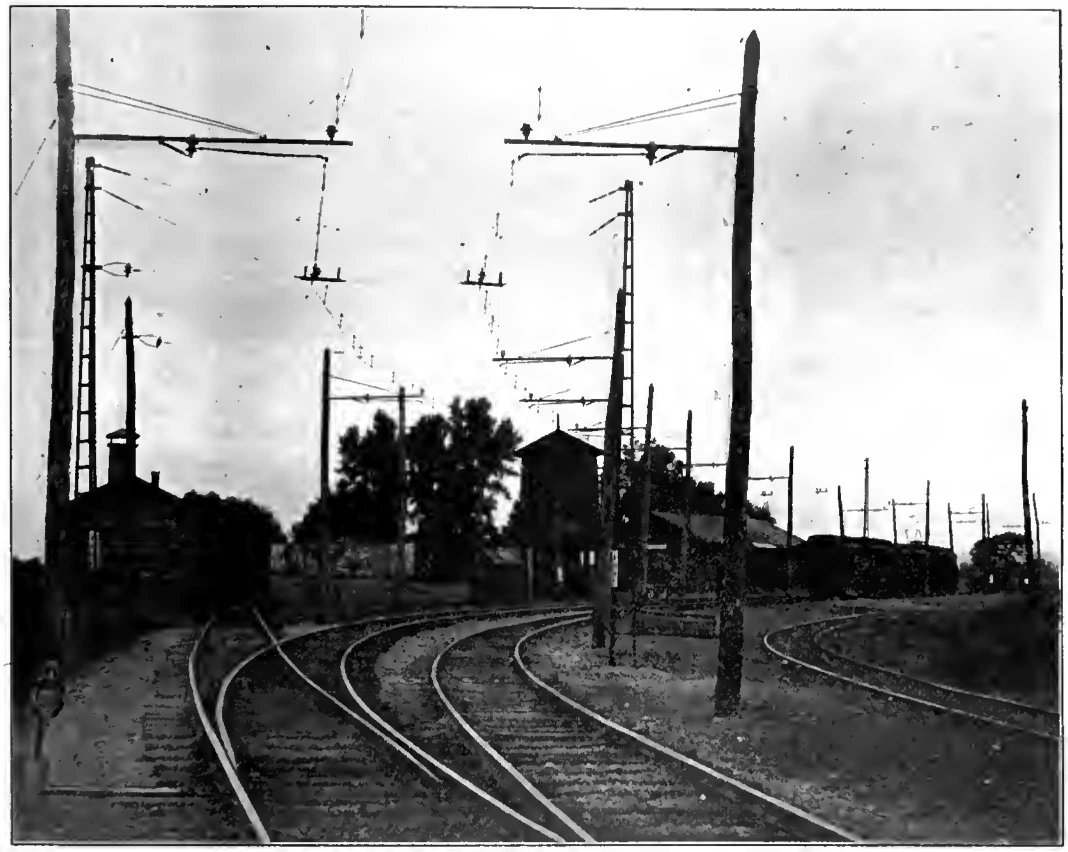
to a thermometer in the top of the transformer tank is similarly made to operate. The station itself does not require the continuous presence of an attendant, which is needed in the case of a rotary converter sub-station. The working force is so organized that the car-repair men are always available for manipulating the sub-station circuit-breakers, and the cost of attendance is thereby reduced to a minimum.

Catenary Trolley Construction.—The overhead trolley construction is in many respects unique. It was the first of all catenary installations to operate regularly at 11,000 volts. There were very few precedents to follow; many of the details of the overhead work are entirely original, and nearly all of them were especially designed for this installation by the engineers who executed the work.

The poles are of chestnut, averaging 25 in. in circumference at the top, and about 42 in. at the butt. Most of them are about 35 ft. long, but 40-ft. poles were used where the embankments were narrow and steep, and in span construction. Nearly all the construction is of the bracket type, except at the railroad yards at Rochester, Avon and Mt. Morris, and for some distance at Mortimer, where there is a siding on each side of the main track, which prevented the use of bracket construction there.

The poles are given about 12 in. rake. They are tamped with cobblestones, of which plenty were available from the coarse gravel with which the road is ballasted. The ground proved very deceptive as regards the nature of the digging, much water-bearing gravel and quicksand being encountered, and oil-barrels had to be resorted to in many instances, to prevent caving in of the holes during pole setting.

The brackets are of an entirely original design, each consisting of a 3 x 2½-in. tee, 10 ft. long, the heel of which is fastened to the pole by a pair of bent straps, the outer end being supported from the pole-top by two ⅝-in. steel truss rods, instead of the single rod commonly used for bracket work. The two rods are attached about 27 in. back from the outer end, and run one to each side of the pole, and are fastened there to a pole clamp devised for this work, which grips the top of the pole instead of requiring the bolt or truss rod to pass through it. In this way the timber of the pole is kept intact, and does not have a hole bored through it which will admit moisture and induce rot. The two truss rods are threaded at both ends, and at the upper end each one passes through a small iron casting which is in turn carried upon a bolt projecting out from the cast-iron portion of the pole clamp, like a trunion. The whole construction is extremely rigid, and is stronger and more conductive to a long life for the pole than any bracket hitherto used. Where necessary, at switches, extra long brackets are employed, being lengthened by splicing and an extra truss rod being attached by means of a clamp to the outer end of such a bracket and run to the extreme top of the pole.



Overhead Construction, Mt. Morris Terminal.

The insulator pins are of malleable iron, of a type specially devised for this work. The lower portion of the pin was divided and fitted closely over the flanges of the tee bracket, being provided with a single ⅝-in. bolt by means of which the lower split portion of the pin is clamped securely against the bracket. The brackets and pins were furnished to the engineers' designs by the Electric Service Supplies Co.

The insulator is of R. Thomas & Sons manufacture, 6⅞ in. in diameter and 6 in. high, made in two parts, but of the three-petticoat type, and known as No. 3029. It was designed by the engineers especially for this installation. As most of the overhead work was done during the winter months, and had to be rushed, a quick-setting cement of litharge and glycerine was used in place of Portland cement, which not only permitted rapid work in construction, but obviated troubles due to the freezing of hydraulic cement while setting.

The insulator pins are ordinarily about 12 in. from the end of the bracket, but there is 27½ in. space between the end of the bracket and the point where the truss rods support it, which permits sufficient variation in location of insulator to meet most of the requirements in shifting the alignment of the trolley wire on curves.

The messenger wire is of "extra high strength" steel, furnished by the American Steel & Wire Co. It is of seven strands and is 7/16 in. in diameter. Joints are made by using the so-called "open" and "closed" cable sockets, the sockets being sweated on to the abutting ends of the cables and joined by a pin connection through the eyes of the sockets. The trolley wire is No. 000 B & S grooved copper, the lengths being spliced with the usual type of soldered splicing sleeve.

The spans on the straight line track are 120 ft. in length, and as much shorter than this on curves as required by the radius of the curvature The maximum deflection from the center line of the track, on curves, is 7 in. each way. The catenary hangers were of the Electric Railway Equipment Co.'s drop-forged type, being modified by the engineers to suit the requirements. The messenger clip and the trolley clip are of the same type but grooved differently to accommodate their respective wires. They are joined by a ⅝-in. iron hanger-rod, with right-hand threads on each end, the longer rods being flattened in the middle to admit of bending them slightly, so as to conform to the divergence of the messenger and trolley wire near the ends of the spans. Both trolley and messenger ears are secured in position by jam nuts. This type of suspension was developed especially for this installation, and is so constructed that there is no possibility of parts coming loose and falling apart on account of vibration. It is also very quickly and easily adjustable on trolley wires. The hangers are spaced every 10 ft.

The steady strain rods are of treated wood of the Westinghouse Electric & Mfg. Co.'s make, and they are mounted at one side of the bracket instead of directly underneath, in order to give sufficient clearance for the pantagraph trolley on curves, where the super-elevation results in the tilting of the shoe from the horizontal.. Each steady strain rod is hinged to a spool type Thomas porcelain strain insulator, which is clamped to one side of the bracket in such a manner that the hinged end of the rod is almost at the elevation of the top of the tee bracket. The method of attaching the steady strain insulators to the bracket is such that they can readily be shifted along the bracket to follow up any change in alignment of the trolley wire that may be required by curvature or for any other reason. The clamps holding the steady strain insulators are of 3 x ⅜ in. bent iron. The spool type insulators are cemented on to pieces of ¾-in. pipe, through which passes the ⅝-in. eye-bolt by means of which they are attached to the bent irons. Steady strains are used only on curves and turnouts and were not found necessary on tangent track.

The tie wires are of No. 9 Extra BB, galvanized telegraph wire, because it was thought best not to make too rigid an attachment between the messenger wire and the insulator; so that if a bracket became detached from the pole for any reason, its weight and the shock of detachment would tear the wire clear from the messenger and allow the bracket to fall entirely away from the wire and reduce the chance of steam railroad trains colliding with it. An accident to the electrical equipment of a railway operating both steam and electric trains may shut down the electric service, but will not automatically place any check upon the steam service, so that accidents to steam trains must be guarded against, as a steam train might easily be wrecked by an obstruction which would automatically prevent power from being supplied to an electric train. This was one of the reasons for installing the system of "ground rods" from the brackets to the rails, which is carried out very consistently throughout the installation. Every bracket is

grounded to the rail, so that an insulator failure will instantly throw off the power, as it will cause a complete metallic short-circuit. There is thus no danger of setting the wooden poles on fire, which would be possible if this precaution were not taken. The burning of a wooden pole would not of itself necessarily cripple the electric service, but it would be quite likely to cause an obstruction dangerous to the passage of steam trains which are, of course, independent of any disturbances on the electric motive-power system. Up to the present time, however, there have been no cases where the overhead construction has caused any obstruction to the passage of the steam traffic.

The ground rods consist of 3/8 x 1 1/4 in. flat steel, their upper and lower ends being bolted to track rail and bracket respectively.

The span construction is as nearly as possible similar to the bracket construction and uses the same type of pin and insulator. A piece of 3 x 2 1/2-in. tee about 30 in. long is suspended from the span wire by hangers of galvanized strand cable, adjustable in length, and fastened to the span wire cable by specially designed clips, the construction forming a sort of stirrup upon which the pin and insulator are carried. The messenger wire rests upon the insulator just as in the case of regular bracket construction. This form is used, not only for spans where there is but one track, but also in the yards at Avon, and Rochester, where three or four parallel tracks are electrified. Span construction, in general, was only used where conditions absolutely required it.

The Rochester yard was a difficult piece of construction on account of the distance between supports (which reaches a maximum of 94 ft. where spanning seven tracks, four of which are electrified), and also on account of the uncertain nature of the soil which, on the river bank, is filled in with gravel and cinders. For these long spans, where it was impossible to use guys of the usual type (the river bank being on one side and the main highway which gives teams access for loading and unloading freight cars on the other side), it became necessary to use self-supporting span construction, and this was done by using the "Tripartite" type of steel pole, set in concrete. This type of pole being constructed of re-rolled Bessemer steel rails is less subject to rust and consequently more durable than any other available type of metal pole, and all of its surfaces are always open and easy of inspection. On account of the great tensile strength of the material, there is considerable saving in weight, and the fact that it was a standardized product enabled quicker delivery to be made than though special riveted poles of structural steel shapes had been specially designed for these locations. The span wires consist of the regular messenger cable fitted with cable sockets sweated on at each end, the same being fastened to turnbuckles and pole collars at the tops of the poles. There are two span cables at each pair of poles, the upper one being used to carry the weight, the lower one acting to steady the arrangement and also to act as a relay in case of an accident to the upper span. Similar construction was also used at Avon, where guying of side poles was not always possible.

A very simple type of pull-off was devised for curves in span construction, and it so happened that both the Rochester and Mt. Morris yards have considerable curvature. The pull-off consists simply of a spool-type insulator, with a piece of pipe cemented through the center, this pipe being slipped over the hanger spacing-rod joining the messenger and trolley clips, thus giving an insulating connection through which an ordinary pull-off cable can be attached to both messenger and trolley wires wherever required. The division of the horizontal pull between the messenger and trolley wire is easily adjusted to suit the conditions, by shifting the spool-type insulator up and down the spacing rod, by inserting longer or shorter nipples of pipe underneath it. In general, when near a span wire, the messenger cable is supported rigidly on its insulator and the trolley wire needs all the side pull; but in the middle of a span, the pull must be equally divided between messenger and trolley wire.

The presence of several through-truss bridges over streams, and two low bridges over the Erie right of way, necessitated the employment of special construction at these points, particularly at the bridge at Clarissa St., on the outskirts of Rochester. The original clearances here were so low that the road-bed had to be excavated and the track lowered about 2 ft., the minimum clearance between the rails and the trolley wire being finally 18 ft. The messenger is fastened to a horizontal spool-type insulator mounted at the center of a substantial piece of turned oak, which is long enough to carry two more similar insulators, one on either side of the center one.

The steel hangers reaching down from the overhead bridge structure carry the two side insulators, so there are always two insulators in series between the 11,000-volt messenger cable and the steel work of the bridge. These insulated supports are suspended at short intervals from the under side of the steel-work of the bridge and are further supplemented by the use of steady strains which prevent any side displacement of the trolley wire. The shortest sizes of hanger spacing rods are used in such places. Where the bridge truesses are high enough to permit it, an iron stirrup is employed like that used in span work, which carries the standard form of straight line insulator, and the regular type of catenary suspension is employed.

At either side of these overhead obstructions it was necessary to provide warnings for brakemen upon the tops of freight cars, as substitutes for the warnings of hanging pieces of rope previously used. They consist of the well-known type of horizontal, suspended, swinging wooden rod, mounted with its axis at an angle, so that it swings up as it is pushed to one side. The pantagraph trolley is fitted with a set of springs on each side, one of which strikes this warning sign a blow as it passes under and instantly throws it one side. The blow is struck upon a heavy leather strap held taut by a coil spring of steel wire in tension, the whole contrivence being fastened to the lower half of the pantagraph trolley mechanism so that it is at the right height for striking the warning sign. The swinging rod is mounted upon the pole by means of insulators, effectually preventing any leakage to the ground, even though a car might stand still directly under the sign and make contact with it for an indefinite length of time.

Nearly all the telephone and telegraph wires which cross over the 11,000-volt trolley wire have been put underground, particularly in the case of the leads composed of only a few wires, but where the line is crossed by heavy telephone trunk lines, they have been protected by the basket type of construction, so designed as to effectually prevent a broken telephone wire from falling across the messenger or trolley wire. This consists primarily of four galvanized steel cables stretched between opposite ends of two cross arms, one placed above and the other below the wires of the intersecting telephone line, and the four cables are joined by a basket-work of light strap-iron ribs placed at intervals of 3 to 4 feet across the whole span, forming the sides and the bottom of the cradle and effectually preventing a broken telephone wire from dropping any further. This construction was also followed in the case of an electric wire at Avon.

The telegraph department of the railroad company, in connection with the signal department, constructed a private telephone line of two copper wires between Rochester and Avon, with instruments at all signal towers and stations in the dispatcher's office, and at the sub-stations, and car shed, and master mechanic's office. This telephone system is run upon the trolley bracket poles, transposed every third pole, and has worked satisfactorily.

Lightning protection for high tension single-phase railway lines not having as yet been standardized, only a part of the line was equipped with line lightning arresters, which are of a swinging fuse gap type made by the Westinghouse Electric & Manufacturing Co. This type consists of a gap one side of which is connected directly to the trolley through a No. 4 copper wire, and the other side directly connected to the ground rod through a fuse enclosed in a tube which, while the fuse is intact, is maintained in an inclined position like a pendulum held back from its position of rest; but when the fuse is blown, a latch is released which allows the fuse tube to swing to a vertical position which shows conspicuously from the ground, and signifies to the patrolman that the fuse should be replaced. The fuse tube can then be lifted off the suspending lugs by a pair of insulating tongs made for the purpose, and the fuse renewed and replaced in a few moments.

On the other half of the line, lightning arresters were not installed. During the summer, two of the poles were struck by lightning, but the metal-work of the brackets and truss rods being entirely grounded, these poles were not damaged below the topmost point of attachment of the truss rods, which is generally not over 18 in. from the top of the pole. In a number of instances the lightning-arrester fuses have blown, but it is not known how many of them have blown simultaneously. Although the extent to which this type of arrester is fully protective is hardly established as yet, it can be stated that at no time since regular operation started has any injury to the car equipment resulted from lightning, though there were several severe storms during June and July.

The trolley line is divided into seven sections—one comprising the Rochester terminal, one the Avon yard, three sections in the main line between Rochester and Avon, and two sections south of Avon.

The sections are divided by trolley section insulators, made by the Westinghouse Electric & Manufacturing Co. They are of the overlapping type, made of impregnated wood, and are of sufficient length to insure insulation at 11,000 volts. Each section insulator is carried upon two brackets, mounted on poles spaced 10 ft. apart. As the trolley and messenger must both be completely insulated on opposite sides of the breaker, heavy strain insulators are introduced upon which the messenger is dead-ended, the two insulators being connected across the gap by a heavy steel rod. This entire combination is supported upon standard insulators mounted upon the regular brackets.

One of the breakers, that opposite the sub-station at Avon, is different from the above-mentioned type, in that it is not of the overlapping type, it being necessary to absolutely separate the two halves of the trolley line in order to utilize the separate phases of the trolley current of each half.

The only feeders necessary are those connecting the sub-station with the trolley on opposite sides of this section break. The principal object of cutting the trolley into additional sections is to facilitate the locating of line trouble.

The conditions of electric traction upon this line are such that no feeder is necessary besides the trolley wire, and consequently there is no necessity for feeding the sections separately. A jumper is therefore provided at each section insulator, in which is placed a hook-type knife

switch that can be operated in case it is desired to cut that section out. Normally, however, the switches are closed, and the effect of the jumpers is to make the trolley wire continuous.

Another detail peculiar to the catenary type of trolley construction is the "deflector," a sort of mechanical fender placed in the angle formed by the intersecting trolley wires at switches. The deflector here used consists of four or five bars of flat steel, ½x¼ in., suspended by riveted hangers from crossbars spaced 5 ft. apart, which in turn rest on standard trolley clamps, fastened to the trolley wire. The particular advantage gained by this construction is that no extra tension is needed to keep the bars from sagging and getting crooked, this type of deflector being of minimum weight and entirely self-contained. They are placed in both angles of each switch. The object of the deflector is to prevent the end of the pantograph shoe, when traveling under either wire, from becoming hooked over the other.

There being an open space between the abutting vestibules when two motor cars are coupled together, due to the rounded and projecting buffer beams of the platforms, this opening being nearly 18 in. in width, which is wide enough to allow a person to fall between the cars, there were provided canvas curtains about 5 ft. high, with snaps attached, which enable them to be quickly stretched across the space, one on each side of the vestibule end door, so as to insure the safety of trainmen and passengers when walking from one car to another with the train in motion.

The trucks are both alike, wheel base being 6 ft. 8 in. The axles are 6½ in. diameter. The trucks are of the standard M. C. B. swing bolster type, with heavy framing. The brake shoes are inside hung.

The heating equipment consists of 32 of the Consolidated Car Heating Co.'s electric heaters of the truss plank type, and 450 watts capacity each, in the main portion of the car, and two "No. 192 M. S." heaters in each cab.

Overhead Construction Showing Trolley Section Insulator, Rochester.

Cars.—The cars equipped with electric apparatus are six in number, and, together with their trucks, were furnished by the St. Louis Car Co. The electrical apparatus was installed upon the cars and trucks by the engineers at the railroad company's car shops in Buffalo, N. Y. The cars are 51 ft. 4 in. over bumpers, 43 ft. over corner posts and 29 ft. 4 in. between truck centers. They are 8 ft. 9 in. wide over sheathing and 13 ft. 8⅝ in. in height above the rail. Four of the six have two passenger compartments, the other two having a baggage compartment about 14 ft. long, and a smoking compartment, with six seats, besides the regular passenger compartment.

Each car is fitted with a 50-c. p. headlight at each end, on top of the hood, and it is also fitted with a gong, air whistle and with the standard train air signal used by the Erie R. R. The toilet is in the center of the car, adjacent to the partition between the compartments. The "Standard" steel type of platform buffer is used, and the regular M. C. B. coupling, air hose connections and safety chains are provided, so that the cars can couple up to any of the standard Erie rolling equipment.

Electrical Equipment.—The electrical equipment of the cars consists of four No. 132-A Westinghouse single-phase railway motors, with a nominal rating of 100 h. p. each, the gear ratio being 20:63. The suspension is of the nose type, and solid gears are pressed upon the axles.

The control system is of the Westinghouse electro-pneumatic type and includes three distinct circuits, the high potential, the low potential and the control circuit.

The high potential circuit includes the pantograph trolley, line switch and the transformer. The pantograph trolley mechanism is operated by a pair of springs and by an air cylinder. The trolley is raised and held against the wire by means of springs against its own weight, and it is lowered by the application of air pressure to pistons working in cylinders that form part of its base. When down it is automatically locked, and the latch of this lock can only be withdrawn by applying air pressure to another small piston, which then unlocks the pantograph, allowing the springs to raise it. This trolley mechanism is so connected with the control circuit through the line relay that any interruption in the supply of high-tension current immediately causes the trolley to be lowered by applying the air to the main cylinders in the trolley base.

The line switch is equivalent to a main high-tension circuit breaker. It is opened and closed by air pressure, admitted by electrically operated valves. In case the supply of air is exhausted, as when the car has stood for some time unused, the line switch must first be held in mechanically by means of a handle provided for the purpose, until the air pump, which can then be thrown into operation, has compressed air to about 50 lb. pressure, which is enough to properly actuate the control system. To raise the trolley when there is no air pressure there is provided a small automobile tire pump, placed underneath one of the car seats, which is connected by a three-way cock into the trolley air piping system, and enables the air-operated trolley latch to be withdrawn and power obtained that will start the air compressor and set going the motor generator set, which is used for charging the storage battery and supplying current to the control circuit.

The transformer is of 200 k. w. capacity and is of the oil insulated type. It has three high-potential and eight low potential taps, the latter running from 300 down to 110 volts, at which latter pressure current is provided for heating, lighting and auxiliary purposes.

The high-tension wiring of the car is done mainly with varnished cambric cable, drawn through loricated iron conduit. A small amount of high-grade rubber cable is used, but it is thoroughly protected with varnished cambric tape wherever there is danger of a brush discharge to ground breaking down the insulation.

In the main low-potential circuit are the switch group, the preventive coils and the reverser. The switch group is a set of air-operated switches, controlled by magnet valves, all mounted in one frame. It is placed athwart the car as near as possible to the low-tension end of the main transformer. The switches of the group are all provided with interlocks, which automatically govern the connections in such a way that each switch of the group acts only when the current in the motors has reached a predetermined value, thus making acceleration automatic. Preventive coils are used across the terminals of some of the switches of the group, to prevent excessive current flowing at the instant of closing the switch. Each switch in the group is fitted with its own blow-out coil. There are two reverser switches actuated by air pressure, one for each pair of motors.

Current from the main motor circuit is led through the motor limit switch, which makes effective the functions of the interlocks on the switch group, and renders it impossible for the successive switches to be thrown in unless the limit switch is closed.

The control circuit includes a master controller in each vestibule, the train line wires and their connections to the valve magnets, and interlocks a storage battery supplying current for these wires, and a motor generator set, which is used either to charge the batteries or to actuate the control system. The master controller makes the proper connections, by means of which the 15-volt storage battery actuates the valve magnets which control the action of the air-operated main contactors in the switch group, and the reversers. The controller handle is normally held in a vertical central position by springs, unless it is moved to one of the running points by the motorman. When released from the grasp of the hand it flies to the vertical position, cutting off the power, and enabling the emergency application of the brakes by means of brake relay valve alongside of it. There are two holes in the face of the master controller, directly under the handle, and attached to the handle by means

of a chain is a plug which may be inserted into either of these holes. The master controller is not operative unless this plug is pushed all the way into the lower hole, which closes the line switch connects the generator and battery, and puts the brake relay valve into circuit. This is the ordinary running position of the plug. In case the line switch is opened by an overload, which generally causes the trolley to be lowered, the plug is taken out of the lower hole and placed in the upper, which action immediately closes the line switch, releases the trolley and allows it to spring up against the wire. As soon as the power is thereby returned to the main circuit the plug is taken out of the upper hole and replaced in the lower one.

There is a push button upon each side of the bottom of the master controller case. That on the right-hand side is used for dropping the trolley and opening the line switch. When the button on the left-hand side is pressed the switch group is stepped up to the last, or high speed, notch and remains in that position until the handle of the controller has been returned to the off position.

There are four distinct notches on each side of the controller, the first corresponding to the coasting position with the power off, the others enabling such gradations of speed as may be desired. Reversal is effected by moving the controller handle to the opposite side of the center, or dead, point. If the controller stops on the dead point, as it will if released by the hand, it will immediately apply the brakes.

The motor-generator set is a compact machine of about 1/6 k. w., the motor being of the self-starting induction type, wound for 110 volts, the generator being normally of about 23 volts. It is placed under one of the seats in the car and is covered by a box with removable lid, so that it can easily be reached for such small attention as it requires. It is mounted upon rubber bushings, and runs so quietly that its presence in the car can hardly be detected.

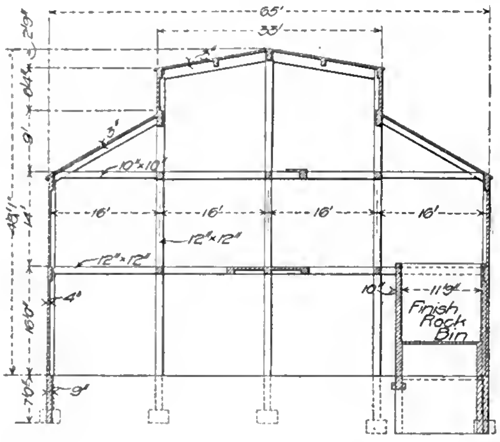
The storage battery consists of seven cells contained in a wooden box with handles, carried in an enclosed box underneath the car. No other auxiliary lines for any purpose are connected to the control circuit, in order to prevent it from being disabled by accidental grounds.

In one vestibule there is located in an asbestos-lined compartment, enclosed with steel doors, a slate switchboard panel, upon which are carried all the switches and fuses for the control of the battery and motor-generator set, the lighting circuits and heaters, and also the main connection from the low-tension side of the transformer to the auxiliaries.

The control circuit is fitted with junction boxes, branches running to receptacles at each of the four corners of the car directly under the end sills. The jumpers for connecting the cars and the receptacles are of the 12-point type, there being 12 wires in the main control circuit.

The low-tension wiring between the transformer and switch group and motors is all enclosed in a boxing of "Transite" to insure its protection against mechanical injury, as the inductive effect of heavy currents at low potentials renders the use of iron conduits impossible for this part of the wiring.

Operation.—The equipments above described were intended to be sufficient for operating single cars, with one stop per mile over the entire road, at an average schedule speed of 24 miles per hour, or to haul one trailer, making stops about 2½ miles apart, at the same schedule speed. The company has furnished shelters where the public highways cross the line, there being 22 of these flag stations, besides the regular intermediate way stations, at which steam trains stop, six in all, or a total of 28 stations at which electric cars may be required to stop. Practically the electric cars stop at all the regular way stations, but at only a portion of the flag stations. A single passenger coach is frequently attached to a motor car, and on some trains baggage, milk or postal cars are regularly hauled. When two trailers are hauled two motor cars are required, making a four-car train. The service has proved immensely popular throughout the Genesee Valley, through which it passes, and it is intended to increase the number of motor cars, in order to handle the business a little more comfortably next season. It is found that the electric trains on their 34 miles of line can be depended on to keep to their running time rather better than the steam passenger and freight trains operating over the main line.



Transverse Section of Plaster Mill.

Signal System.—The railroad company has installed a positive block system for insuring the safety of trains with the frequent headway at which they are obliged to be run upon the single-track road, which must also handle steam passenger and freight traffic at the same time. The blocks extend between the regular way stations, or if such blocks are too long switch towers are added, making the blocks average about 4 miles in length from one end of the line to the other. The sidings are fitted with interlocking switches controlled by the block operators in the towers or in the way stations, and the movement of trains is thus regulated with the greatest care. The towers are all connected by the private telephone line, while the way stations retain the usual telegraphic comunication with the train despatcher's office at Rochester. By means of the telephone communication it is instantly possible for a train crew to get in touch with the chief despatcher and be properly located, but all train orders are transmitted by telegraph and written out on Form 31, as is the uniform steam railroad practice throughout the country.

Telegraph System.—As is well known, the single-phase trolley system causes interference with telegraph lines along the right of way, and unless both the electrostatic and electromagnetic induction are properly compensated there is always danger of telegraphic communication being seriously affected. The static effect is particularly annoying, as it is absolutely continuous as long as the trolley line is charged, whether or not there are any cars moving. Various means were proposed and tried by the Western Union Telegraph Co. for the elimination of the "static," which always causes the telegraphic relays to chatter, but the most successful thus far known is that due to the inventive genius of Mr. E. W. Applegate, quadruplex expert for the Western Union Telegraph Co., who has developed a very simple means for overcoming static interference. Mr. Applegate worked upon the theory that it was useless to try to compensate for the static, and that the thing to do was to pacify the instrument by additional devices.

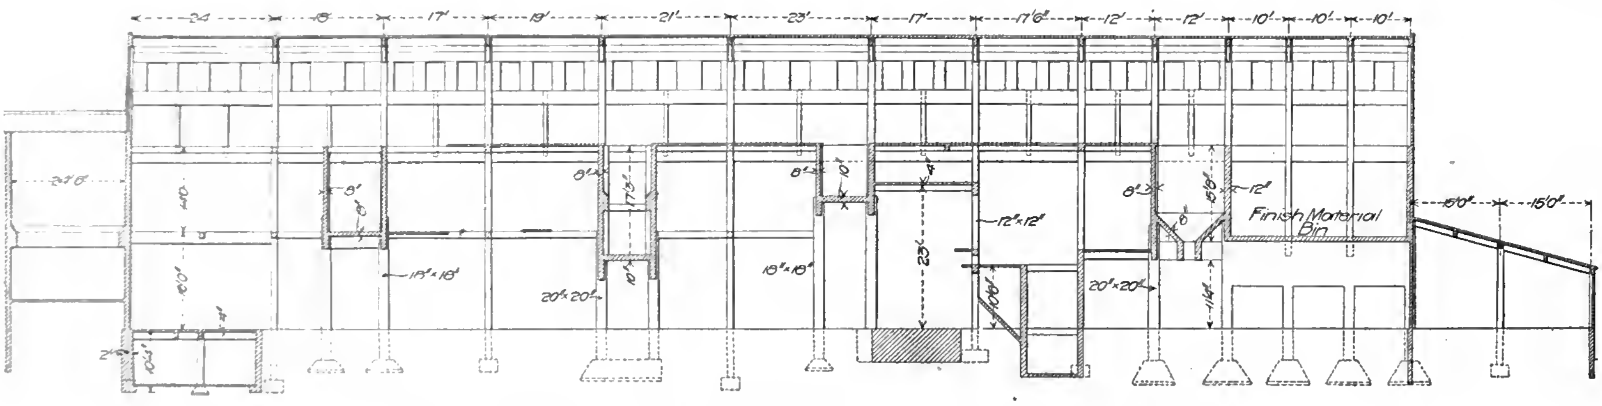
By this arrangement all the telegraph wires are "singled," and metallic circuits, the necessity for which was at one time pending, were discontinued, and the repeater service which they necessitated was also discontinued, and there is now a spare wire between Rochester and Mt. Morris through the entire zone of static interruption.

Speech over the telephone line is very clear and distinct, and, although the wires and instruments have a heavy static charge, a few simple precautions enable it to be of great use to the operating department. It is intended to carry portable telephones upon the cars.

Miscellaneous.—The single-phase system was recommended for the electrification of this division by the Electric Traction Commission of the Erie R. R., and after authorization by the company was installed under the general direction of Mr. J. M. Graham, vice-president and head of the construction department of the Erie.

The engineering and the construction work were carried out and the system brought into operative condition by Westinghouse, Church, Kerr & Co., who designed and erected the buildings and the catenary trolley construction, bonded the track and installed the electrical apparatus in the sub-station and on the cars.

The adjustment of the telegraph system was carried out jointly by the Western Union Tele-



Longitudinal Section of New Plaster Mill of the American Gypsum Co.

graph Co. and the telegraph department of the railroad company.

The order was given to the engineers on June 6, 1906, and, although the intense activity in construction work all over the country at that time rendered it difficult to secure materials and labor promptly, the work was pushed so rapidly that about 7½ months later, on January 22, 1907, the first official trial trip was run between Avon and Rochester. The severe winter weather thereafter prevailing delayed the completion of the work until spring. During April and May the whole equipment of sub-station apparatus, lines and cars was thoroughly tried out in a course of experimental operation, which also enabled the railroad employes to become familiar with the new system. On June 18 commercial operation began and has since continued, with marked success.

The Erie is one of the oldest steam railroads in the country, but that it is also one of the most progressive is demonstrated by its policy of giving a thorough trial to a system of electric traction whose characteristics of simplicity in construction and economy in operation make it so eminently fitted to replace steam motive power wherever the economic conditions point to the desirability of its substitution for the betterment of either passenger or freight service.

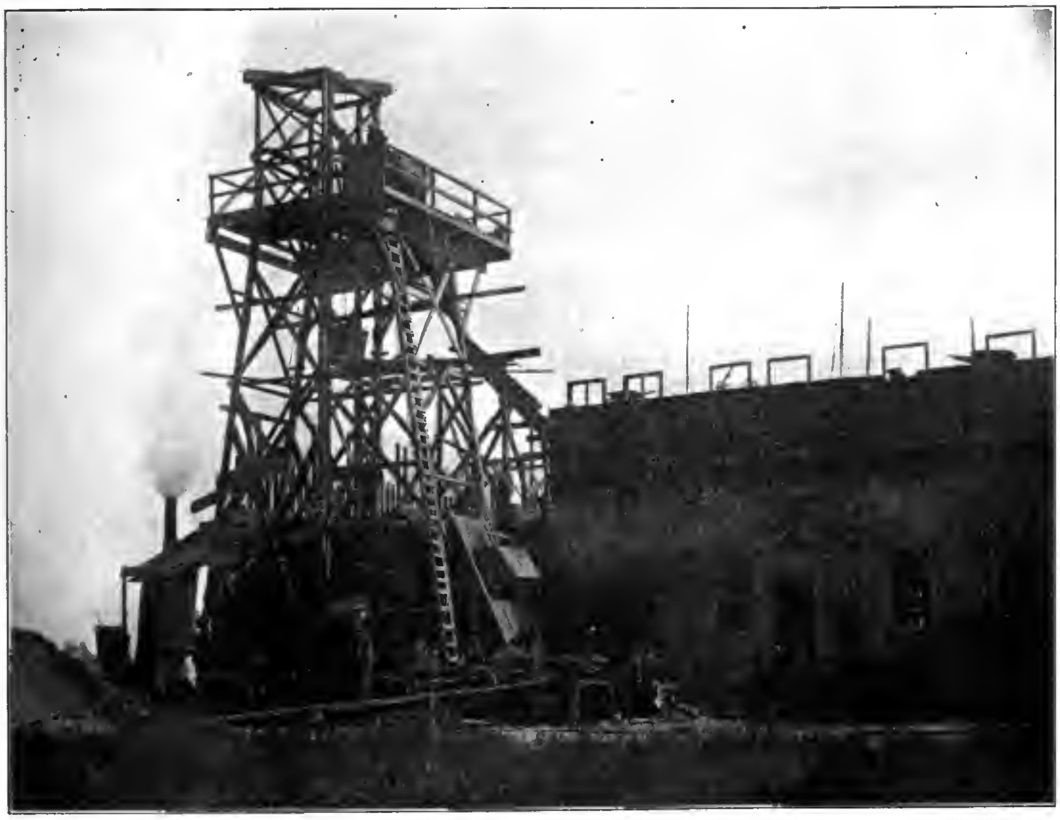
Steel Reinforcement in Brickwork is advocated by an architect of York, England, who has carried out a number of experiments with brick walls, in which the joints contain galvanized wire netting in the mortar. As a result of the experiments many claims are made for this type of construction, some of which seem a bit far-fetched, such as the assertion that by reinforcing its mortar joints, brickwork can be rendered as monolithic as reinforced concrete. On the other hand, the reinforcement of brick-work, when skillfully done, adds materially to the resistance of the walls to collapse after cracking. Probably a good many readers of The Engineering Record are aware that the brick walls of the famous Palace Hotel, of San Francisco, were reinforced by iron straps on the joints, and one reason that the masonry stood so firmly was unquestionably the presence of this reinforcement.

The New Plaster Mill of the American Gypsum Co.

The new plaster mill of the American Gypsum Co., situated three miles from Port Clinton, O., on the main line of the Lake Shore & Michigan Southern Ry., is 65 ft. wide, 270 ft. long and 35 ft. high from top of foundation walls to the plate of the building. It is constructed in skeleton form entirely of reinforced concrete.

The building was originally designed in steel with corrugated siding for walls, enclosing several very large steel storage bins with runways connecting the bins at various levels, but owing to the poor delivery quotations on the steel, it was decided to construct the entire building and the bins and runways of reinforced concrete. The resulting structure is absolutely fireproof, and the owners do not intend to carry any fire insurance at all, either on the building or equipment.

The price, as usual, was a consideration that had to be dealt with, and as the building originally designed in steel was covered only with corrugated siding, the use of brick or heavy concrete outside walls for the reinforced concrete building was out of the question. The contractors therefore decided to construct it in the skeleton form, using very thin reinforced concrete outside walls.



Concrete Mixing Outfit for Plaster Mill Mounted on Flat Car.

All foundations for building and machinery were built of concrete composed of one part Portland cement, three parts lake sand and six parts of 2-in. ring broken stone. The foundation walls, except those for basements, are 9 in. thick and are carried up to the ground floor, approximately 5 ft. above grade. This 5 ft. to floor level is filled in with the earth from the excavations and broken gypsum rock from the mine. In the heavy kettle foundation about 70 per cent. of it was composed of this rock laid in courses to within 16 in. of the top of foundation.

The building is divided into panels, 16 ft. across the width of building and from 9 to 24 ft. lengthwise of the building, the varying spacing lengthwise being due to the machinery required for the mill.

The floors at ground level over the basements in most cases support very heavy jaw crushes. The floor slabs are 6 in. thick, reinforced with ½-in. rods on 6-in. centers, and are approximately of 8-ft. span, between beams of 18 to 20-ft. spans. The runways throughout the building were designed to support a load of 80 lb. per square foot, except in special cases where there was machinery to be taken care of.

All of the outside walls above the ground floor are 4 in. thick, designed to resist a wind pressure of 60 lb. per square foot. The first 16 ft. of wall rests directly on top of the 9-in. foundation walls and the upper section of 14 ft. is carried on wall girders, joining all the exterior columns together and forming a belt around the building. The upper belt or plate, 30 ft. above the ground floor, was run at the same time the last section of wall was run, and all the steel reinforcement for the roof beams was placed at the same time, so that it would be securely anchored at the ends. The centering for the walls was made of wood panels 5 ft. high and 8 to 10 ft. long, bolted together with ½-in. bolts threaded at both ends. After the concrete had set 60 hr. the bolts were driven out and used again when raising the panels. Special care had to be exercised in raising the panels so as not to crack the walls, the concrete being green and the walls thin.

At the 16 and 30-ft. levels, cross struts were carried over to the interior columns in very much the same manner as for a steel frame. The struts are 12 in. square at the 16-ft. level and 10 ft. square at the 30-ft. level, with just sufficient reinforcing in each to take care of its own load, with a factor of safety.

The columns supporting these struts also supported the beams. Running lengthwise of the building, the columns, in most cases, were 12 in. square, reinforced with one 1⅛-in. rod in the center. The columns supporting bins were of sections varying from 16 to 24 in. square and reinforced with eight 1-in. rods, fastened together with hoops 12 in. on centers. These hoops were ⅜ in. in diameter, and each hoop was wired to every rod very carefully. The outside wall columns or pilasters were run in sections with the wall and reinforced with one 1-in. rod set 9 in. from the outside of the wall.

The beams are of rectangular section and support shafting, motors, dust bins and runways. The method used for securing the shaft bearings to beams proved to be very efficient; it was accomplished by a timber of the size and length required and fastened either on the top, side or bottom of beams with U-shaped iron clamps and the bearings bolted or screwed on to the timber.

All of the bins except the finish material storage bins have flat floors resting on beam construction supported by columns. The floors of bins are all approximately at the 16-ft. level, reinforced with ⅝-in. rods, on 5-in. centers in both directions for spans between beams 8 ft. 9 in. center to center; the walls of the bins extend to the roof plate in all cases. In several cases the end walls of bins form part of the outside wall of the building. The thickness of bin walls in most cases is 8 in. reinforced with ⅝-in. rods 6 in. on centers vertically, and ¼-in. rods horizontally 12 in. on centers.

The finish material storage bin, 65 ft. wide by 40 ft. long, supported on twelve columns 20 in. square, is designed with arch floor construction, the arches being 16 ft. span, 6 in. thick at the crown, reinforced with ¾-in. rods 12 in. on centers wherever bending occurs. The haunches form beams which are supported every 10 ft. by one of the columns. The outside walls are 18 ft. high, 12 in. thick from bottom to top, and are reinforced with ¾-in. rods vertically on 9-in. centers for the first section of 12 ft., and ½-in.

rods on 9-in. centers for the next section. The outside walls for this bin were run with 3 per cent. of Sandusky waterproof cement added to the concrete while mixing to insure an absolutely waterproof wall.

The roof of the building is the usual type, the first slope being a 1/3 pitch and the roof of the monitor nearly flat. The running of the concrete on the first pitch was somewhat difficult, as it had to be floated smooth and worked up the incline practically by hand. However, after the forms were stripped the under side presented a very even and smooth surface. The roof slabs are 3 in. thick, of 8 ft. span, reinforced with 3/8-in. rods on 7-in. centers with 1/4-in. distributing rods on 12-in. centers.

After the roof had been run about 18 days the concrete base was covered with a three-ply composition roof, cemented to the concrete with a roofing cement. After the roof had been down about two months, although not entirely completed, a very severe wind storm wrought havoc with the roof covering. The edges of the covering along the eaves of the building had not been securely fastened, and for this reason all of the roof covering of the monitor, or approximately 9,000 sq. ft., was carried away, although it had all been cemented to the concrete base. This same wind wrecked several other buildings throughout the country, and undoubtedly gave the 4-in. walls and the entire mill a very severe test, as the velocity was about 77 mi. per hour.

All of the concrete for the building above the ground floor was composed of a 1:2:4 1-in. ring broken stone mixture, using lake sand and Excelsior Portland cement furnished by the Cleveland Builders' Supply Co.

The steel rods used for reinforcing varied in size from 1/4 in. to 1 1/4 in. in diameter, and between 80,000 and 90,000 lb. in ultimate tensile strength. The 4-in. outside walls were reinforced with 1/4-in. rods in both directions. The outside wall columns and interior frame columns are reinforced with one 1 1/8-in. round rod. Special reinforcing for beams and girders was required, as in most cases they did not have floor slabs to help take care of the compression. All steel reinforcing was very accurately placed and wired before the concrete was run.

The most important factor entering into the construction of the mill was considered to be the vibration, as in buildings of this class it is generally very noticeable. The mill has been in operation since the first of the year and up to date has not developed any signs of weakness or fracture from this cause. There is a very great deal of noise in the building produced by the crushers, grinders, elevators, conveyors, and especially by the tumbling of rock in the steel rotary dryers, 80 ft. long, all of which tends to cause a slight quiver in all parts of the building, that can only be sensed by placing one's ear against one of the members or the wall. This, however, can never cause any damage.

Another remarkable test which has been going on ever since the building was started is caused by the blasting of gypsum rock in the mine directly under the building. The shock of these blasts can sometimes be felt in the neighboring houses about one-half mile from the shaft. The bottom of the shaft is about 50 ft. below the surface.

The concrete mixing and placing was one of the most interesting features of the job, as the equipment, consisting of a mixer, elevating tower and hoist, was placed on a 33-ft. flat car, which taveled alongside of the building.. The sand, stone and cement were all placed in the slip bucket at the rear of the tower and hoisted to the mixer platform and dumped. The water for mixing was controlled by a man standing in front of the mixer. The same man dumped the contents of the mixer into a side dumping elevator bucket. The entire batch was then hoisted to the top of the tower and discharged into a steel hopper, from which it could be spouted the entire width of the building, a distance of about 75 ft. from the center of the tower. When working under the best conditions, it only required eleven men to mix, place and tamp the concrete, including the hoisting engineer and one man carrying cement. The best day's run of the mixer on floor work was 90 cu. yd. in 10 hr.

The amount of lumber required was approximately 460,000 ft. B. M. The percentage of waste lumber was very great, because the building was of skeleton construction and lacked typical details. The lumber for surface work was No. 2 pine shelving, bought at $16 per M., and would not stand hard usage.

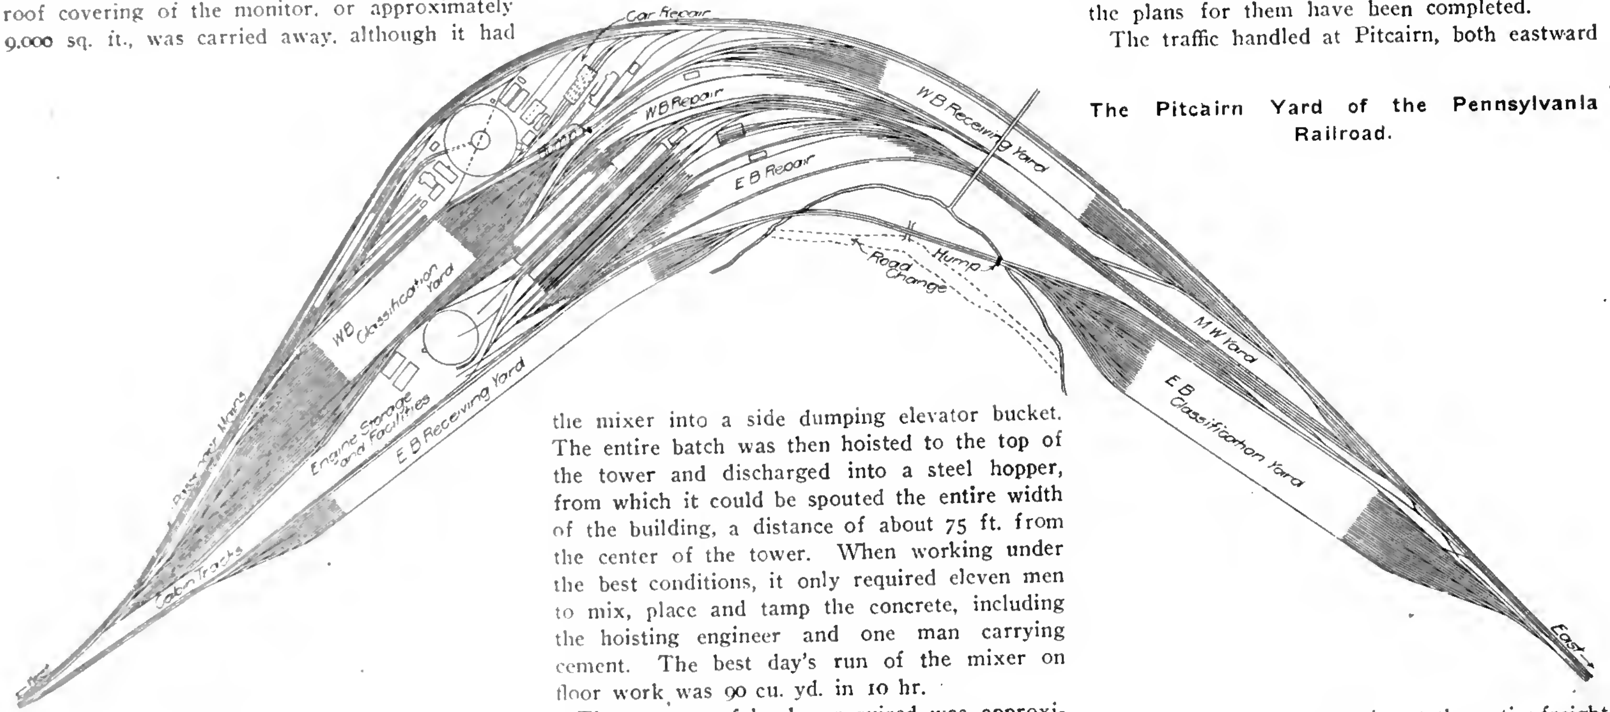
The entire building was designed and erected under the direction of Mr. W. S. Ferguson, chief engineer of the Carey Construction Co., of Cleveland, O., the contractors for the building. Mr. F. W. Griswold, engineer of the American Gypsum Co., had general supervision of the entire plant.

THE SALVING OF THE "SUEVIC," the 550-ft. White Star liner wrecked off the Lizard last spring, has been successfully accomplished. The uninjured part was first cut away and towed to Southampton. The cutting was done by exploding gelagnite cartridges, ranging from 2 to 10 lb., laid close to the outside of the plates in canvas covers and fired electrically. At Southampton the jagged plates and framing were cut away and preparations made for attaching the new section of the hull. The latter was made at Belfast and, according to "The Engineer," was to be launched and floated to Southampton Oct. 5. There the new 180-ft. part will be joined to the other in a dry dock.

The Pitcairn Yard of the Pennsylvania Railroad.

The Pennsylvania R. R. is at present making extensive improvements in its freight yard at Pitcairn, Pa., 15 miles east of Pittsburg, which were undertaken in order to increase the capacity of the eastbound yard and of the engine and car repair facilities. The westbound yard at the present time has a capacity of about 2,900 cars, and the eastbound receiving and classification yards a capacity of about 1,500 cars, the eastbound advance yard holding about 684. The total capacity of the yard when the new eastbound yard and the new car and engine facilities and transfer tracks are completed will be approximately 7,800 cars, exclusive of running tracks and short connections between the various buildings of the mechanical plant. The total length including the eastbound advance yard is about 15,000 ft. The work on the new yard is now in progress and track is being laid in the classification end, but the new motive power and car repair facilities and the additional transfer storage tracks may not be built for some time, although the plans for them have been completed.

The traffic handled at Pitcairn, both eastward



The Pitcairn Yard of the Pennsylvania Railroad.

and westward, represents almost the entire freight movement of the Pennsylvania R. R. in the Pittsburg district, which requires distribution and transferring from one branch or division to another. The total movement amounts to 4,000 cars per day, divided about half and half between eastbound and westbound traffic. A considerable part of this originates with or is intended for the large steel and rolling mills and manufacturing plants in the Pittsburg district, and this has necessitated the assignment of classification tracks for the sole use of freight for these industries.

Although the traffic movements in the two directions are about equal in the number of cars and in the proportion of loaded to empties, there is some difference in the classification requirements, though not sufficient to make any radical change in the operation of the two yards. Twenty-seven classifications are required in the eastbound movement and 33 for the westbound, the cuts averaging 2 cars eastward and 1 1/2 cars westward. The tonnage ratings in both directions allow train lengths running from 40 to 50 loaded cars, or 80 empties, and these train lengths naturally have affected the lengths of tracks in the classification and advance yard.

The yard is situated in a valley through which runs Turtle Creek, a muddy stream that rises rapidly in the spring and carries a large volume of water. The creek, forming the boundary of

the yard on the north, and the hills, about 300 ft. high, on the south, effectually check the expansion of the yard in these two directions. The creek originally flowed along the base of the hills now occupied by tracks and its bed was thrown 1,500 ft. to the north when the yard was first constructed. The east and westbound passenger mains, the through line between Pittsburg and New York, are carried beside each other along the north of the yard, the westbound main following for some distance the bank of Turtle Creek. Only a few tracks to accommodate the coaches for the Pittsburg suburban traffic, the terminus of which is Pitcairn, are placed north of the passenger mains, and are operated independently of the freight movement in the main yard.

The center of the yard is on a curve or series of curves, the total central angle of which is approximately 68 deg. The east end of the eastbound receiving yard is on a 2-deg. curve, which compounds near the end of the exit ladders into a 4-deg. 45-min. curve. This is followed through the yard by a tangent which ends in the beginning of the classification tracks in 3 to 4 deg. curves, depending somewhat on the direction of the ladders. This yard hugs along the base of the hill on the south, and the passenger mains gradually depart to the north until the maximum width of the yard becomes 1,600 ft. The passenger mains forming the northern boundary of the yard going eastward from the end of the main tangent start on a 2-deg. 45-min. curve when nearly opposite the car repair roundhouse. This compounds near the Pitcairn station into a 1-deg. 50-min. curve and finally into a 30-min. curve alongside of the westbound receiving yard. The tracks of any particular group are as far as possible on tangents and the curvature is thrown into the throats between groups. This, however, was not possible in all cases and consequently the west end of the westbound receiving yard and parts of the car repair and transfer tracks are on curves.

The westbound receiving yard contains one ladder feeding 16 tracks, averaging 62 cars each, and having a total capacity of 968 cars. Exit from it is by means of 2 ladders, 10 tracks on one and 6 on the other. A thoroughfare is maintained around the yard to allow ready access to the transfer or shop tracks without delay in the receiving yard. Two tracks connect with the exit ladders which lead over the hump, where the 2 scales are located, to the gravity classification yard. The latter contains 29 tracks with a capacity of 60 cars each, divided on 4 ladders, and 5 shorter tracks for preferred freight. The total capacity is 1,900 cars.

Alongside the 2 inner ladders are thoroughfare tracks on which the locomotives which bring the car riders back to the hump are operated. Each locomotive is fitted with poling car and the thoroughfare on which it runs, being located alongside the ladders, can be used as a drill track for poling such cars as may stick on the switches. This provision allows of the uninterrupted use of all tracks whose head blocks lie between the hump and a stalled car, since it is not necessary to send an engine in over the ladder, the grade being so designed that a car once freed from the switches is quite certain to have no difficulty in running along the open track. Under the older method of sending an engine in over the ladder, all of the tracks in that particular group are often put out of service until the engine has finished its work and backed out over the hump.

The switches in this yard until a year ago were thrown by hand, but this method has been superseded by an electro-pneumatic system installed by the Union Switch & Signal Co. A switchboard built in 5 banks, with 12 sets of controlling push buttons to a bank, is located at the hump, and at the present time with 42 switches in operation is easily handled by two men. Hand operation of the switches under present traffic requirements would require 11 men, the system therefore effecting a saving of nine men on each shift. Each switch is controlled by two push buttons, above which is a dial indicating the position of the switch, whether opened or closed. The cut slips are handed to the switchboard operators, and no difficulty is found in throwing switches as fast as the cars can be pushed over the hump. The maximum number of cars classified under the new method in 12 hr. is 1,400, while with hand operation 600 cars was the maximum obtained for the same period. Fifteen car riders are employed, and a similar number will probably be required in the new eastbound yard.

The present starting grade on the hump has been found satisfactory, though originally a lighter grade was used. The grade of the first 100 ft. is 3½ per cent., of the next 200 ft., 2½ per cent.; the next 700 ft., extending to the end of the ladders, 1½ per cent.; the following 900 ft., reaching about the middle of the yard, ½ per cent., and the remaining 1,000 ft., extending to the beginning of the exit ladders, 0.2 per cent. The ladders themselves are on a 0.1 per cent. down grade.

The tracks in the classification yards are on 13-ft. centers, excepting where the poles for the arc lights are set, in which case 17 ft. is used. The yard is well lighted by night by lights without reflectors placed along the ladders and the thoroughfare tracks. Access for pedestrians to the portion of the yard lying south of the westbound tracks is had through a twin concrete passage directly under the hump and at the grade of the car repair tracks.

Between the westbound yard and the passenger mains is one part of the car repair plant, consisting of a roundhouse for housing cars which are being overhauled, and the various auxiliary shops for blacksmith, machine, carpenter and paint work. The principal part of the car repairing facilities, however, lies between the east and the westbound yards, and it is in this portion that the proposed improvements in buildings and tracks are to be made. There will be two distinct groups of repair tracks, the westbound having eight tracks with a combined capacity of about 340 cars, and the eastbound 13 tracks with a capacity of 480 cars. These tracks are connected with the receiving and classification yards of the west and eastbound movement by thoroughfare tracks, so that cars can be interchanged without interfering with the other business of the yard. In the repair yards the tracks are alternately on 15 and 24-ft. centers, an extra track of standard gauge with dead ends being placed in the wider space to afford means of conveying repair materials on low push cars to points where needed.

The transfer facilities are very extensive and are demanded by the great volume of freight which requires changing from through to local cars or such other transfer as is usual in a yard of this description. The eastbound transfer storage tracks when completed will have room for about 260 cars and the westbound tracks, eight in number, a capacity of 200 cars. In addition to these there will be four tracks holding about 100 cars, which can be used either for shop or transfer storage. The transfer tracks, in the same manner as those devoted to car repairing, are connected by thoroughfares with both of the receiving and the classification yards, so that access is had to them from the receiving yard, and from them to the end of the classification yards without interfering with the normal handling of freight.

There are at present two 800-ft. transfer sheds in use, each 40 ft. wide and surrounded by platforms. It is proposed to extend one of these sheds 320 ft. and build a platform of the same length adjoining the other. Two open transfer platforms, each 15x1,115 ft., will also be built. For the transfer of heavy freight a 50-ton and two 5-ton cranes, spanning four tracks, will be installed.

A novel arrangement for transferring freight from damaged bottom dump cars is also planned It will consist of a track elevated 22 ft., beneath which will run a track on the ground level. The damaged cars will be pushed up a 2½ per cent. incline on to this elevated track and dumped into the cars standing on the track below. This elevated track is level for 400 ft. In addition to this arrangement two tracks, each 1,160 ft. long, are provided for transferring from a damaged to a good-order car, such materials as can be shovelled or easily handled and do not need separation to different branch roads.

A considerable increase in engine facilities is planned in connection with the improvements, but the work has not yet been begun. The area now devoted to engine storage tracks and part of the present eastbound yards will be entirely rearranged so as to afford ample room for the motive power department. Seven tracks, each 360 ft. long, located west of the engine roundhouse, will be built first and a large area adjoining these tracks will be left for future extensions. The present roundhouse has 46 stalls, and there are large machine and blacksmith shops for making the repairs usual at a large engine terminal. Seven or eight new buildings are proposed, including a large bunk and store house, 65x180 ft. in plan. The inspection and ash pits are also to be increased in size.

New Eastbound Yard. The eastbound yard is divided into receiving, classification and advance groups. The first two groups of the old yard are now being replaced by the new yard lying to the south at the foot of the hill, and when these are completed the total capacity for eastbound movement will be about 3,300 cars, 915 in the receiving yard, 1,700 in the classification and 680 in the advance yard. The receiving yard lies opposite the westbound classification yard and is separated from it by the engine and car repair tracks. The classification yard is east of the westbound receiving yard, the entrances of the two being about opposite each other, and the advance yard, being still farther east, is entirely out of the main-yard area. The throat between the receiving and the classification track has been made very long, about 1,400 ft., this being necessary to throw the classification yard as far as possible beyond the hill which curves here to the north and ends in a neck through which a wide cut has been made to accommodate the yard entrance.

The receiving yard has 13 tracks, each about 3,050 ft. long, with a capacity of 76 cars each. Six of them are on one ladder and seven on the other, while the last track is devoted to running purposes. The classification yard has 26 storage tracks with an average capacity of 66 cars each, arranged on five ladders. Four thoroughfare tracks have been provided, two of them placed between adjacent pairs of ladders, one alongside the remaining ladder, and the last on the extreme south side of the yard. These thoroughfares will be used, as described for the westbound yard, for operating engines hauling poling cars, which will perform the double duty of freeing such cars as stick on the switches and returning the car riders to the hump.

The receiving yard is on an ascending grade of 0.7 per cent., which at the beginning of the exit ladders changes to 1.4 per cent., and continues at that rate through the throat until within 200 ft. of the hump. The starting grade on the hump for the first 100 ft. is 3½ per cent.; for the next 200 ft., 2½; for the next 800 ft., 1½;

for the next 2,300 ft., 0.4 per cent. From this point there is an ascending grade of 1 per cent. for 800 ft., where the tracks connecting the classification and advance yards attain the same elevation as the main-line tracks. This arrangement of grades puts all of the ladders on a 1½ per cent. grade, and this fact combined with the use of poling cars on the drill track alongside the ladders will insure against cars sticking and giving trouble on the switches. The centers to be used are the same as in the present westbound yard, 13 ft., except between those tracks where the poles for the electric light wires are placed, the centers here being 17 ft. The lighting of the yard has been given special consideration, and as a result of the experience gathered in the westbound classification yard the arc lights have been placed not only along the ladders, but throughout the entire yard.

The advance yard contains six tracks with a total capacity of 680 cars, each track being long enough to hold two loaded trains.

The drainage of the yard has proven quite a troublesome question, and has necessitated four distinct drainage channels through the yard. As stated before, Turtle Creek originally skirted the hills which now form the southern boundary of the yard, and the changing of its course to its present location makes it necessary to convey by artificial means the water draining from the hills and through a number of small draws. At the west end of the yard a drainage ditch 10 ft. wide and about 6 ft. deep has been constructed to carry a stream from one of the draws and discharge it into an 8-ft. arch culvert leading under the tracks to Turtle Creek. The ground which will be occupied by the new engine facilities is too low to drain by gravity, and for that reason a pumping system will be installed. Suitable catch-basins and drains will be provided to convey the water from the low area to a sump, 25 ft. in diameter and 25 ft. deep, built of concrete. Part of this sump will be partitioned off into a chamber in which two pumps, one electrically and the other steam driven, will be installed. The pumps will be started automatically by means of floats, the electrically driven pump being relied upon for the major part of the work and the steam-driven held in reserve as an auxiliary. From the sump the water will be forced through a 24-in. cast-iron pipe to Turtle Creek. The pipe was laid under the network of tracks by opening up a ditch of the length of two sections of pipe and completing it before carrying the work farther. The ground through which the pipe runs was of such a nature that it was not deemed safe to lay the pipe without a foundation, and for that reason it has been constructed on a layer of concrete 34 in. wide and 5 in. in depth. After it was in place and caulked it was completely surrounded with a concrete covering just sufficient in thickness to cover it well on all sides. Another drain pipe, 36 in. in diameter, runs through the area which is to be drained by the pumping system just referred to, but is on such a grade and at such a depth that it can carry only the water collected at the foot of the hill.

Continuing eastward through the yard, another drainage system is encountered, near the hump of the new eastbound classification yard. It consists of two 36-in. cast-iron pipes laid side by side and draining three small draws. The water is delivered to these pipes from the points where it is collected by an open concrete drain 2½ ft. deep and 4½ ft. wide. About 600 ft. from the end of the classification yard a double 3x4-ft. box culvert has been built to care for the drainage of that portion of the yard. A ditch 2,500 ft. long collects the water and carries it to the south end of this twin box. Between the eastbound classification and advance yards Brush Creek crosses the right-of-way through a six-track, three-span masonry bridge. The spans are each 25 ft., with a 9-ft. rise, the springing line being 8 ft. above the bed of the creek.

Ample provision for fire protection has been made by water mains throughout the entire yard, hydrants being placed at convenient intervals.

The Construction of the New Yard.—The work on the new eastbound receiving and classification yards was started in April, 1906, and at the present time the tracks are laid in the receiving end, but the grading is still in progress for the classification tracks. The greater part of the receiving yard is constructed on a fill from 8 to 25 ft. high, rising toward the east end of the yard in order to attain the proper elevation for the hump. The material for this fill is secured from the heavy cut at the entrance to the classification yard. The latter lies partly in the cut referred to and partly upon filled ground, the cut in one place running to the maximum of 70 ft., and the fill from 5 to 30 ft. The total excavation is 1,175,000 cu. yd., of which 804,282 yd. are in the large cut above referred to.

The material encountered is principally shale, which disintegrates upon exposure to the weather, but which had to be blasted for rapid removal. A light layer of mixed soil, sand and gravel overlies the shale, which is about 25 ft. thick, and beneath the latter is a bed of low-grade lime-stone. The holes used for the blasting were drilled by three Star portable drilling machines, and in all cases went down to the grade it was desired to secure at the point where they were sunk. The holes averaged between 35 and 40 ft. in depth, the maximum being about 70 ft. The diameter of the holes was 6 in. Where solid rock was encountered eight Ingersoll-Rand steam-driven drills were used. Large masses of stone and shale which could not be economically broken up by hand were mud capped. Soil was removed by Bucyrus 70-ton steam shovels, two working on each side of the hill through which the throat of the yard has been cut. After the major part of the work was completed, but two of the shovels were required to complete the work, and these are still in operation. The earth and rock were removed by 3-yd. side dump cars running on 42-in. tracks, and wherever possible these cars were operated in good sized trains so as to avoid delaying the shovel. In order to do this it was necessary in one case to cut a bench of considerable length on the side of one of the hills in order to back a long train of dump cars on to it and thus save time over the other method of merely backing a few cars at a time alongside the shovel. The first cut of the shovel was taken in the hillside at the sub-grade level and the soil merely thrown to the opposite side, thus forming a bench upon which the narrow-gauge track was laid. The work was continued in the customary fashion, the narrow-gauge track being moved laterally as fast as the fill outside of it was completed. The work has required the use of 17 narrow-gauge locomotives and 180 side-dump cars. The contractor for the work is H. S. Kerbaugh, Inc., Philadelphia.

The Nelson Street Viaduct, Atlanta, Ga.

In connection with this work it has been necessary to make a road change about 2,000 ft. long and to construct an arch beneath the throat between the receiving and the classification yards in order to connect the highway with an overhead bridge spanning the old yard. The arch is of masonry 46 ft. long, with a span of 30 ft. and a rise of 7½ ft. A track running off to the right at the east end of the eastbound classification yard has necessitated a change of the channel of Brush Creek, and this was done by means of a steam shovel working in the new bed of the stream. Another piece of work done at the same time, but independent of the new yard construction, was a retaining wall of concrete at a change in the course of Brush Creek alongside the advance yard. The wall is 5 ft. high, 3½ ft. thick and 1,400 ft. long. It is composed of 1:2:5 concrete with dredged sand, and gravel up to 1½ in. in diameter. The material was mixed in a Smith mixer mounted alongside a track on the north side of the creek; although the retaining wall itself is on the south bank. This arrangement requires all of the concrete to be wheeled across the creek, and for this reason light timber runways were thrown across from bank to bank at three different points, and the mixer moved opposite these as the work progressed. The advantage of keeping the mixer on the north bank was that only one class of material, the mixed concrete, was wheeled across the water, whereas if the mixer had been placed on the south bank the sand, gravel and cement would all have had to be taken over the creek separately.

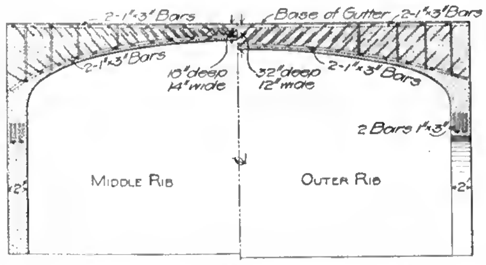
The construction of the new yard is in charge of Mr. N. F. Brown, assistant engineer, Pennsylvania R. R., Pittsburg, Pa.

The Nelson Street Viaduct at Atlanta.

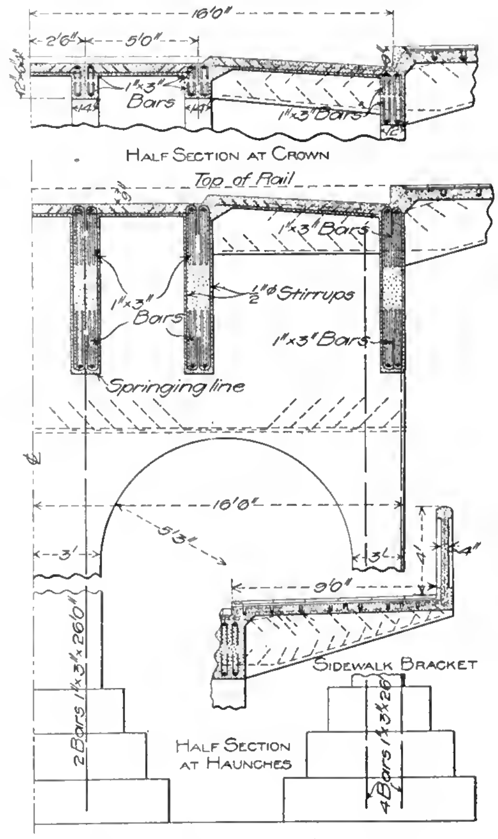
The old steel viaduct, which formerly carried Nelson Street, Atlanta, Ga., over the yards of the Southern Railway, recently has been replaced by a reinforced concrete structure 479 ft. 3¼ in. long, made up of ten flat arch spans, seven of which are between 40 and 50 ft. in clear span, the remaining three having spans of 75 ft., 53½ ft., and 20 ft. 5⅝ in., respectively. The width of the new viaduct from center to center of outside arch ribs is about 32 ft. This is the width of the roadway proper on which is carried vehicular traffic and in the center a double-track street car line. Outside the roadway on each side is a 9-ft. sidewalk carried by reinforced concrete cantilever beams, as shown in accompanying illustrations. The clear headroom over the main and freight yard tracks is 21 and 18 ft., respectively. From one end the roadway rises on a 2 per cent. grade for 100 ft.; then it meets a vertical curve 40 ft. long; and the remaining 339¼ ft. is on a 2 per cent. downgrade to the other end. In the yard the viaduct crosses over two canopied freight platforms, inbound and outbound respectively, one of which may be seen in an accompanying illustration.

The arches are of the ribbed type, reinforced with Kahn trussed bars and built continuously through the supporting piers. There are six ribs supporting each span, four in the center spaced 5 ft. on centers under the street car tracks and the two outside under the curb lines of the driveway. The cantilever beams supporting the sidewalks are 10 ft. on centers and are attached to the two outer ribs on each side. The ribs are designed to support: The dead load imposed by the concrete and road materials, assumed as 140 lb. and 100 lb. per cubic foot, respectively; 100 lb. per square foot live load on the sidewalk; 100 lb. per square foot or a 15-ton moving road roller on the driveway; and a succession of 40-ton electric cars on the track ribs.

Five successive spans over the freight yards, ranging from 40 ft. ⅛ in. to 44 ft. 2¾ in. in length are typical. In these spans each of the four ribs under the car track is 14 in. wide and 18 in. deep at the crown, while those under the curb lines are 12 in. wide and 32 in. deep at the same point. The depth in each case includes the 6-in. floor slab which was built continuously over the ribs in the same manner that the latter were built through the piers. Each rib in these spans is reinforced in both intrados and extrados with ribs with ½-in. transverse bars 18 in. on centers. Between the outside rails and the curb line the reinforcement is ½-in. transverse rods 15 in. on centers. The 5-in. sidewalk slabs have ½-in. longitudinal rods 15 in. on centers. Over the four center ribs the floor slab is depressed about 4 in. to afford room for the street car rails, the tops of which are flush with the 4-in. wood block pavement. The reinforcement of the cantilever sidewalk brackets and the concrete railing is in-



Sections of Ribs of Typical Span.



Cross Sections of Typical Span.

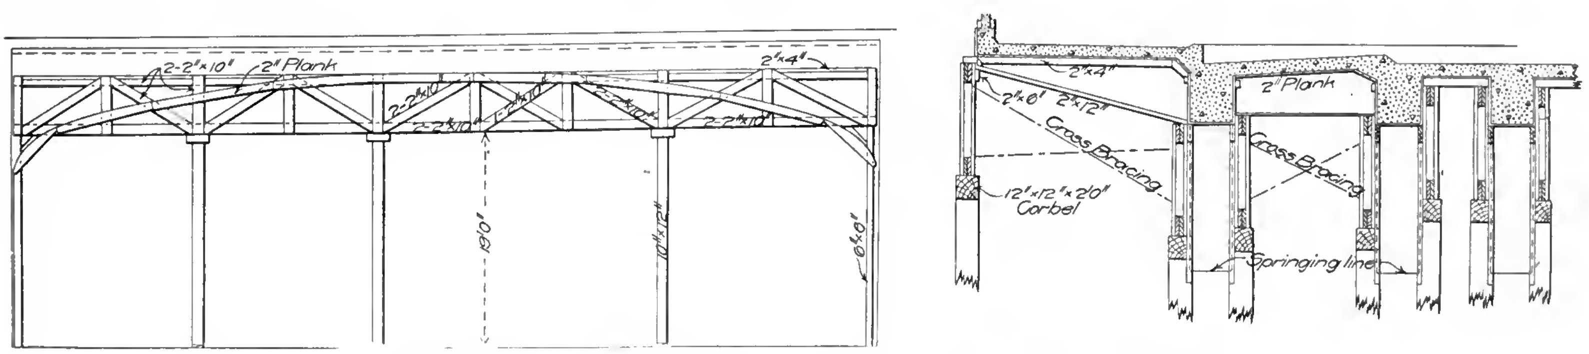
wide each, while the middle one has a width of 6 ft. Each leg rests on separate stepped footings carried down to a maximum depth of 6⅔ ft. below the top of the rails. The reinforcement in the piers of the typical spans consist of two 1x3-in. bars placed just above the soffit plane of the arch openings and four 1x3-in. bars in each pier leg extending from the bottom of the footings up to the floor slab.

The construction of centering for most of the spans presented no problems of unusual difficulty. Two spans, however, 47 and 75 ft. long, over the main line tracks had to be constructed without interrupting or endangering traffic on any of these tracks. This prevented the placing of the usual intermediate falsework between the piers and necessitated carrying the centering on wooden Howe trusses arranged as shown by accompanying sketches. The concrete was prepared in a No. 1 Smith mixer, a 1:2:4 mixture being used for the arch ribs and floor and a 1:3:5 mixture for the piers and footings. The stone was crushed in an Aurora crusher, driven by a 15-h.p. Frick engine, and was hoisted into bins from which it was drawn out as needed on a platform at the mouth of the mixer. The latter delivered to skip cars which were hoisted up an inclined track to the deck of the bridge by a Lambert single-drum hoist taking steam from the crusher engine boiler. On the bridge the skip cars were switched on to the proper track by a turntable. The entire contract involved the placing of about 2,500 cu. yd. of concrete and 100 tons of reinforcing steel. Work was begun May 1, 1906, and was completed January 1, 1907.

The viaduct was designed by the Trussed Concrete Steel Company, subject to the approval of Mr. D. W. Lum, chief engineer of maintenance of way, Southern Railway. Mr. W. W. Griffin, of Atlanta, was the contractor.

Perforating a Well Casing in Position.

Drilling apparatus has been used by Messrs. Merryweather & Sons, Greenwich, England, in sinking an artesian well. The well, which was lined with 12-in. pipe, had been driven through a water-bearing stratum in the hope of securing a more abundant flow at a lower level. This hope was not fulfilled, and it was decided to tap the stratum that was first penetrated. The well casing had cut off this flow, and it was necessary to perforate the pipe by drilling from the inside. Two drills, to each of which was keyed a bevel gear-wheel, were mounted horizontally,



Elevation and Section of Centering for 75-Foot Span, Nelson Street Viaduct.

two 1x3-in. Kahn bars arranged in general as indicated on an accompanying diagram. Toward the ends of each rib, where the shear prongs of the bars in the intrados and extrados do not meet, ½-in. stirrups are used as shown. The top rib bars are continuous through the piers, the ends of successive rods lapping at the centers of the spans. In general this system of reinforcement is characteristic of the other spans, though it differs in detail owing to variation in span and size of arch ribs.

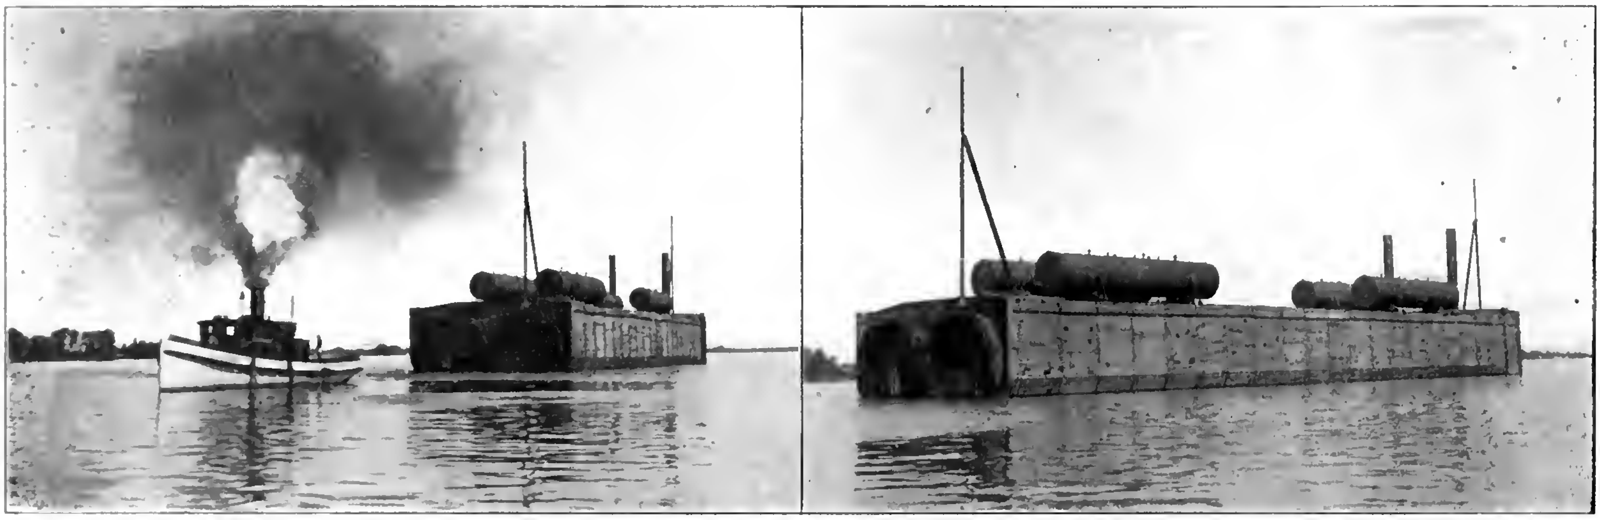
The 6-in. floor slab is reinforced over the track dicated on the drawing. Where the beam opposite the bracket is omitted, as it has been where the position of the piers prevented its construction, the upper rods of the bracket are extended into the floor slab and the lower rods are tied into the outside arch rib.

The piers in the freight yard, where the clearance is 18 ft., are 2 ft. thick, while those supporting the higher spans over the main track are 3 ft. thick. Each pier is pierced with two arched openings 10½ ft. wide, three legs being thus formed. Of these, those on the outside are 3 ft.

pointing in diametrically opposite directions, and a third bevel gear-wheel, keyed to the vertical boring rod, meshed with these two. To feed the drills the inner ends of the drill shafts were threaded, and each carried a miter wheel tapped to fit the drill shaft. Another wheel on the vertical shaft engaged these wheels, and, the gear ratio of this set of wheels being different from that of the driving gears, as the boring rod turned the drills revolved more rapidly than the threaded spindle wheels, and so were fed forward.

The Detroit River Tunnel Caissons.

The general design of the Detroit River tunnel was illustrated in The Engineering Record of Feb. 17, 1906, and details of the method of construction finally adopted were explained in the issue of March 2, 1907. There are to be two tubes, 20 ft. in interior diameter and 26 ft. 4 in. apart on centers, leaving a clearance of 3 ft. between them on the center line. Each tube has a riveted steel shell 23 ft. 4 in. in diameter, the pair of them for each section being placed in a long pontoon, which also serves as a mold or form to retain the concrete, which will be filled in around the steel shells after the section has been sunk into place in the trench dredged for it. The upper part of the trench is excavated by a dipper dredge, and the lower part by a clam-shell dredge provided with a specially designed bucket. The subaqueous portion of the tunnel will consist of ten sections like that illustrated, each about 260 ft. long. The shells on top of the section are air chambers, which are used in sinking the tubes, an operation which it is planned to carry out as follows: Inlet valves in the bottoms and outlet valves in the upper part of the bulkheads are opened, so that water enters through the former and air escapes through the latter, causing the tubes to sink slowly until the outlet valves are submerged. The latter are located so as to retain a certain quantity of air above them, which gradually escapes through vent valves, operated from the attendant scows. Finally enough additional water is admitted to sink the tubes below the surface, until the air cylinders on top commence to be submerged and maintain the tubes in a horizontal position, preventing them from sinking farther until their buoyancy is overcome. The air cylinders are ballasted by admitting water ballast or expelling it with compressed air, until the combined weight of the tubes and the cylinders produces a tension of only about 10,000 lb. on the lines attached to each end of the section. It is thus maintained in even balance and gradually lowered to the bottom under perfect control, without danger of severe stresses or distortion. The tunnel is being built, under the supervision of Mr. W. S. Kinnear, chief engineer of the Detroit River Tunnel Co., by Butler Bros.-Hoff Co., of New York City. The general plan followed is a modification by the contractors of a plan suggested by Messrs. W. J. Wilgus, H. A. Carson and W. S. Kinnear, the committee which originally studied the project for the New York Central interests. The committee outlined four different methods of construction which would be acceptable, and permitted the contractors to suggest modifications, or entirely different plans.



Tunnel Caisson for Twin Tunnels under the Detroit River.

A By-Product Charcoal-Iron Plant at Marquette, Mich.

The Marquette, Mich., charcoal-iron plant of the furnace department of the Cleveland-Cliffs Iron Co. is fully equipped to reclaim a large percentage of the by-products from the smoke produced in the manufacture of the charcoal used in the plant. The latter has an average daily output of 125 tons of first grade charcoal pig-iron, which is produced by a single blast furnace. A group of eighty-six bee-hive brick charcoal kilns, a number of buildings in which by-products are made from the smoke and a large central power station supplying steam and power are also included in the plant. The iron-ore used in the manufacture of the charcoal iron is delivered from the mines of the company at Ishpeming and Negaunee over the Lake Superior & Ishpeming Ry. The latter was built, and is operated for handling iron-ore from mines in the Marquette district to docks on Lake Superior at Marquette. The construction, equipment and operation of this road were briefly described in The Engineering Record of Aug. 31, 1907. Switching connections are extended into the plant from the Marquette & Southeastern Ry., an allied line which extends along the site of the plant. The large quantities of wood required in making the charcoal used in the manufacture of the iron are also delivered by rail from extensive forests reached by the Marquette & Southeastern Ry., and by the Munising Ry., a second allied line.

An outline general plan of the plant, showing the relative location of the principal parts of the latter, is given in an accompanying illustration. The iron-ore is delivered to a large stock house containing a number of elevated storage pockets. In front of this house are the blast furnace and a casting house, the central power station and the auxiliary buildings of the plant. In the rear of the stock house are the charcoal kilns, and back of them, the group of buildings in which the by-products are made from the smoke produced from these kilns during the manufacture of charcoal.

The ore stock house, 100x300 ft. in plant and 44 ft. to the eaves line, has sheet-iron sides and a corrugated sheet-iron roof, carried by steel roof trusses. Two switch tracks are extended longitudinally through it on trestles, at a height of 25 ft. above the floor. One of these tracks is over a row of fourteen ore storage pockets, with a capacity of 100 tons each, which are along one side of the building. The other is approximately on the center line of the building and is intended to deliver ore to piles on the floor of the building in case the mechanical equipment installed for handling ore from the storage pockets to the blast furnace is out of commission.

The ore is handled from the storage pockets to the base of a steep incline leading to the top of the blast furnace, in electrically-operated scale hopper cars. A 36-in. gauge track extends the length of the row of storage pockets in a pit depressed slightly below the floor of the building. A system of tracks also extends to the charcoal kilns. Each of the cars operated on this system of tracks has its hopper-shape body arranged so it can be swung on a weighing-scale frame carried by the car truck. These cars are equipped with street railway motors and controllers. Power is taken from a double trolley supplied with current from the central station. The cars each have half the capacity of one of two skips in which the materials are hoisted up the incline leading to the top of the blast furnace. The charcoal and the lime used for flux are delivered to these charging skips in two-wheel iron carts on transfer cars handled by electric locomotives.

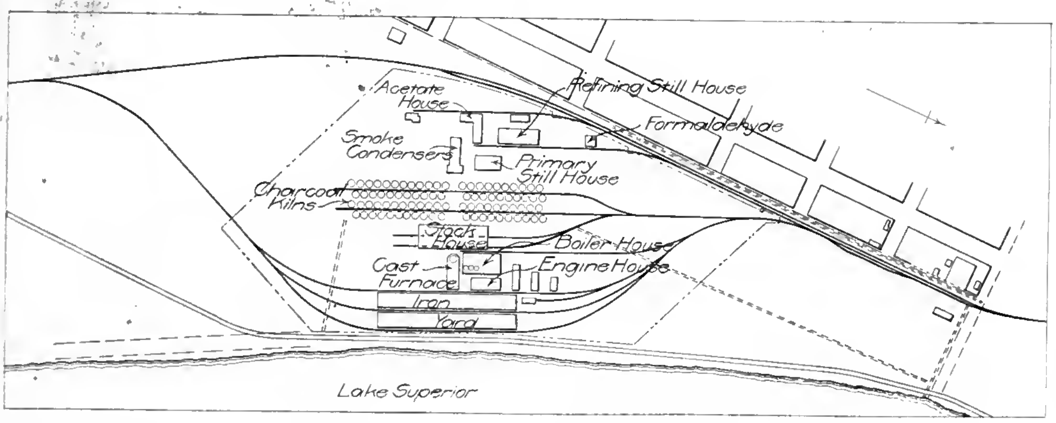
The blast furnace is at one end of the cast house, the latter being 50x155 ft. in plan. The furnace is very similar in arrangement to the modern blast furnaces in which iron-ore is reduced to pig with coke, and it is operated in practically the same manner as are those furnaces. It is 12 ft. in diameter and 70 ft. high. A large blowing engine in the central power station supplies heated air blast to it at a pressure of 8 to 12 lb. per square inch. The gases driven from the top of the furnace are utilized in firing part of the boilers in the central station, and also three 17x70-ft. Cowper Roberts brick-lined stoves through which the air blast is passed before reaching the furnace. The charcoal and iron-ore are placed in alternate layers when the furnace is charged, but, as in the coke-fired process, a fire is always maintained. Four heats are drawn from the furnace every 24 hr., two heats during the day and two during the night.

This blast furnace has made a phenomenal record for charcoal practice, since it has been in continous operation for over four and a half years. This record, however, is eclipsed by the Gladstone furnace of the same company, which has been in continuous operation for over six years and seven months. These records are the more remarkable when it is considered that the average blast of charcoal furnaces in Northern Michigan averages something less than two years. These long blasts are due to the fact that the furnaces are equipped with the Farrell bosh jacket, used in connection with the Gayley bronze bosh plates. The Farrell jacket absolutely prevents the tipping or sagging of the bosh plates and the moving of

the bosh brick through expansion or contraction.

The floor of the cast house is a deep bed of lake sand into which the iron is drawn from the furnace. One central ditch, or furrow, extending the length of the building from the tapping hole of the furnace, is thrown up in this sand. Latteral transverse furrows are taken from this main furrow at intervals of about 6 ft., and a row of smaller, secondary longitudinal furrows, each 54 in. long are taken from each latteral, thus forming a complete gridiron of furrows.

The transverse lateral furrows are at succeedingly lower levels, receding from the furnace, so those closest to the latter are filled first when the cast is made. The molten-ore is drawn freely from the furnace into the furrows until slag appears in it, when a skimming gate is placed in the central furrow near the furnace. As the proportion of slag increases this gate is gradually lowered, the iron being heavier passes under it, while the slag is diverted to one side into a ditch leading to an open area at the side of the building. Meanwhile, as each lateral and the secondary longitudinal 54-in. laterals leading from it are filled, a loose paddle-shape iron gate, coated with fire clay, is thrown into the connection with the main furrow to cut off the supply from the latter. The iron in the 54-in. laterals is broken from the main laterals while hot with hand sledges. The whole mass is then cooled by sprays of water applied from overhead perforated pipes along the side of the building. When sufficiently



General Plan of Charcoal Iron Plant.

cooled, the iron is removed and preparations are made for another cast.

The central power station comprises a 90x168-ft. boiler house and a 50x130-ft. engine house. The boiler house contains twelve five-drum Stirling water-tube boilers, each with 3,412 sq. ft. of heating surface. Eight of these boilers are in a row along one side of the boiler house, and operate at 140 lb. pressure; the remainder are in a second row along the other side and also operate at 140 lb. pressure. The boilers in the row of eight are each equipped with a Murphy stoker for coal firing, but are fired chiefly with gas from the blast furnace and with liquid tar and oils furnished from the by-product portion of the plant. Such coal as is used is delivered at the boiler house in cars, from which it is dumped into a track hopper. The coal passes from the latter through a coal crusher and thence into a Link-Belt overlapping-bucket conveyor that elevates it to a row of storage bunkers over the row of eight boilers. The tar and oils used under the boilers are quite fluid, and are supplied through nozzles under a pressure of 100 lb. They are delivered to the boiler house through brass pipe lines, as they attack all metals, except copper. The blast furnace gases and the tar and oils can be fired separately or together, as desired. The boilers in the row of four are fired with furnace gases, tar and oils and coal breeze.

The boilers are all operated on induced draft and are served by a Green economizer with 13,340 sq. ft. of heating surface. The induced draft is supplied by either of two 5.5x14-ft. fans, each driven by a separate 12x16-in. direct-connected simple condensing engine. A 12x40-ft. steel stack serves all twelve boilers.

The feed water for the boilers is supplied from a hot well by either of two Prescott compound condensing 9x18x12x9½-in. pumps in the engine house. All other units in the engine house are also operated condensing, the condensed water being delivered to the hot well. Condensation from the chemical plant is also returned to this well. The feed-water connections to the boilers are made at the front end of the latter, but all feed-water supply lines are in duplicate, and duplicate connections are provided at the boilers.

A 22-in. steam-supply main under a pressure of 140 lb. is extended overhead from the boiler house to the buildings in which the by-product processes are carried on, large quantities of live steam being required in these processes. A 12-in. steam-supply main, also under a pressure of 140 lb., extends from the boiler to the engine house; and an 8-in. auxiliary steam line is extended to this house for emergency use. All of the boilers in the boiler house are connected so steam can be supplied from any of them to any of the mains.

The blowing engine in the engine house which furnishes air blast for the furnace is a Southwark cross-compound condensing unit, with 22x36-in. and 46x36-in. steam cylinders, and two 48x48-in. air cylinders. The two sides of the unit are disconnected so either side can be operated separately in case the other is out of service. This arrangement assures a continuous supply of air to the furnace with the one unit. The latter is served by a Weiss counter-current condenser, with a capacity of 24,000 lb. of water per hour. This condenser also serves the other steam-consuming units in the engine house. Circulating water for it is obtained from the general distribution system of the plant.

Electric current for operating the industrial railway system, for lighting and for driving motors in various parts of the plant, is supplied by two 150-kw. 220-volt direct-current Westinghouse generators, each direct-connected to a 16 and 27x16-in. compound-condensing automatic vertical Westinghouse engine. Either of these two units is capable of carrying the load on the station, so they are operated singly at alternate intervals.

The engine house also contains three horizontal 11½, 18 and 30x24x20¾-in. triple-expansion condensing Prescott pumping engines, each with a capacity of 5,000,000 gal. These pumps supply water from an intake in Lake Superior to the general system of the plant, at a normal pressure of 60 lb. per square inch, but can operate against a pressure of 180 lb. for fire service. Any two of them are capable of furnishing the water required, the third being held in reserve.

The eighty-six kilns in which the charcoal is made are arranged in four parallel rows, twenty-one in each of two rows and twenty-two in the other two. These kilns are 30 ft. in diameter and are arranged much the same as an ordinary brick kiln. Various kinds of wood, including hard maple, elm, beech and tamarack, are used in making the charcoal. This wood is all obtained about 60 miles east of Marquette, where extensive forests are to be found. As practically all of the wood in a tree can be utilized, very little waste is occasioned. The wood is delivered to the plant on standard-gauge flat cars, 260 cords, or about 17 cars, being furnished to the charcoal kilns each day. A switch track is laid between each two side rows of the kilns, and the latter have doors on the side next to the track, so the wood can be placed directly in them from the cars.

The wood is placed in the kilns in regular rows and layers, in order to utilize the capacity of the kiln as fully as possible. On the average, however, about 5 per cent. of the space in the kiln cannot be filled. After the kiln is charged, the wood is fired and the charging door is closed tightly with brick masonry, to prevent oxidation of the carbon in the wood. The kiln is then allowed to burn out, which requires from six to eight days, the wood shrinking about 20 per cent., on the average, during that time. When a kiln has been burned, it is allowed to cool, after which the charcoal is handled directly to the charging hoppers of the blast furnace in the two-wheel iron carts on the electrically-operated transfer cars.

Every kiln in the group has a smoke flue connected to a main flue leading to the by-product portion of the plant. These flues are each arranged with a damper, so any kiln can be completely isolated. The draft in the flues is induced by seven 70-in. copper fans, each driven by a 15-h.-p. motor. The smoke being conveyed by the main flue to a series of fifty-six cooling towers in which it is reduced to a liquid. These towers are large wooden, vertical surface condensers supplied with water from the distribution system of the plant. The liquified smoke is delivered to settling tanks in which the tar and oils, which make up about 3 per cent. of it, settle to the bottom, being heavier than the remainder. When the contents of a tank are completely settled the lighter liquids at the top are drawn off and delivered to the by-product buildings by a centrifugal pump driven by a water wheel operating on the water discharged from the condensers. The tar and oils are then pumped to the boiler house by a motor-driven centrifugal pump, as no attempt has been made as yet to refine them.

The lighter liquids are pumped to a 60x112-ft. building containing a number of large stills in which a secondary separation is made. The distillate from these stills is delivered to a 66x182-ft. refining still house, while the residue is utilized in producing lime acetate. The lime is added to the liquid in large mechanically-stirred mixing tanks in the primary still house, after the first distillation is made. The residue from the second distillation is conveyed to a 38x96-ft. building containing a long steel-plate drying floor, heated from beneath, on which the moisture is driven from the acetate. Rotary kilns, similar to cement kilns, have been tried for this process, without success. Equipment is also being installed to make lime acetone as a by-product of the lime acetate process.

The liquids delivered from the primary still house to the refining still house are passed through a series of stills in the latter, the final product of which is wood alcohol. This is produced in various grades up to 99½ per cent. pure. A further refinement is made in a separate 48x96-ft. building in which pure formaldehyde is made.

Mr. Wm. G. Mather is president and treasurer of the Cleveland Cliffs Iron Co. Mr. Austin Farrell is manager, and Mr. Geo. J. Slining is chief engineer of the furnace department.

The Panama Canal Relief Map at the Jamestown Exposition.

By Charles H. Johnson.

Early in January, 1907, the authorities at Washington decided to construct at the Jamestown Exposition a large relief map which should show the Panama Canal as finally planned, together with the topography of the surrounding country. After some correspondence the writer was selected to undertake the actual construction, finally receiving orders early in March to proceed to the Exposition via Washington. The office end of the work was in charge of Mr. Ralph Whitman, then on the staff of the Isthmian Canal Commission, who had collated all available information in regard to the topography and placed it on a large map of the route of the Canal, scale 1 = 50,000, taken from the report of the Commission of 1905, and mounted on cloth.

On arriving at the site of the work on March 11, the space allotted to the model was found to be covered with contractors' shanties, one being in the process of demolition. The labor situation was bad, wages for common labor being $1.75 for eight hours, and the labor very scarce and inefficient. Cement finishers were almost impossible to obtain and wanted 50 cents an hour. Stone and cement for the concrete were bought from one of the large contracting firms doing work at the grounds, and were taken from cars on a track alongside the work; sand was obtained from the beach, about 200 ft. away.

After looking the situation over the map was laid out, the dimensions being 122 ft. east and west and 50 ft. north and south, its axes corresponding with the center lines of two of the government exhibit buildings, its horizontal scale being 1 = 2,000. The ground at the site was level; excavation showed, first, 1 ft. of top soil mixed with roots, then about 3 ft. of sandy clay, then 18 in. of sand, then clay at ground-water level. It was decided to make sea-level on the map about 2 ft. below the natural surface of the ground, so that by grading up the spoil to form a raised walk around the map visitors would be sufficiently above it to see over the tops of the hills.

Some Greeks were put to work stripping off top soil and excavating for the Atlantic Ocean. A search for cement finishers produced a couple of negro helpers or second hands, who were willing to work for $2.50 a day and stayed with the work to the end. The Greeks proved unsatisfactory and were discharged after about a week, their places being filled by negroes, who were, on the whole, very satisfactory labor. One white man, at $60 per month, was hired to run rod, hold tape, assist on carpenter work, etc., and, with the writer and the negroes, varying from 6 to 12 in number, constituted the entire working force.

As soon as a sufficient area had been stripped work was started on laying out the Atlantic Coast line. The first method used was by setting up a plane table at one of the corners of the relief map, setting the edge of the alidade rule through the corresponding corner of the paper map and the point to be staked out, then scaling the distance and setting the corresponding point on the ground. This method proved to be too slow and was discarded in favor of one, developed by the writer, which was as follows: The paper map was ruled off in rectangles corresponding to 20x30 ft. on the ground, then a piece of tracing cloth the size of one of these rectangles was ruled off in squares corresponding to 1 ft. square on the ground. The tracing cloth was laid on one of the rectangles on the paper map, the corners of the corresponding rectangle on the ground were staked out, and poles, marked off in feet, were laid 1 ft. apart, parallel to one side of the rectangle. Then noting where the coast line crossed the lines of the tracing, a line was drawn on the ground through the corresponding points of the poles. When the coast line had been thus marked out the clay was carefully cut away with a mattock and the bottom of the ocean leveled off 6 in. below sea level, thus allowing 3 in. for concrete and 3 in. for water.

As soon as two or three hundred square feet of subgrade was ready the concrete was laid, the base being 2½ in. thick, one part cement, three parts sand and six parts gravel or broken stone, mixed fairly wet. The top was ½ in. thick, mixed one part cement and two parts sand, and was troweled to a smooth finish when it was to be covered with water. After the bottom of the Atlantic had all been laid work was started on the land, the hill tops and rivers being located

The Relief Map of the Panama Canal at Jamestown.

by the same method as the coast line. Stakes were set to the proper grade for the hill tops, the river valleys were chopped out of the clay, being tested frequently for grade with the transit as the work proceeded, then the country between the hill tops and the rivers was modeled in to correspond with the contours on the paper map, and concreting begun.

The vertical scale was set at 1 = 333, a vertical exaggeration of six, after several scales had been tried and this had seemed to be the most effective and natural. In finishing the land surface, practically all of which on the Isthmus is covered with a very dense forest of low growth, the attempt was made to get a finish which would have the same appearance as the real country were the latter viewed from a balloon at a sufficient height to make it appear the same size as the map. This effect was obtained by beating the surface of the concrete after it had been floated and partly set, first with a board set with wooden knobs and then with a block of wood and an irregular surface covered with battered tin.

When the map was about half completed work was started on the concrete wall surrounding it. This wall showed 5½ ft above the sea level of the map on the inside and 2½ ft. above the surface of the walk on the outside; it was 12 in. thick and paneled on the outside. The panels were 16 in. high, about 5 ft. long and 2 in. deep, the moulding above the panels being 6 in. wide. By making the panels this length it was possible to divide the wall into 12 sections, exactly alike, and one set of forms was used for the entire work. The inside forms were in two pieces, one 12 ft and the other 18 ft. long, the full height of the wall, and were built of inch boards nailed to 2x4 in. verticals spaced about 2 ft. on centers. The outside forms were built in panels, one form for each panel, and were 2 ft. 9 in. high, the concrete being brought to the level of the bottom of the forms with slip boards. The forms were held in place by stakes at the bottom of the inside forms, through ties of telegraph wire at the bottom of the outside forms, and board ties about 6 in. above the top of the forms. The wall concrete was one part cement, three parts sand, six parts gravel, mixed wet. The forms were pulled the morning after a section of wall was finished, and the exposed surface plastered with a thin coat of one to two cement mortar brought to a floated finish. The top of the wall was given a granolithic finish.

When about half of the map and surrounding wall had been completed a start was made on the painting. The land surfaces were sized and painted one coat of flat green, shaded off dark and light to give the proper hill and valley effects, the rivers being lined out in light blue. The bottoms of the oceans and lakes were stained blue, with light blue shading close to the shore. The paint stood all right, except when put on cement not thoroughly dry, when the first rainstorm turned it light yellow.

Three concrete boxes were built outside the wall, 2 ft. 6 in. square in plan, with the top flush with the top of the walk around the map. A 1-in. iron pipe was connected with the water main and run into one of these which was located at the head of the Chagres River. This furnished the water supply to keep the lakes and oceans at the proper level, the water flowing down the Chagres, filling Lake Gatun and then overflowing into the Atlantic and through the canal into Sosa Lake and the Pacific. A 1-in. pipe under the locks permitted the draining of

Lake Gatun, which, together with that of the other bodies of water, had to be done every fortnight. The outlet boxes for the Atlantic and Pacific were supplied with 6-in. earthenware drains connected with the sewer. The outlet was in the bottom of the concrete box and was stopped with a wooden plug sawed off at the desired water level and having a central hole, which took care of the overflow during rains. When it was necessary to drain the oceans the plugs were pulled, and when replaced were made tight by shaking sand around them.

The accompanying photograph gives a very good idea of the appearance of the finished map. The cost of construction was about $4,000.

A Bad Case of Rusty Steelwork.

A steel freight shed about 80 ft. wide, 200 ft. long and 22 ft. high to the eaves was built in 1878 at an Atlantic port and has since been exposed to salt atmosphere and moderately high wind. During recent construction operations, a portion of the framework was exposed and it was found that the feet of many of the columns were badly corroded, as indicated by the accompanying photograph of one of them, where the flanges broken away were merely kicked out by one of the laborers. At this point the thickness of the flange had been reduced from 3/8 in. originally to a minimum of 1/8 in., the remaining metal being soft and spongy. This extreme corrosion did not, however, exist to a very great height and was greatly diminished at a distance of 4 ft. above the base. A lighter had recently been in collision with one of these posts, which bent 3 or 4 ft. of it without breaking it, although its condition was the same as that of the one shown in the engraving.

The posts were only 8 in. wide and were braced merely with a 4-ft. kneebrace strut at the top. The cross-sections were built up with a single 8x1/4-in. web plate and four 3x2½x3/8-in. angles, and if ever exposed to the assumed wind pressure of 20 lb. per square foot, must have sustained a high total stress. It is remarkable that the structure has so long served and is still in service and not very much distorted. It is evident that considerable water leaks through the eaves and, following the column to its base, collects there to a certain degree and exposes this part of the metal to excessive corrosion. Little or no evidence of proper painting or other care of the steel work could be observed.

Book Notes.

The interest shown in the public works of Frankfort, Germany, is so great that the city engineer, Herr Koelle, has prepared an excellent "Guide to Some of the Public Works" of that city. It is a handsome book of 79 pages, printed in English, French and German editions. The book takes up in turn the growth of the city and its extensions, the streets and roads, the street cleaning methods, the sewerage and sewage disposal, the water supply, the harbor works, the bridges, and the systems followed in laying out new parts of the city. A large number of excellent illustrations are provided and the salient features of each subject are stated concisely so that the visitor can readily grasp them.

In view of the rapidly growing use of hollow concrete blocks as a building material the publication of a thoughtful paper by Mr. E. S. Larned, entitled "Regulation and Control of Concrete Construction," is decidedly timely. The author points out at the outset that while cement is a very important element of concrete work of any sort, nevertheless the other materials with which it is combined and the manner of mixing and placing those materials and the forms to contain them are also of prime importance, and should be submitted to the same inspection and study by competent persons as are usually required of the cement. This is not so well appreciated by architects and builders who use concrete blocks as is desirable. In order to afford a basis for discussion of the subject Mr. Larned then outlines a set of specifications for the materials for such blocks and the methods of mixing, moulding and curing them. The paper has been printed for free distribution by the Association of American Portland Cement Manufacturers, Land Title Building, Philadelphia, and deserves a wide circulation.

In these days of widespread concrete construction for works formerly executed in brick or stone masonry, there is some danger of overlooking the many merits of these latter materials. Attention may well be called, therefore, to an excellent pocketbook of rules, directions and tables, bearing the title of "The Building Mechanics' Ready Reference." The author is Mr. H. G. Richey, a superintendent of construction of United States public buildings. The volume explains the different classes of masonry, the

Badly Corroded Foot of Wall Column.

methods of carrying on work and of estimating quantities, various practical features useful to masons, gives numerous tables of the properties of building stones and other materials employed in connection with them, and furnishes a large variety of tables useful in connection with masonry construction. The author's long experience in supervising the erection of different grades of buildings for the federal government has naturally made him familiar with masonry work in many parts of the country, and many of the hints he gives are likely to be of interest to those who consider themselves in complete touch with all that is known in one section, but have not become familiar with the way work is done in other parts of the country. Special mention should be made of the excellent character of the illustrations, which are well chosen to make clear many things connected with masonry and the methods of constructing it which cannot be explained in words. (New York, John Wiley & Sons, $1.50.)

A useful handbook on the principles and methods of warming buildings has been prepared under the title of "Principles of Heating," by Mr. Wm. G. Snow. The book is apparently intended for the use of steam fitters and others who wish to have a practical guide to the design of satisfactory installations, and is not an elaborate theoretical treatise. The heating power of fuels and the construction boilers and heaters are taken up in the first chapter. In the second chapter the use of gas, oil and electricity for heating is discussed. The third chapter goes into the details of the capacity and fuel consumption of heating boilers and describes methods of testing furnaces. The next three chapters are devoted to a consideration of the phenomena that take place in heating and cooling air and in warming by direct radiators, and to the computation of radiation for direct warming and for use with blower systems. Information is also given concerning the methods of heating water and computing the size of coils for the purpose. The ninth chapter is a discussion of the flow of steam in pipes, the methods of computing the sizes of steam mains for different systems of heating, the selection of exhaust pipe sizes and the effect of back pressure on engines. The next chapter is an explanation of the methods of designing hot water mains, while the last chapter is devoted to vacuum and vapor systems of heating. On account of the interest now shown in such systems, the space devoted to them is considerable and probably more information is given regarding such methods of warming than is available in any other single book. Throughout the volume the author has laid special stress on the application of the heat-unit method of design. (New York, David Williams Co., $2.00.)

A "Hand-Book of Steel Reinforcement" has recently been prepared by the engineers connected with the American Steel & Wire Co. It opens with an explanation of the position which concrete now holds among engineering materials and then takes up the use and properties of reinforced concrete. Afterwards the cost of the material is discussed and there are chapters on the strength of concrete, steel for reinforcing, the protection of metal imbedded in concrete, fire protection, the modulus of elasticity and other properties of concrete, the methods of bonding old and new concrete, the effect of freezing and methods of finishing the surfaces of concrete. These chapters are mainly derived from various standard works. They are followed by tables of the weights, areas, sizes and other features of triangular and square mesh reinforcements, a specialty the company is now pushing and the advertisement of which in a mild way is evidently the main purpose of the book. These tables are followed by others giving the safe bending moments, weights and thicknesses of slabs and panels, with diagrams of the same data for the benefit of those who prefer to work from them. The manner in which the tables are prepared is explained at length and information is given concerning the various sizes of wire that can be used in slabs. The tables are based on a working stress of 16,000 lb. per square inch in steel, and a 1 : 2½ : 5 Portland cement concrete. The book does not take up the design of columns, beams or girders. (Chicago, American Steel & Wire Co., $2.00.)

The last number of the "Mitteilungen ueber Forschungs arbeiten," published by the Society of German Engineers is a monograph by Dr. R. Biel on the nature of the operation of centrifugal pumps and ventilators, "die Wirkungsweise der Kreiselpumpen und Ventilatoren." It is the author's belief that satisfactory information concerning these principles can be derived only from a study of experimental data, from which general laws can be deduced. Accordingly he opens this monograph with a statement of what has been done in the subject heretofore and an explanation of the theoretical fundamentals, after which he takes up in detail a series of experi-

ments with machinery of this class. Complete data are given regarding these trials and they are followed by a series of discussions concerning the important facts indicated by the test results. The monograph is published at 1 mark by Julius Springer, Berlin, who also publishes at the same price the author's thesis submitted for the degree of Doctor of Engineering at the technical academy at Charlottenburg. This is a remarkably interesting discussion of the loss of head attending the flow of liquid and gaseous fluids. "Ueber den Druckhöpenverlust bei der Fortleitung tropfbarer und gasförmiger Flussigkeiten." The first part of the thesis is a discussion of the critical points at which the curves of loss of head are interrupted, and the second part is an investigation of the loss of head in pipes when the velocity exceeds the upper critical point. This investigation leads the author to suggest a new formula for the loss of head, $h = LR\ (av^2 + bv)$, where h is the loss of head, R is the hydraulic radius, v the velocity and a and b are coefficients selected from diagrams based on experimental results which are tabulated for ready comparison. The third and final section of the thesis is a discussion of the application of the formula to open channels and streams.

Letters to the Editor.

Lattice Bars.

Sir: Mr. Horace E. Horton in a letter regarding "Lattice Bars in the Quebec Bridge," which appeared in your issue of Sept. 28, states, "The relation of lattice to the member is not specified anywhere in any general specification. That the individual lattice with its rivets should have some relation to the stress of the member surely appeals to us as reasonable since the failure of the Quebec Bridge, and yet no one has ever put in print anything that has come to my notice on the subject."

In an article on wrought iron columns, published in the "Lehigh Quarterly," June, 1891, the writer made a suggestion which he shortly afterwards incorporated as a clause in the New Jersey Steel & Iron Co. specifications as follows: "The lattice bars shall be so spaced that each channel between lattice connections shall be stronger than the column considered as a whole, and their size shall not be less than would be obtained by treating the column as a lattice girder supported at the ends and loaded at the middle with a load equal to 3 per cent. of the total compression on the column."

Henry S. Prichard.

Beaver, Pa., Oct. 4.

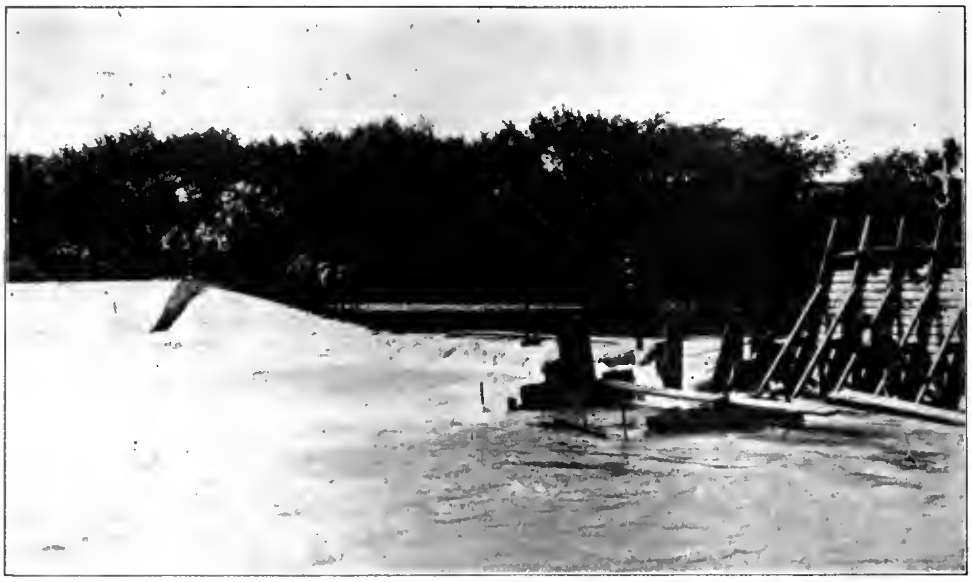
An Undermined Dam.

Sir: In your issue of November 24, 1906, there was a letter by the writer illustrating a reinforced concrete dam of original design which was being built at Dayton, O. The method of construction and a typical cross-section of the dam were there shown. At that time the dam was completed to within about 50 ft. of the end. The part left open was a deep channel, with a gravel bed. A large valve had been built into the completed part near the end, the intention being to pass the normal flow of the river through this while closing the end. The whole uncompleted end was then enclosed with a cofferdam, the top of which was several feet below the crest of the dam. The cofferdam was completed and the work progressing nicely, the water meanwhile flowing through the valve, when a sudden flood overtopped the cofferdam and undermined the end of the completed structure, which rested only on gravel. As a result about 25 ft. of the dam broke off and gradually dropped perpendicularly, thus remaining in line with the rest of structure. The broken piece contained the valve, and this had not been damaged. High water continuing, the work was temporarily abandoned, with the intention of resuming it this last spring. Litigation put off the renewal of the work until this fall, and it was then decided to leave the sunken piece in the river bed and build over it.

Instead of now constructing a cofferdam enclosing the whole of the open end and high enough to cause all flood water to flow over the crest of the dam, only the abutment end was enclosed, leaving an open gap of about 6 ft. between the cofferdam and the sunken part, the top of which was now slightly below water and about 7 ft. below the crest of dam. Into this abutment end a new valve was to be built, and then the gap was to be enclosed and filled in, thus completing the dam. Work was proceeding slowly when another flood came, and the water in its mad rush about the ends of the submerged part undermined some more of the dam, and a piece about 20 ft. long broke off, as shown in the accompanying photograph. The submerged end has fallen upstream, is badly out of line, and work is again at a standstill. The part submerged is the first piece that broke off, and the water is here over 20 ft. deep and getting deeper. Upstream a short distance the water is comparatively shallow.

If the dam had been commenced from the end that is now being put in very little trouble would have been experienced, for the river is very shallow on the completed side of dam. If the first flood had not occurred the dam would have been completed in about two weeks, but it seems that the contractors were taking chances on floods, with the present results. A small additional cost would have built a cofferdam of sufficient height to have avoided the first break, with its costly after results. Yours truly.

Dayton, Sept. 30. Edward Balbach.



An Undermined Dam at Dayton.

Wire Rope for Concrete Reinforcement.

Sir: Referring to the description of the reinforced concrete reservoir appearing on page 312 of your issue of Sept. 21, 1907, is not the use of steel cables for reinforcement very bad practice, on account of the permanent and material increase in length and decrease in diameter which takes place in steel ropes subjected to high tension? While he knows of no tests of the kind, the writer would expect to see concrete beams reinforced by wire ropes fail under loads which such beams would carry with safety if ropes were replaced by steel rods of corresponding number and diameter, especially so, if the ropes were new and did not have most of the stretch taken out of them by repeated high stresses.

Possibly second-hand wire ropes long in use under heavy loads would not be subject to further material increase in length and decrease in diameter, but surely the theories of reinforced concrete design are quite complicated enough without introducing and adding the stretch of a wire rope to the uncertain ratio of elasticity existing between steel and concrete.

In the design in question the steel cables are apparently stressed about 20,000 lb. per square inch, neglecting all tensile strength in concrete. This is a pull quite sufficient to produce a material stretch in a new wire rope, quite apart from the elasticity of the metal therein. In defence of the design in question, it may be said that there is no beam action and that the total stretch of the cable will be so uniformly distributed that there will be no visible resulting cracks in the concrete. We are not at all certain that the last assumption about the stretch is true. Quite generally, we think, it would not be true. Messrs. Westinghouse, Church, Kerr & Co. are such an able and reputable engineering firm that one is led to anticipate that there were some exceptional conditions justifying the design in question. Any general use of wire ropes in reinforced concrete would certainly result in many failures. Moreover, the item of cost is entirely against it. Yours truly, J. L. Campbell.

El Paso, Tex., Sept. 29.

Cost of Riveting.

Sir: The cost of machine riveting is hard to get at, as so many conditions enter. Generally speaking, however, as a machine will drive rivets as fast as they are fed to it, the chief cost is that of handling the work. This varies with the class of work, heavy and bulky work being, of course, harder to handle. Assuming $4.50 a day for the labor (exclusive of heater), if a machine drives some 700 or 800 rivets per day, the cost for labor, power and general charges will be from 5/8 to 3/4 cents per rivet.

Pneumatic hammer rivets in ordinary shop work will cost hardly less than 1 1/2 cents per rivet for similar charges. To be very conservative assuming only 1/2 cent saved per rivet, there is $1,000 or $1,200 saved per year. As a matter of fact, much larger returns generally result, for, if you double the machine rivets driven per day, the cost per rivet is practically cut in half and the savings are enormous.

This comparison applies only to an air machine, which, for 2,500 rivets, takes about the same amount of air as one pneumatic hammer. For hydraulic driven rivets several hundred dollars additional must be allowed per year for power.

Chester B. Albree Iron Works Co.

Allegheny, Oct. 2.

THE ENGINEERING RECORD

PUBLISHED WEEKLY BY THE

McGraw Publishing Company

James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.

MAIN OFFICES:

239 WEST 39TH STREET, NEW YORK.

BRANCH OFFICES:

CHICAGO: Old Colony Building.
PHILADELPHIA: Real Estate Trust Building.
CLEVELAND: Schofield Building.
SAN FRANCISCO: Atlas Building.

LONDON OFFICE: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico............$3.00 a year
Canada ....$4.50 a year
Foreign subscription.......................$6.00 a year
25 shillings. 25 marks. 31 francs.

Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of THE ENGINEERING RECORD on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

REMITTANCES.—Remittances should be made by check, New York draft, or money order, in favor of THE ENGINEERING RECORD.

CHANGES OF ADDRESS.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

BACK COPIES.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.

DATE ON WRAPPER indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

CLUB RATE.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. The rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 14,500 copies are printed. Total circulation for 1907 to date, 611,500 copies, an average of 14,560 copies per week.

TABLE OF LEADING ARTICLES.

The Power Load as an Equalizer of Output.

In the central station industry the growth of the power business has modified the conditions of current generation to a remarkable extent, enabling the machinery to be utilized at hours when it would otherwise stand idle and altering the shape of the load curve beyond all precedent. There is a lesson in this for the general power producer, although in an industrial plant the conditions are greatly narrowed, in comparison with the operating flexibility of a well-designed central station. The influence of the power load on a large scale appears daily in plants like that at Niagara, Montreal and other great centers of electrical generation or distribution.

The ordinary load curve of a lighting plant is characterized by a pronounced peak in the late afternoon or early evening, necessitating the maintenance of considerable extra generating capacity throughout the day and raising the fixed charges correspondingly. The results which can be secured by a judicious cultivation of power business are little short of remarkable in a large system, measuring their effect upon the load peaks. In Montreal, for example, the connected power load aggregates 37,000 h. p., and the connected lighting load 30,000 h. p. On a typical summer day last August the total output of the Montreal Light, Heat and Power Co.'s stations was held within a close average of 25,000 h. p. from 7:30 a. m. to 6 p. m., except during the noon hour. The mean variation in load was less than 4,000 h. p., and the lighting peak of 8 p. m. did not reach the maximum of the day load. Doubtless these results could not be duplicated in the winter season, but they show the value of a large distributed motor load in any plant which caters to a considerable lighting business.

Impermeable Concrete.

One of the most desired characteristics of concrete at the present time in connection with its physical resistance to the results of loading is impermeability to water. Although the ultimate compressive resistance of the strongest concrete is far below that of the best natural building stones, it is high enough to meet the exacting requirements of masonry in most engineering structures, and its lack of tensile resistance is effectively cured by steel reinforcement. In spite of the fact that its real merits, intrinsically of a high order, have at times been greatly exaggerated and grossly overworked by ignorant and ill-judged advocates, concrete is rapidly becoming one of the most valuable of all our structural materials for engineering purposes, if, indeed, it has not already reached that position. It is employed in many cases where its main function is that of carrying loads, but at the same time where the quality of real impermeability would add greatly to its value. This is not only true in an extended range of engineering structures, such as dams and aqueducts, but also in its application to buildings both en masse and in blocks. If concrete could be given a truly impermeable character its value would be greatly enhanced and its field of usefulness would be even more rapidly extended that at present.

The great obstacle heretofore experienced in making concrete waterproof has been its highly porous character. With the dry mixtures used in times past, the porosity of concrete was excessive and not the least of the many advantages accruing to the use of wet mixtures is the greater solidity or density conferred upon the mass. A wet mixture not only causes all portions of the mass to run together in greater solidity but it enables the finer materials of the aggregate to flow freely and thoroughly into the spaces between the coarser particles, thus producing a much more nearly continuous and dense interior mass. This means obviously a greatly reduced permeability to water or a much enhanced capacity to resist seepage through it. In fact, if the cement were ground sufficiently fine to enable it and the finest parts of the sand to enter freely into all the interior spaces of the aggregate, a waterproof material under high intensities of pressure would result; but the wettest mixtures which it is possible to use neither eliminate all the air bubbles nor fill all the interior spaces. However, much care may be taken in securing a thorough and intimate admixture of the component parts, all porosity is not eliminated and some seepage results under pressures of forty to sixty pounds per square inch or even less.

If suitably mixed concrete could be put under a high pressure before the initial set takes place, so as to squeeze out all air and surplus water, should there be any, in much the same way as molten steel is compressed, in order to produce grades of that metal of special value, it is altogether probable that the resulting density would be sufficient to secure essential impermeability under very high heads. This obviously is impossble, but some recent investigations appear to indicate that there may be other simple means of attaining the much-desired quality of impermeability. In a discussion by Mr. Richard H. Gaines of the paper presented to the American Society of Civil Engineers in April of the current year by Messrs. W. B. Fuller and S. E. Thompson, there are set forth some results of tests made to determine the effect of the addition of certain substances on ordinary concrete mixtures. In the search for materials which may enhance the waterproof character of concrete it is clear that none must be used which will prejudice the resistance or durability of the mixture. Mr. Gaines, who is the chemist of the New York Board of Water Supply, shows that the addition of small percentages of alum solution and fine clay to Portland cement mortar and concrete enhances greatly the impermeability of the mixture and that both compressive and tensile resistances were increased. Although the number of the tests was relatively small and the life of the test specimens was not long enough to settle conclusively such a question as that under consideration, the results obtained show that the line of investigation followed is worthy of being carried further in order to determine just what value may be attached to the mixtures of such materials as were employed with the usual proportions of cement, sand and gravel or broken stone in the manufacture of mortar and concrete.

It has been indicated by tests that, contrary to the former opinions of engineers, the presence of small percentages of fine clay of a suitable character and properly mixed does not necessarily injure the strength of concrete, and it has also been shown that the same mixture may aid in attaining more nearly waterproof qualities. Up to the present time, however, investigations of this kind have not been carried far enough to give quantitative results of sufficient range for practical purposes. It has generally been considered that the effect of fine clay in reducing the porosity of concrete was wholly mechanical, but the modern view of physical chemistry, so to speak, may disclose a different significance to the results of use of fine clay for such a purpose. With the modern wet concrete mixtures, the presence of the clay is asserted by Mr. Gaines to induce a colloidal action which is apparently aided by such a solution as that of alum, so that the result is a modification of the interior mass, tending to eliminate ordinary porosity.

There is nothing new in the employment of an alum solution as well as various soap solutions to afford concrete a certain degree of impermeability to water, but the purpose hitherto has been to produce an impermeable surface rather than an impermeable mass, which the results of Mr. Gaines' experimental work appear to indicate as attainable. The great advantage of securing an impermeable or waterproof mass of concrete over superficial effects is so clear as to need no comment. This observation is especially pertinent to all reinforced concrete work, in which it is of the first importance to protect the steel reinforce-

ment from corrosion. It is to be hoped that in its investigations connected with the construction of the Catskill aqueduct, the Board of Water Supply will extend its investigations thoroughly into the field indicated by the results already obtained by Mr. Gaines. At the present time it is difficult to imagine any greater benefit to be conferred upon all classes of concrete work than to find some simple and effective method of making it waterproof under reasonably high pressures. Such an investigation should also include tests with hydrated lime and the various proprietary waterproofing compounds now extensively used, some of which seem to be giving good results when added to the usual concrete mixtures.

The Cost of Industrial Service.

A peculiar feature of many industrial organizations is the difficulty with which actual operating costs are determined for separate departments or classes of service. Questions of engineering are so often involved in these problems that it is worth while to consider some of the weak spots in the study of costs, especially in technical plants. It is very important for some of these organizations, particularly public service corporations under the fire of popular criticism, to be able to determine with a fair degree of accuracy what it costs to serve different classes of customers. Such information may be withheld from publication advisedly, but if a company does not know what its service costs in detail, it is certain to be misunderstood by outsiders. The idea is widely held that failure to figure detail costs of service covers abnormal profits. The central station ought to know fairly closely what it costs to serve a suburban customer in comparison with a heavy consumer in the business district, and the telephone company ought to have some reasonably good method of finding out what party line service costs it as compared with private line service. The manufacturing plant ought to know pretty closely the total operating expenses and fixed charges, either in its different departments or for a given class of products.

It must be admitted that the determination of such costs is a complex problem in many instances. The mere fact that two kinds of coal are burned in different furnaces in a plant, for example, means that every pound burned must first be weighed and charged against the proper process or furnace, if the fuel cost in each furnace or process is to be known. This simple case is often overlooked, and the total amount of each kind of coal burned recorded without reference to the use which was made of it. Perhaps it is guessed what each process took in fuel, but the total figures are generally given alone in such cases, or lumped in the total of the entire operating expenses of the plant. The fact is that the combined experience and judgment of the accountant and the engineer are needed in all but the simpler problems. The classification of accounts needs the scrutiny of the technical staff before it is established as a standard method of analysis.

The engineer can help in securing these segregated costs more than is often realized by the commercial man. Financial problems are closely associated with the planning of all important tasks in engineering, and the money side must be recognized in operation, no less. Just as in buying materials and equipment the engineer can save the non-technical purchasing agent endless trouble if he is consulted at difficult junctures, so can he help the auditor and the bookkeeper in unravelling the intricacies of new technical combinations and relations in a growing industry. In the routine determination of costs the engineer can make certain that proper methods of measuring power, of counting and weighing materials, and of figuring labor costs are practiced. As a general rule, a physical separation of materials, supplies or products at the right time in the manufacturing process is the fundamental requisite for the securing of an accurate basis of cost calculation. This is the task of the betterment engineer and the production expert in a great many cases, but it is within the province of the regular engineering staff of a company to provide the necessary facilities for keeping an accurate count or measurement of the substances and agents pressed into its services and to be included in the separated operating expenses of the organization.

General expenses and fixed charges deserve the examination of the engineer in many of these companies, no less than pure operating expenses. The actual amounts of money diverted to this or that use is not the point at issue so much as the principle by which the charges are made. Knowledge of construction and replacement expenses can often be supplied by the engineering staff with far greater accuracy than is obtained from non-technical clerical figures. Arbitrary assumptions are no doubt often necessary in estimating general and fixed costs, and here technical knowledge of the conditions of a given industry is a valuable check upon the errors in judgment natural to the clerical department obliged to deal on its own initiative with involved relations between processes and employees.

The Utilization of Peat.

The renewed interest shown in the utilization of American peat bogs may possibly be traced to the activities of the American Peat Association, organized largely by members of the technical staff of the United States Geological Survey. This new society will hold its first meeting at the Jamestown Exposition the last of this month, and at that time we shall probably have an opportunity to learn more definitely just what degree of practicability there may be in the proposed utilization of peat in this country. According to a report by Mr. M. R. Campbell to the U. S. Geological Survey, there was not any very marked interest shown in the subject. About the usual number of companies were organized and glowing prospectuses were issued, but little or nothing was done toward the development of the peat industry in general. Many of the plants that were in operation experimentally in 1905 closed down during the year, he states, so that at the end of 1906 it is probable that there were fewer plants in operation than at the close of 1905.

According to Mr. Campbell's report, three companies have worked on an experimental scale in 1906 in this country. The Winter Park Electric & Fuel Co., in Orlando, Fla., which uses the Leavitt machine; the Wolverine Peat Fuel Co., near Vicksburg, Mich., which uses the Dolberg machine, and the Lamertine Heat, Light & Power Co., near Vicksburg, Mich., which uses a machine of special type owned by the company. The method of handling the peat is essentially the same in the three plants, namely, digging from bog either by hand or machine; transporting in car or conveying apparatus to mill; disintegrating in mill; molding into bricks, and finally drying by natural exposure until the water is reduced to about 15 or 20 per cent. The Winter Park Electric & Fuel Co. has departed from this practice slightly, as it now dispenses with the molding into bricks, simply dumping the disintegrated peat on the ground and letting it dry in irregular masses, which later are broken with hammers into lumps. This is reported to give excellent satisfaction; it is cheaper, though it requires more space for storage. A very complete plant, that of the International Fuel & Power Co., is nearly ready for operation at a bog located not far from Ogdensburg, N. Y. It is built on a large dredge, and the progress of the peat through the machine from the time it leaves the bog until it is delivered in the form of briquettes is entirely automatic. The bog is located on the east side of Black Lake, in a position that makes dredging operation easy. The peat is raised from the bog in bucket conveyors, dropped into the hopper of a disintegrating machine, passed through steam-jacketed pipes to drive off moisture, and then, while hot, is briquetted under immense pressure. The product, according to the claims of the company, contains less than 5 per cent. of moisture.

The reasons for the interest in this problem of utilizing peat are discussed at considerable length in the "Electrochemical and Metallurgical Industry" of the current month. The chief reasons are on one side, the enormous extension of peat deposit areas, at present practically worthless, and on the other side the undeniable fact that peat, according to its chemical composition, contains so considerable material values and energy values that their recovery would be highly desirable. But the process of recovery should be cheap, its cost should certainly be considerably less than the amount of the values to be recovered. This is the great difficulty. We might compare the peat problem with a very low-grade ore proposition. As long as high-grade ores are available, low-grade ore propositions are not very attractive. But in recent years we have seen great changes in the attractiveness of such propositions in the case of several metals, both as the result of the scarcity of high-grade ore and of the advances made in the metallurgical art. The peat problem may be considered from the same point of view. There have been considerable changes in recent years in the object aimed at as well as in the means for handling the peat.

In the old peat problem the object was to convert the peat into fuel suitable for both domestic and steaming purposes, this fuel to be shipped to consumers to compete with coal. In the new peat problem the object is to erect plants in the peat districts themselves for recovery of the values. Two essentially different means are available. One is dry distillation for the production of coke, with recovery of the by-products. The other is using the peat in gas producers for the production of power, also with recovery of by-products. With respect to the by-products, the nitrogen content of the peat is significant, since it is possible to recover it in form of ammonium sulphate; in view of the rapidly increasing importance of the artificial fertilizer industry the fixation of the nitrogen in peat is certainly as attractive a problem as the fixation of atmospheric nitrogen. Concerning the coke produced from dry distillation of peat it is to be pointed out that its quality naturally depends on the composition of the raw peat, especially its ash contents, but that its freedom from sulphur should go a long way to make peat coke desirable for metallurgical purposes. Finally, as to the desirability of producing cheap power from peat there can hardly be any disagreement of opinion. If power can be produced cheap enough there will be uses for it even in peat districts which have not yet any industry.

All the essential troubles with peat are due to its content of water and to its porosity. Much has been done in the construction of suitable machinery for kneading and treating the peat, so as to mold it and remove a considerable portion of the water. For the dry distillation of peat, the enormous advances which have been made in by-product coke ovens for the dry distillation of coal are of direct importance. Finally, as to the development of power from peat, the whole idea of doing this has become possible only through the development of the modern gas pro-

ducer and large gas engine. It is evident there are vast possibilities, but it should not be amiss to finally sum up what has been actually achieved.

The Electrification of the Erie's Rochester Division.

The comprehensive description by Mr. W. N. Smith, of the electrification of the Rochester Division of the Erie R. R., printed last week, has a double interest in that the line in question was not only the first to use single-phase motors in regular railway traffic, but also utilizes for this traffic power transmitted at 60,000 volts from Niagara.

By a combination of energy and good fortune, too, the road went into operation some months ahead of the electric system of the N. Y., N. H. & H. R. R., on which work had been long in progress. It is a capital example of the easy applicability of single-phase high voltage traction to existing steam roads, leaving the freight service undisturbed, to be taken up later if desirable The system involves many novelties and many very ingenious features of construction. To begin with the high-tension transmission line, one finds here an unusual type of construction, forming an ingenious compromise between the ordinary pole line and the tower system which has of late come into extensive use. It employs an A frame for the support of the wires, composed of two heavy cypress poles united at the top. In virtue of the extra support thus given the normal span is lengthened to 220 ft., thus greatly decreasing the number of insulators.

The lightning protection is also out of the ordinary, horn arresters being installed at every fifth pole. It is, of course, early to speak of the efficiency of this particular feature, but the horn arrester, although somewhat insensitive, has given a good account of itself on some of the important lines on the Pacific Coast and requires little attention, a great virtue in case of its use on pole lines. At the sub-station the lightning protection is more elaborate, consisting of three horn arresters in series, grounded respectively through a concrete column, an electrolytic arrester and a copper fuse wire. The special feature of the sub-station arrangements is the ingenious utilization of the three-phase-two-phase transformation, the two resultant single-phase currents being transmitted over the two nearly equal sections of the road to the north and south of the sub-station respectively. The actual working conductors thus fed are of No. 000 ground copper, carried by a catenary bracket construction. An interesting feature of this is that each steel bracket is permanently grounded to the rails, so that the failure of an insulator means a dead short circuit, the intention being to avoid any danger of poles burning off and obstructing traffic in case of a partial ground. Another safety precaution adopted is the abolition of practically all telegraph and telephone wire overhead crossings, such wires being taken under the track by cables. In a few cases, to which cables could not be conveniently applied, a basket construction of guard wires has been used to obviate any chance of crosses with the high-tension trolley wire.

On the motor car the equipment consists of four 100-h.-p. motors with Westinghouse electro-pneumatic control. Many ingenious details have been here introduced to provide for safe and certain operation. The service undertaken over the 34-mile line is based on the use of motor cars capable of handling a single trailer when desirable, at an average schedule speed of 24 miles per hour. There are 6 regular stations on the line and 22 flag stations, at some or all of which stops are to be made, so that to maintain schedule a flexible speed control such as this system furnishes is highly important. Experience has already shown that the electric trains can be made to hold the schedule rather better than the steam trains which they have supplanted. The operation of the four classes of trains employed, viz., electric, steam passenger, through freight and local freight, over a single-track road such as the Rochester branch is, involved some complications, but these have been successfully overcome.

Of the technical problems arising for solution in this plant one of the most serious was the interference produced by the current upon telegraph and telephone lines in the vicinity. On an ordinary transmission line such trouble is not formidable, for by proper transposition the inductive effects can be reduced to comparative insignificance. On this single-phase system with track return, kept in electrical instability by the shifting of the load both the electro-dynamic and electro-static effects were very noticeable, especially the latter. No suitable means of eliminating the trouble by working upon the line itself was found, but it did prove practicable to remove the baneful influence by providing the telegraph relays with fairly high resistance discharging shunts. This obviated the necessity of complete metallic circuits for the telegraph service. Such circuits are now in general use for telephone work, and if properly installed give good service, even in proximity to a single-phase line. This result is very satisfactory, since the question of interference from such systems has been a matter of no small concern. Altogether the engineering work on this Rochester division of the Erie seems to have given suitable solutions for a good many of the practical problems of single-phase teaching, and will probably lead to a freer use of the system than has heretofore been judged discreet.

Notes and Comments.

Rail Corrugations have been investigated by a committee of the American Street and Interurban Railway Engineering Association, and its inquiries show a great variance in the experience with these troubles. It appears that corrugations have been observed in different types of rails, and that the length affected ranges from a yard to several hundred feet. Sometimes the corrugations have appeared within a few months after the rails were laid, and in other places they were detected only after the rails had been in use a number of years. The length of the individual corrugations is 1 to 15 in., and their depth is sometimes as much as 3/16 in. Apparently deep girder rails are most liable to become corrugated. Seven companies have detected corrugations on the outer rails of light curves, one company on the inner rail of light curves, and three companies in straight track. Braking seems to have little effect in causing them although three companies find corrugations where brakes are applied most frequently.

The Excavation Records being made at the Isthmus of Panama are of the most gratifying nature. The total excavation for September was 1,517,412 cu. yds., which not only exceeds the amount taken out in any previous month, but all estimates for a month. These figures include about 36,000 yd. of material taken outside of the canal prism in accessory work, but work on the prism exceeds by nearly 207,000 yd. the excavation of the prism for August. This record is particularly remarkable for the fact that nearly 12 in. of rain fell during September, a slight excess over the rainfall in August and nearly 3 in. more than that in July. The relocation of the Panama Railroad is proceeding rapidly, and during August over 65,000 yd. of material were placed in the new embankment. The general indications are that the excavation from now on will considerably exceed the rate necessary to keep pace with the construction of the locks and dams, to the promotion of which Colonel Goethals is now devoting special attention. These conditions are noteworthy because heretofore the rainy season has been looked upon as a probable check to the forward progress of excavation work. The fact that such records have been made is to be accepted as conclusive proof that the stories of dissension among the Commission's employees are without basis, for no such progress would be possible were dissension rife.

The Manufacture of Public Opinion concerning engineering works of the greatest magnitude was well described recently by witnesses in the investigation which the Public Service Commission is making into the affairs of the Metropolitan Street Railway of New York. It is perfectly well known that public opinion on engineering works is so manufactured, although very few of those signing petitions or attending mass meetings know the extent to which they are manipulated. For one reason or another some corporation, city or state may find it desirable to have a certain kind of undertaking pushed forward rapidly or else hindered as much as possible. The ways in which it proceeds to arouse the interest of the public to its way of thinking are manifold. In the special case referred to, a lawyer was employed who succeeded in having petitions signed by many thousands of people in favor of certain rapid transit plans, one of these petitions being signed by over a million residents of Greater New York. It is, of course, possible that a great many of these signers of these petitions thought they were acting voluntarily in the matter, but the contrary was the case. The same lawyer who engaged people to circulate these petitions assisted in forming various associations of citizens in different sections of the city for the same purpose, the expenses in every case being comparatively small when the enormous interests involved were considered.

The Condition of the Ship-Building Industry in the United States is outlined in a report of the Census Bureau just completed. In 1880, according to these figures, there were 2,188 ship-building plants in the country, while in 1904 there were but 1,097. In the former year the capital invested was approximately $21,000,000, but in 1904 the investment had increased to $121,600,000; the number of employees increasing from about 21,000 to nearly 51,000 in the same period. The value of the work done was about $37,000,000 in 1880 and about $83,000,000 in 1904. The changes have been largely due to the shutting down of small plants building wooden vessels and the great development of the steel ship industry. Since 1900 there has been an increase of over 50 per cent. in the production of boats under 5-ton rating, due to the development of gasoline engines for such craft. About three-fourths of the total value of the products of the ship-building industry in 1904 came from establishments in the Atlantic and Gulf districts. Although the number of ship-building plants in the Great Lakes district was nearly double the number in the Pacific Coast district, the output of the latter was slightly greater than that of the former. Although the number of vessels of 5 tons and over launched during 1904 was 167 less than the number launched in 1880, the tonnage had increased 40½ per cent. during this period. The average value of the vessels launched in 1880 was not quite $8,000 whereas in 1905 the average value was $32,700.

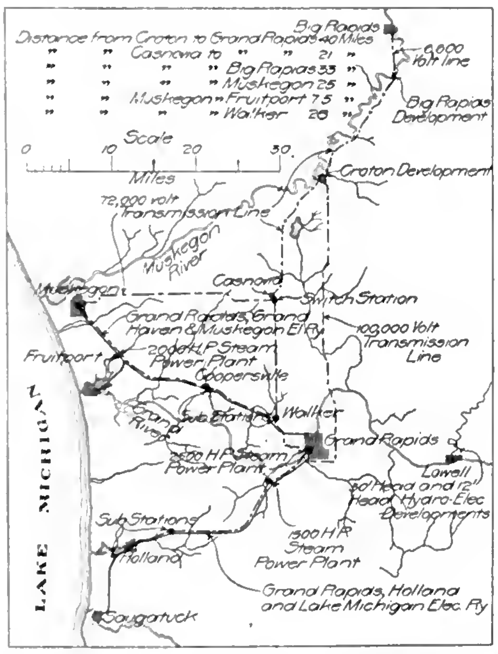
THREE LOW-HEAD HYDRO-ELECTRIC DEVELOPMENTS IN MICHIGAN.—PART I.

Three low-head hydro-electric developments, involving a number of similar features of design and construction, have been placed in service recently in the southern and western parts of Michigan. Two of these developments are a part of the system of the Grand Rapids-Muskegon Power Co., of Grand Rapids, Mich., and the third was built by the Commonwealth Power Co., of Jackson, Mich. The financial interests of these two companies are allied, but their generating systems and the fields of their operations are entirely distinct. Electric current is generated by the former company in two steam-driven stations and by four hydro-electric developments. The steam-driven installations are part of existing systems that were acquired by the company; two of the hydro-electric developments are on the Muskegon River, and the other two are on the Flat River, a tributary of the Grand River. The Commonwealth Power Co. operates seven hydro-electric stations, one on the Grand River and six on the Kalamazoo River.

The Grand Rapids-Muskegon Power Co. supplies power to operate two interurban electric railway lines which enter Grand Rapids; to the Grand Rapids Edison Co.; to several large factories in Grand Rapids and Muskegon; and for commercial lighting in Big Rapids, Coopersville and Grandville. The location of the various generating stations and transmission lines of this company, and of the two interurban railways supplied with power by it, is shown in an accompanying map of the district covered. The two hydro-electric developments on the Muskegon River are at Croton and near Big Rapids, 43 and 58 miles, respectively, from Muskegon, which is at the mouth of the river, and 40 and 50 miles from Grand Rapids. Power is transmitted from both stations to Grand Rapids and to Muskegon. The two developments on the Flat River are at Lowell, 18 miles east of Grand Rapids, to which the power generated in them is transmitted. One of the interurban electric railways extends from Grand Rapids to Muskegon, and the other from Grand Rapids through Holland to Saugatuck, on Lake Michigan. A 2,000-h.-p. steam-driven station on the Grand Rapids-Muskegon interurban system and a 1,500-h.-p. steam-driven station on the Grand Rapids-Saugatuck line are connected with the general distribution system. The company also controls dam sites on the Muskegon and Grand Rivers, which, including those already developed, will produce an ultimate capacity of 60,000 h.-p.

The Muskegon River is the longest river in Michigan, its general course being from the north to the south. The river has its source in Higgins and Houghton Lakes, which have a combined area of about 50 square miles. The entire catchment area of about 1,800 square miles above the Big Rapids dam has a clay subsoil, overlaid to a depth of about 10 ft. with sand and gravel, and is mostly covered with a growth of scrub pines and oak. The rainfall is therefore largely absorbed by the soil and is delivered slowly to the streams. The course of the river from the north to south, together with its considerable length, causes thawing of the snow in the Spring to begin at the mouth of the river, and to proceed northward gradually, so considerable Spring floods due to a quick thaw over the entire watershed are uncommon. This normal absence of spring floods and the slow delivery of the rainfall to the streams makes the variation between high-water and low-water flows comparatively small. In fact, the minimum flow of record at the Big Dam is 700 second feet, which occurred Sept. 2, 1907, while the maximum is 5,000 second-feet, occurring in March, 1904. Practically the same stream-flow conditions also exist at the Croton development, where the total watershed above the dam is approximately 2,300 square miles. The variation between the minimum and maximum flows is proportionately somewhat greater at this dam than at the Big Rapids dam, however, as the Little Muskegon River, with a watershed tending toward a more rapid discharge of the rainfall, enters the main river between the two dams. The relatively high minimum flow and the uniform flow throughout the year, together with a rapid fall in the middle section of the river, indicate the value of the stream for power developments.

Croton Development.—The development at Croton, which is the more important of the two on the Muskegon River, renders available a head of 40 ft., and contains equipment with a capacity for developing continuously 14,400 h.-p. It was built at a bend in the river, where the valley is 600 ft. wide, with a bank a little over 40 ft., high on one side and one 120 ft. high above the water on the other side. The works that make up the dam embrace essentially the following: A waste-gate section, 238.75 ft. long, which is built of concrete and is at one side of the river valley; a power house, 160 ft. long, that adjoins the outer end of the waste-gate section; and a hydraulic-fill embankment, 200 ft. long, extending from the power house to the high bluff on the opposite side of the valley. One of the chief features of the design of the dam, and of the dams at the other two developments to be described, is the use of flood gates of sufficient capacity and so arranged that the pond above the dam is maintained at a constant level throughout the year. These flood gates are of the Tainter type, built of steel, each gate being 20 ft. wide and 12 or 13 ft. high. Another feature of the hydraulic design common to all three developments is that the water is discharged from the waste gates into a tumble bay, from which it spills over a low concrete weir into a waste channel.



Map Showing Hydro-Electric Developments and Transmission Lines of the Grand Rapids-Muskegon Power Co.

The site of the development at Croton is underlaid at a depth of 20 to 40 ft. below the surface by a stratum of hardpan, deposits of sand, gravel and clay overlying this hardpan. A continuous row of steel sheet piling was driven far enough into the hardpan under the waste-gate section and the power house to form an effective cut-off; this row of piling was also continued from the power house across to the opposite side of the valley, under a corewall in the embankment. The waste-gate section and the power house are carried largely by round wooden piles driven to the hardpan. They were both built on a flat at one side of the river channel, almost without encroaching on the latter. After they were finished the river was diverted through temporary openings in the waste-gate section and the hydraulic-fill embankment was built across the channel.

Waste-Gate Section.—The waste-gate section contains eight Tainter gates, each 20 ft. in width, and a log sluice, 40 ft. wide, that is controlled by a 40 x 3.5-ft. movable crest, or bear-trap dam. Four of the Tainter gates are on each side of the log sluice, the adjacent gates being separated by heavy concrete piers. The normal water surface in the pond above the dam is at Elevation 135.5, while the upper edge of the gates when closed is at Elevation 136, and the water in the tail race is at Elevation 95. The gates seat on a spillway which has a hollow reinforced-concrete gravity section. The details of the design of this spillway, the arrangement of the tumble bay and the concrete apron for the waste-way channel below the dam are shown in an accompanying cross-sectional elevation through the waste-gate section of the dam. The base of the downstream edge of the spillway is 45 ft. 8 in. from the upstream edge of the crest of the weir which forms the tumble bay. The crest of this weir is 7.5 ft. above the heavy reinforced-concrete floor of the tumble bay, this floor being continuous with the base of the dam. A concrete wall is continued from the piers on each side of the log sluice to the overflow weir, thus separating the tumble bay into two parts. Each of these parts has three 12-in. circular weepers connecting it with the tail race, so by closing the four Tainter gates on either side of the log sluice, the corresponding part of the tumble bay can be drained and the under side of the hollow spillway section entered from it.

The bottom of the waste-way channel below the gate section is protected by a reinforced-concrete apron that extends downstream for 200 ft. from the overflow weir of the tumble bay. The bottom of the log sluice is on a slope of 8 in. to the foot, a vertical curve connecting it with the apron protection for the waste-way channel. The retaining walls on each side of the sluice are also continued 20 ft. downstream from the overflow weir of the tumble bays so the flow through the sluice and that over the weir at each side of it are separated. A reinforced-concrete wall, extending downstream to the end of the protection apron separates the waste-way channel and the tail race of the power house. This wall is reduced in height from a maximum of 35 ft. at the power house to 10 ft. at the downstream end, and largely prevents back water in the tail race.

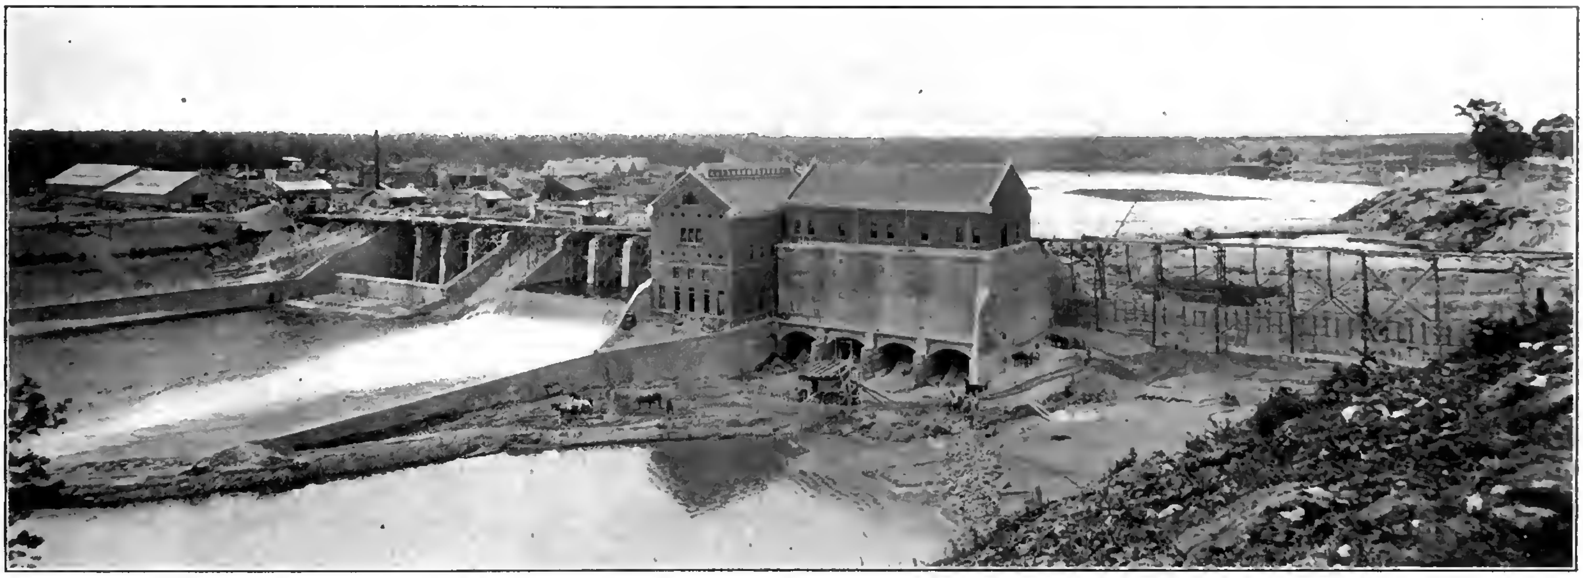
The Tainter gates were specially designed for the three developments that are to be described herewith. Each gate swings on two bearings, one on the pier on each side of the opening which it controls. These bearings are on 6-in. cold-rolled, turned, steel pins, that are imbedded in the piers. The frames of the gates are trussed across so these pins are only required to extend about 1 ft. from the face of pier, thus eliminating the usual bearing at the center of the gate and the necessity of providing a long, heavy steel shaft to extend the width of the gate.

Each gate is fitted along the lower edge of its face with a heavy oak block, which, when the gate is lowered, seats on a wooden sill carried by a 15-in. channel imbedded in the crest of the spillway of the dam. This arrangement makes a

watertight joint, that it is considered will rarely have to be renewed. The joints between the ends of the gates and the surface of the piers between the gates are made practically watertight by attaching 5-in. strips of 3-ply rubber belting to the edge of the upstream face of the gate in such manner that the belting overlaps the end of the gate and bears against the face of the concrete pier.

The gates are raised and lowered by a motor-driven hoisting crab that travels on a 24-in. gauge track of 12-in. I-beams laid the length of the waste-gate section on the piers between the gates and covered with a light section of reinforced-concrete so as to bridge the openings between these piers. This crab consists essentially of an eight-wheel truck, 18 ft. long, that carries a 4-h.-p. motor, worm-geared, through reductions to a horizontal shaft having a grooved drum attached to each end of it. One of these drums is built as a right-hand and the other as a left-hand screw. Each gate has a shackle attached to it at both ends near the bottom of the face, these shackles being arranged so chains can be hooked into them and wound around the drums of the hoisting crab. An 8,000-lb. pull can be exerted on each of these chains by the crab, so the gates are easily handled by the latter. Bearings on this shaft are attached to the leaf at intervals of 6 ft. At about 6-ft. intervals intermediate with the bearings carrying the leaf are thrust bearings against the shaft, which are seated on heavy castings in the top of a concrete ledge under the hinge. The base of each of these thrust bearings is arranged with an adjusting screw so all the bearings may be brought into alignment.

Earth Embankment Section.—The earth embankment between the end of the power house and the side of the valley opposite from the waste-gate section contains 104,000 cu. yd. of sand and gravel that was sluiced into it hydraulically from the high bluff on that side of the valley. This embankment is 20 ft. wide on top, 40 to 60 ft. high, and has a slope of from 2½ to as much as 6 to 1 on its upstream side, while the slope on the downstream side is between 2 to 1 and 4 to 1. The concrete core wall in the embankment is 12 in. thick and is heavily reinforced. It rests on the line of steel sheet piling which forms the cut-off at the base of the dam. The wall is located at the line where the surface of the pond intersects the embankment, projecting 2 ft. above the water level to serve as a wave protection. With this arrangement the greater part of the embankment remains practically dry, to the stream and parallel with axis of the dam. The portion of the substructure of the building in which the turbines are placed is divided by transverse walls into four penstocks, each containing a pair of turbines for each unit. These penstocks are each 22 ft. wide and rise to a height of 33 ft. above the top of the heavy base on which the turbines are set, and in which the draft tubes for the latter are formed. The upper two-thirds of the front end of each penstock is open the full width of the penstock to form an entrance from the pond above the dam. These openings are each protected by an inclined rack, within the penstock, which intercepts floating debris. A heavy boom is also extended from each side of the log sluice in the waste-gate section to the sides of pond to divert logs and large floating debris over the sluice. Stop-log grooves are placed in both sides of each penstock, immediately in front of the rack, in order that the penstocks may be shut off separately. Light steel-frame gates, faced with planks and divided horizontally at the middle, are operated in these stop-log grooves. These gates are handled by a hoisting block running on an I-beam trolley suspended from the roof trusses of the house over the penstocks. The upper half of each gate can be hung on hooks on the side



General View of Croton Development Showing Embankment Being Sluiced into Original River Channel.

Power to operate the motor is obtained from a supply line laid in a conduit buried in the concrete, plugs for making connections being placed at suitable intervals along the gate section. Two hoisting crabs are provided, in order to be certain of one, if the other is out of commission. Both crabs are also arranged with wheels, fitted with grips, so they may be operated by hand in case both motors are out of service, or no current is available.

Movable Crest Dam.—The movable crest dam is set in a depression built in the top of the spillway of the waste-gate section. It has a leaf, 6 ft. 10 in. wide and 40 ft. long, which turns on a shaft in a hinge along the upstream edge, thus permitting the downstream edge to be raised and lowered through a vertical travel of 3.5 ft. The leaf is raised and lowered by two sets of motor-operated worm and spur gears which drive two hoisting drums on a main shaft extending across the opening controlled by the movable crest. Two chains, one attached to each end of the leaf, are wound around these drums, the latter being grooved, one as a right and the other as a left-hand screw.

An 18-in. I-beam extends the full length of the 6-ft. 10-in. leaf, and is attached to the front edge of the latter.

The leaf turns on sections of 3-in. steel shaft. giving it much greater stability than if saturated, while the line of sheet piling prevents seepage under the embankment.

Power House.—The power house is an L-shape structure, with the axis of the stem of the ell coincident with the axis of the dam. The stem of this L-shape building is 65 x 141 ft. in plan and has a heavy concrete substructure carrying the penstocks and containing the draft tubes for the water wheels. The leg of the ell is 44 x 80 ft. in plan, and contains the electrical equipment. This part of the building has hard-burned, red-brick walls, surmounted by a roof of glazed, green tile carried by steel roof trusses, the appearance of the exterior being very satisfactory. A low house, with the same kind of walls and roof, covers the penstocks.

The generator room of the power house contains two 3,600-kw. revolving-field 30-cycle 6,600-volt three-phase Westinghouse generators. Each generator is direct-connected by a 12-in. shaft, 110 ft. long, to four pairs of 45-in. Samson turbines, of the center discharge type, which are in the adjacent penstocks. The units operate normally at 225 r. p. m., but are designed to run without injury at double that speed with no load. The shafts are each also designed to carry 8,000 h.-p. continuously.

The shaft of the main units is at right angles wall of the penstock house, when it has been lifted out, and the lower part is arranged to stand beside the upper part, both parts being placed in these positions for storage by the hoist.

The downstream ends and the sides of the penstocks are of reinforced concrete. These ends are semi-circular, with the reinforcement in them carried backward and downward into the base of the penstocks at an angle of about 45 deg. with the horizontal to overcome any tendency of shearing in the concrete. The sides and ends of the penstocks are designed so any one penstock may be emptied safely while the others are filled.

Each pair of turbines has a draft tube, leading to the tail race, formed in the heavy base on which the penstocks stand. The arrangement of the units normal to the stream, and the location of the corresponding pairs of turbines for both units on the same transverse line in the penstocks, necessitated a special and unusual design of these draft tubes. The upper part of the draft tubes for the pairs of turbines of the units on upstream side are as ordinarily built, but these tubes flare out at the bottom, so a draft tube for one of the pairs of turbines of the downstream unit can be placed in line with each of them. This increase of section is made

in such a manner that the water discharged from the upstream turbine in each case passes on both sides of the draft tube for the corresponding downstream pair of turbines, the velocity of the water where the discharge from the two tubes join being the same, to eliminate as fully as possible any agitation at this point.

The shafts of the two units pass through large glands in each of the division walls between the penstocks, and in the wall between the end penstock and the generator room. These glands are each carried by a heavy cast-iron diaphragm attached to a frame of I-beams and channels imbedded in the walls. The frames for the various glands of each unit are anchored together by heavy iron rods extending from one end to the other of the row of penstocks. The glands are practically watertight, so any one penstock may be drained and entered without interfering with the operation of the turbines in the remainder. Stop-log grooves in each penstock between the corresponding turbines of the two units also permit the downstream turbines to be cut off without stopping the turbines of the upstream unit in the same penstock. Any pair of turbines on either shaft can also be disconnected so the other turbines between the pair in question and the generator may be continued in service.

Two Type N Lombard governors are provided for the four pairs of turbines to each main unit. These governors are placed on the floor of the generator room, where they are belted to the main shafts of the units. One governor controls the operation of two pairs of wheels and the second one the other two pairs, but both are arranged to operate simultaneously.

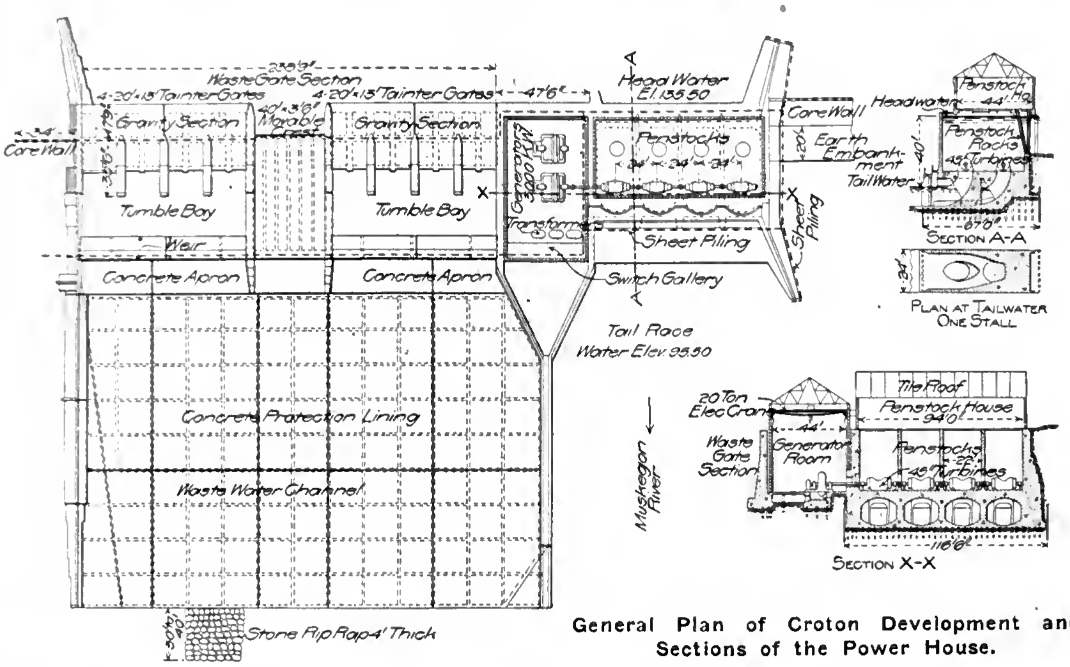
A complete mechanically-forced lubricating feed system is also provided for the bearings of the turbines of each unit, the bearings under water being of lignumvitae. Each of these systems consists essentially of a supply cylinder carrying a piston on a screw, by which heavy oil may be forced into small storage tanks under pressure. The supply cylinders and storage tanks are in the generator room on a bracket gallery against the wall which separates that room from the penstocks. The storage tanks are connected to a pipe header from which a separate lateral pipe is carried to each of the four bearings on every pair of turbines. These lateral pipes are each fitted with a quick-opening valve, which is opened for a short time when oil is to be supplied to a bearing, thus insuring a positive feed.

Excitation current for each main generator is furnished by a 40-kw. 125-volt direct-current generator on the shaft of the unit. The field winding of the generators is so proportioned that with constant speed, constant separate excitation and 100 per cent. load factor, the load may be varied from the normal rated capacity to no load with a voltage rise of not more than 8 per cent. At the normal rated current and voltage, and with 100 per cent. load factor, the efficiency of the generators is guaranteed to be at least 93 per cent. at half load; 95 per cent. at three-quarters load; 96 per cent. at full load; and 95.5 per cent. at 50 per cent. overload. Unusual care to prevent excessive temperatures in the generators under continuous operation was also observed in the design.

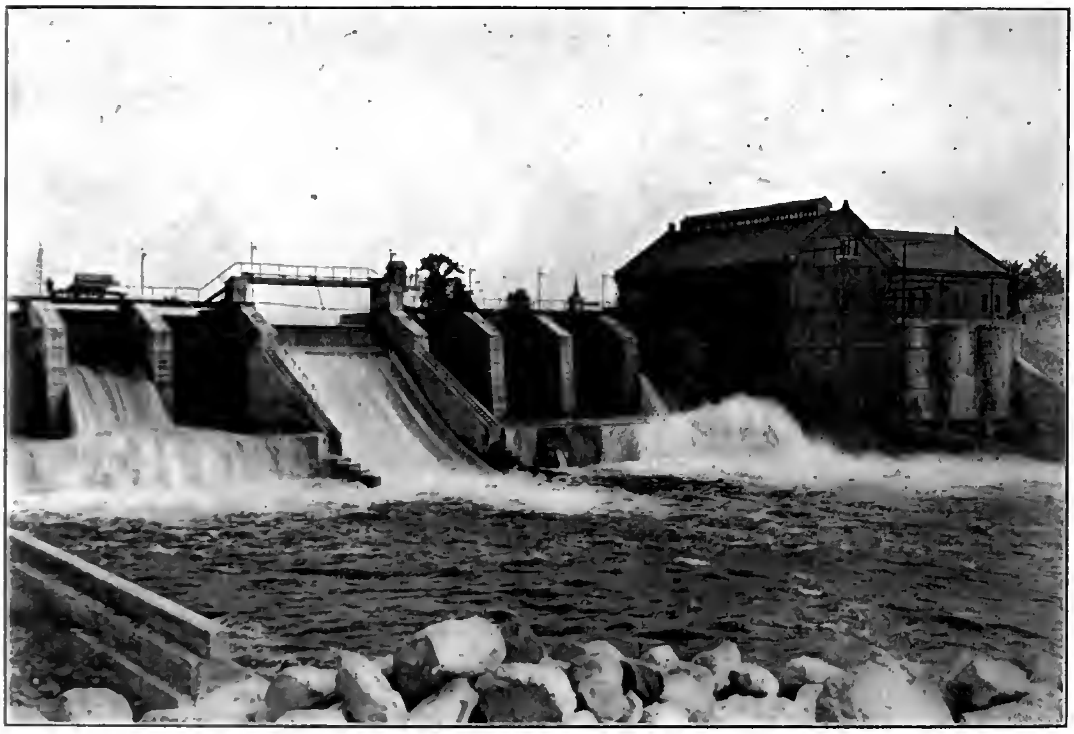
The 6,600-volt current delivered by the generators is stepped up to 72,000 or 100,000 volts for transmission to Muskegon and Grand Rapids by three 3,000-kw. 30-cycle oil-insulated water-cooled transformers, placed at the downstream end of the generator room. The transmission lines leading from the power house will be described later.

The operation of the generators is controlled from a two-panel switchboard at level of the generator room floor. Motor-operated oil switches, also controlled from this switchboard, are provided for the high-tension bus-bars and connections. These switches are in separate fireproof cells, and the bus-bars are all in separate fireproof compartments.

Construction of Croton Development.—The works which make up the Croton development were built on force account by the owner, the Grand Rapids-Muskegon Power Co., under the direction of Mr. J. B. Foote, general superintendent and electrical engineer, and Mr. William G. Fargo, designing and supervising engineer, in charge of the work. Mr. Daniel L. Davis was resident superintendent and Mr. Benj. T. Weston was resident engineer during the construction.



General Plan of Croton Development and Sections of the Power House.



Close View of Waste Gates and Log Sluice at Croton.

In order to facilitate the delivery of supplies and materials, a standard-gauge railroad, 6 miles long, was built from the Pere Marquette Ry. to the site. Standard-gauge switching connections with this branch railroad were extended to all parts of the storage yards at the works, these extensions being carried down on inclines so the turbines and electric machinery could be delivered close to the power house. Standard-gauge cars were handled on these inclines by electrically-driven hoists without any difficulty. A stationary gantry for a cross-travel trolley carrying a 10-ton chain hoist was built over one of the side tracks for unloading heavy material and machinery.

The construction plant for the work included two No. 1 Vulcan turntable pile drivers, two drop-hammer pile drivers, one ½-yd. and two ¾-yd. cubical mixers and a number of derricks, pumps and smaller equipment. All of this equipment was operated by motors, except the turntable pile drivers, which were operated by steam. A 9 x 11-in. motor-driven air compressor, with a capacity of 130 cu. ft. per minute, was also installed in a temporary boiler house on the low bank of the valley. This compressor furnished power for operating two riveting hammers, a chipping hammer, a reversible wood-boring machine and four forges in a blacksmith shop. The compressor and tools, exclusive of the motor and air tank, cost $600.

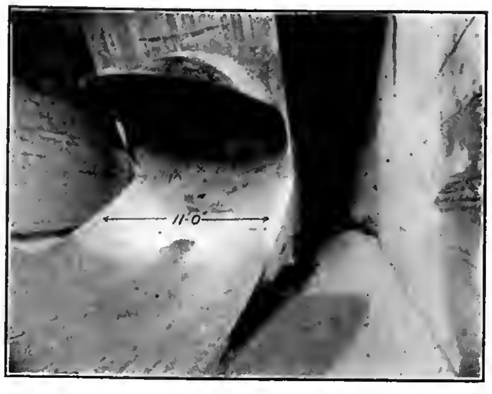
The electric power required to drive the various motors was supplied by a temporary 6,600-volt line extended to the site from the Big Rapids development, which had been completed before construction was started at the Croton dam. A 72,000-volt transmission line, extending from the Big Rapids development to a switch station, with one branch leading to Grand Rapids and a second

branch to Muskegon from this station, passes the site of the development at Croton. The 6,600-volt line was carried on temporary brackets placed on the poles of this high tension line. The 6,600-volt current was stepped down to 440 volts by water-cooled transformers at Croton for use in the construction plant there.

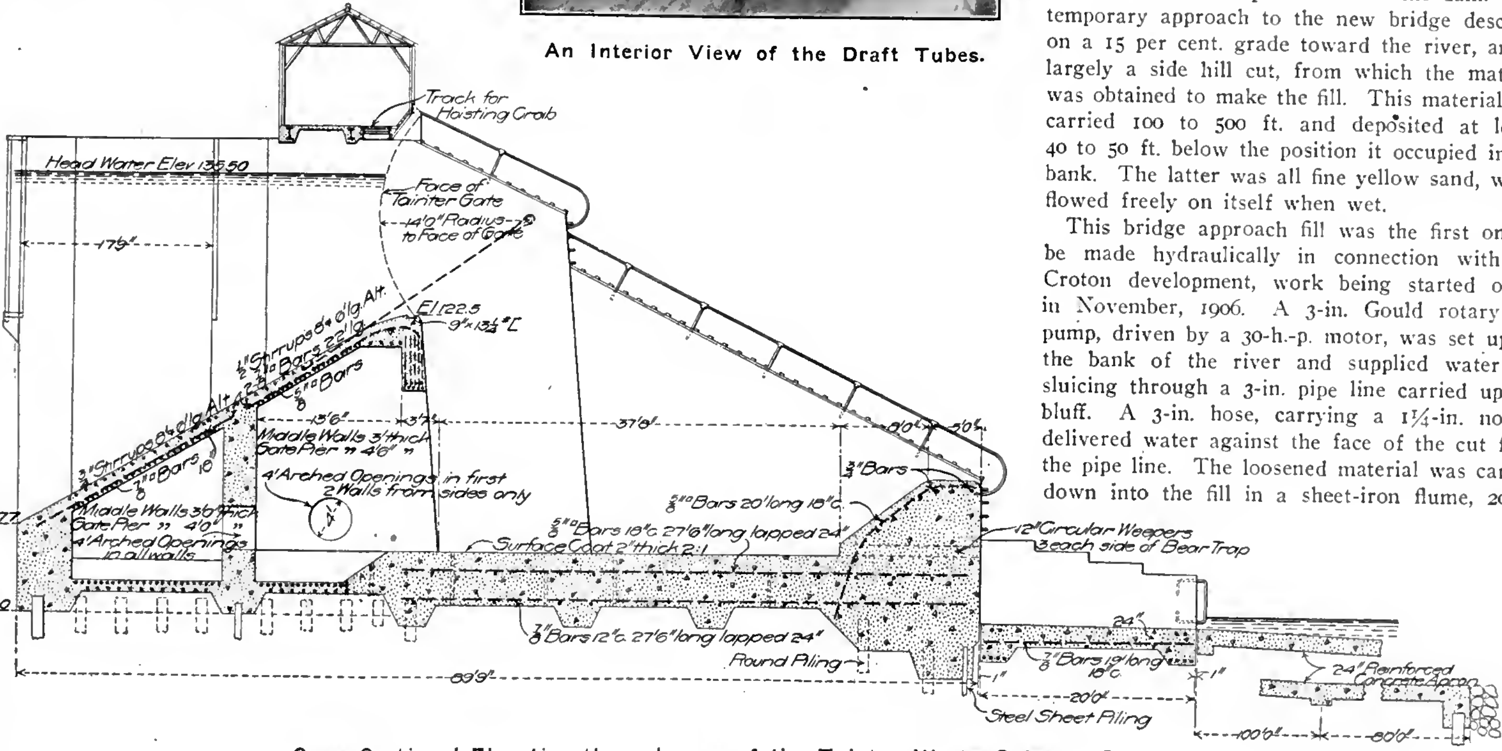
Concrete.—In all, about 20,000 cu. yd. of concrete were used in the dam. This concrete was made in varying proportions, depending on the purpose for which it was to be used. Newaygo Portland cement and unscreened pit gravel were used in all of the concrete. This gravel contained about the proper amount of sand, the voids in it ranging from 14 to 18 per cent. The gravel was obtained from a pit along the branch railroad about a mile from the dam, and was brought to the work in 5-yd. bottom-dump cars handled in trains of 10 cars each, by a standard-gauge locomotive.

A concrete mixing plant was erected near the end of the waste-gate section of the dam, in line with the axis of the latter and back on the edge of the low bluff on that side, about 40 ft. from the limits of the concrete work. The two ¾-yd. motor-driven mixers were set up in this plant so that they would dump into cars on tracks about level with the highest point of the concrete in the dam. A storage for gravel was erected over the mixers, the gravel being delivered into a track hopper at the side of the plant from cars on the standard-gauge railroad, from which hopper it was raised to the storage bin by a bucket elevator. The cement was stored in a shed in the rear of the mixing plant. An incline was extended from this shed up to a working platform around charging hoppers over the mixers and the cement was hauled up a track on this incline on flat cars handled by an electric hoist.

A temporary pole trestle was extended from the mixing plant to the opposite side the valley, crossing the latter on the axis of the dam. This trestle carried two 24-in. gauge tracks, on which ½-yd. Koppel dump cars were pushed by hand to deliver concrete to any part of the work. The concrete was dumped from these cars on the trestle through chutes leading down to the point where it was to be deposited. The concrete work was carried on through the winter of 1906-07, some of the most important parts of it, such as the reinforced semi-circular ends of the penstocks, being placed with the temperature below zero. During the prevalence of low temperatures, the water used in mixing the concrete was heated and a jet of live steam was turned into the mixers, with the result that the concrete was delivered hot from the latter, and retained sufficient heat to permit a considerable set to take place before it became cold enough to freeze after it was placed. Live steam was also piped to all parts of the work and was used for thawing ice from the forms and for other purposes. The steam required for this work was furnished by a 60-h.-p. boiler set up in a house near the mixing plant, the motor-driven compressor also being installed in this same house. No salt was used in the water except in a few heavy walls where no reinforcing steel occurred.



An Interior View of the Draft Tubes.



Cross Sectional Elevation through one of the Tainter Waste Gates at Croton.

The longer reinforcing rods which required bending were heated in a special forge, adjacent to the blacksmith shop, so they could be bent readily. This forge was a heavy slab of concrete, 6 ft. wide by 15 ft. long and 2 ft. deep, with three longitudinal troughs formed in it. A perforated pipe was buried under the bottom of each of these troughs, and air was supplied from the compressor through these perforated pipes. The long rods of high carbon steel were readily heated in this forge and could be bent to templets without trouble.

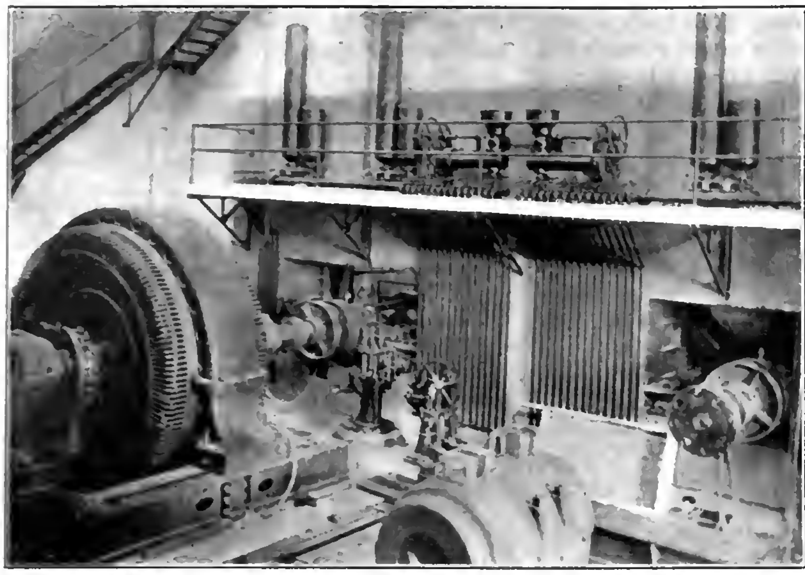
Sluicing Operations and Plant.—After the waste-gate section and power house were practically finished, the river was diverted from its channel between the end of the power house and the high bluff on that side of the valley, and passed through a row of six 7 x 9-ft. openings which had been left in one end of the bottom of the waste-gate section. This diversion was accomplished by rock-filled timber cribs sunk across the channel about 300 ft. above the power house. A low fill of long slope was then made under water on the upstream side of the crib by hydraulically sluicing material into the channel from the high bluff. After this upstream fill had been finished, the channel downstream from the cribs was filled, and the embankment section of the dam was carried up with material sluiced down from the bluff. The temporary closing cribs, when faced with a sluiced fill on the downstream side, were made nearly tight under a head of 15 ft. of water. The water which seeped through and accumulated between the temporary and permanent embankments was removed by a motor-driven 4-in. centrifugal pump running less than a quarter of the time. The possibility of making tight fills with material deposited under water by hydraulic sluicing is thus shown.

In addition to the 104,000 cu. yd. of material deposited in the channel closure and the embankment section of the dam by the hydraulic sluicing process, a fill containing about 20,000 cu. yd. of material, which was required as an approach to a highway bridge just below the dam, was made in the same manner. This highway formerly crossed the river on a bridge about a quarter of a mile upstream from the dam. The temporary approach to the new bridge descends on a 15 per cent. grade toward the river, and is largely a side hill cut, from which the material was obtained to make the fill. This material was carried 100 to 500 ft. and deposited at levels 40 to 50 ft. below the position it occupied in the bank. The latter was all fine yellow sand, which flowed freely on itself when wet.

This bridge approach fill was the first one to be made hydraulically in connection with the Croton development, work being started on it in November, 1906. A 3-in. Gould rotary fire pump, driven by a 30-h.-p. motor, was set up on the bank of the river and supplied water for sluicing through a 3-in. pipe line carried up the bluff. A 3-in. hose, carrying a 1¼-in. nozzle, delivered water against the face of the cut from the pipe line. The loosened material was carried down into the fill in a sheet-iron flume, 20 in. wide on the bottom and with vertical sides 5 in. high. This flume was laid on the ground as the cut advanced on the 15 per cent. grade.

The pump and pipe line were set up by two men in two days. With the exception of the labor cost of handling 3,000 cu. yd. of material out of the cut and putting it into the embankment forming the approach to the bridge, no exact records of the cost of making this embankment were made. Four men with the outfit described moved out of the cut and put it into the embankment between Nov. 15 and 20, 1906, the 3,000 cu. yd. of material on which cost data were kept. The four men who did this work each put in 40 hr. at 20 cents an hour, and a foreman was also required for 40 hr. at 25 cents an hour, making a total of $42, or 1.4 cents per yard for labor.

The sluicing outfit used in building the embankment section of the dam included a pumping plant on the bank of the river downstream from the embankment, a pipe line leading from this plant up to, and along the top of the bluff which forms the bank of the river, hose connections from this pipe line to the face of the excavation and flumes leading from the latter down into the embankment. The top of the bluff



Mechanically Forced Lubricating System for the Water Wheels.

Interior of Penstock Showing Four Pairs of Turbines of a Set.

was yellow sand underlaid at various depths with hardpan and clay. A large percentage of the material in the embankment is sand, however, as under the pressures that were available the hardpan and clay could not be loosened readily enough to sluice.

The pumping plant was comprised of seven Underwriter's rotary fire pumps, one 5-in. Gould, two 3-in. Gould, two 6-in. Gould and two 6-in. Rumsey, all belt-driven by electric motors. Although these pumps were not the most efficient or desirable that might have been obtained for the work to be done, they were used because they were on hand and were readily adapted to be operated by the available motors. While the rotary pumps give good satisfaction for intermittent service of short duration, such as for fire purposes, they are not adapted for the hard, continuous service required in sluicing operations. On this account, an average of 50 per cent. of the pumps were out of order and undergoing repairs the greater part of the time, the breakdowns being for the most part in the gears and cams. For this reason, in future work, of this kind, it is intended to employ either a direct-connected turbine pump, or some other efficient type not subject to frequent breakdowns.

The pumps were placed in a 20 x 24-ft. shed, built on the edge of the river bank so it projected over the bank sufficiently to permit the suction pipes of the pumps to be dropped directly into the water and reduced the suction lift to not more than 8 to 10 ft., as the pumps of this type do not operate satisfactorily at greater lifts. The four 6-in. pumps were set in a row close together and had their discharge pipes connected to a 10-in. header, with the motors on the opposite, or land side of the building. These pumps were designed to run at from 200 to 250 r. p. m.; at the higher speed they should produce a pressure of about 100 lb. at the pump and each deliver 1,125 gal. per minute. In order to run them at this capacity and pressure, assuming their efficiency to be 50 per cent., it would require 140 h.-p.

The first fill above the closing crib across the channel of the river was made with one of the smaller pumps mounted with its motor on a scow. The discharge pipe from this pump was connected by a flexible joint with the force main on land in order that the scow could rise as the pond was filled by the closure of the openings in the crib. The pump used in making the cut and fill on the highway was also set up separately from the main plant.

The force main leading from the pumps in the plant set up for the sluicing outfit used in making the embankment section of the dam was a 10-in. spiral-riveted pipe, with a gate valve between each pump connection to this pipe and with one of these valves beyond the last pump. This pipe line was extended along the face of the bluff about 1,000 ft., being reduced successively to 8 in., and then to 6 in. by wrought-iron pipe with screw connections. Tees with 4-in. outlets for laterals and hose connections were placed in the pipe lines at convenient intervals, 4-in. iron body-gate valves being placed at these tees.

The nozzles used at the face of the excavations were mostly for 4-in. hose, and tapered in 24 in. to an opening 1¼ or 1½ in. in diameter. This taper was uniform, the nozzled end being machined and polished inside for about 2 in. from the tip. Each nozzle was clamped to a 2 x 10-in. plank, about 12 ft. long, that was pivoted to a standard similar to the jack used by a wagon-wheel painter, only heavier. This simple device served the purpose of a more heavily-constructed monitor, or giant, such as is generally used for higher pressures and larger pipes and nozzles. With this arrangement, one man handled each nozzle and was assigned a helper who moved the hose and kept the flumes in shape near the nozzle. Where the grades were sufficient, two men for each line of hose were all that were required in the pit. With such an outfit and the pressure at the nozzle 60 to 80 lb., it was impossible to handle any material more compact than sand and gravel; but, with larger nozzle openings and pressure of 150 lb. at the nozzle, hard clay and loose shale rock may be moved readily.

The nozzles were usually worked in pairs, the force of their streams being concentrated at the bottom of the face of the excavation. In places where the sand was underlaid by clay or hardpan, no special headworks were necessary to divert the water and loosened material to the flumes; but, in sandy and gravelly soil, it was necessary to have a converging box, or a series of boards set up in the form of a V to start the flow into the flumes. The water would cut only a slight channel in the pure clay under the sand and gravel, and as these channels did not seem to be deepened by continued use, they

View of High Bank from Which Material was Sluiced.

Two Nozzles in Operation against the Face of a Cut.

were excellent for sluicing purposes. The nozzles were not used for forcing material along the channels or flumes except when the materials became clogged in the latter.

The flumes were for the most part made of No. 12 gauge black iron in 30-in. semi-circular sections, 10 ft. long. These flumes, including the bending, cost 2¾ cents per pound, or 49½ cents per linear foot of flume. In all, 850 ft. of the flumes were required. The sections of the flumes when lapped 6 in. on an 8 per cent. grade, were tight without any calking or fastening whatever at the joint. Wooden flumes were tried, but they were rapidly cut out by the grinding action of the material carried by the water, although after four months' constant use the iron flumes showed but little wear.

The sluicing work was commenced at the distant end of the pipe line, where the first closure of the river channel was made and where the bluff was lowest. The force main could thus be shortened as the work progressed toward the pumping plant. The total height of the bluff above the finished embankment was 75 ft. On account of the grades required for the flumes, however, the actual face against which the streams from the nozzles were directed did not

TABLE 1. COST OF PLACING MATERIAL IN EMBANKMENT SECTION OF CROTON DAM BY HYDRAULIC SLUICING METHODS.

Cost of Equipment and Materials.	
Two 6-in. Rumsey underwriters rotary fire pumps (new)	$840.00
Two 6-in. Gould underwriters rotary fire pumps (second-hand)	750.00
430 ft. 10-in. No. 16 gauge spiral riveted pipe, cost 60 cents a foot when new, second-hand, 45 cents	193.50
400 ft. 8-in. wrought-iron pipe and fittings (new)	436.45
414 ft. 6-in. wrought-iron pipe and fittings (new); 120 ft. 4-in. wrought-iron pipe and fittings (new)	272.00
Material bought second-hand, including all fittings for the 10-in. line, also 6-in., 8-in. and 10-in. fittings for pumps; 150 ft. 4-in. rubber hose and nozzles; 350 ft. of 30-in. No. 12 gauge flumes used two months on another project	800.00
500 ft. No. 12 gauge 30-in. flume	250.00
Pulleys, belting, 3-in. cotton mill hose and other sundries	200.00
	$3,741.95

Charge 50 per cent. of this total to next job, leaving $1,870.98, to be divided by 104,000, which was total number of cu. yd. of material handled, gives the proportionate cost of plant per cubic yard of material moved, as $0.018.

Items of Labor and Supplies.	
Labor from pay roll, total	$3,774.61
Teams (removing stumps and stone, handling flumes and trestle timber)	248.56
Straw	18.00
Oil, waste, pumps repairs and sundries	118.83
Total	$4,160.00

$4,160, divided by 104,000, cu. yd. of material handled, gives 4 cents per cubic yard of material moved, as cost of labor and supplies.

Power.	Kw.-hours.
Power measured at meter at Big Rapids dam, 18 miles from Croton	138,008
Deduct for line and transformer losses and for power used for other purposes at Croton	46,008
Net power used by pumps of sluicing plant	92,000

92,000 kw.-hours at 1 cent = $920.00, which divided by 104,000 equals $0.0088 per cubic yard of material moved.

Recapitulation of Cost per Cubic Yard of Material Moved.	
Cost of plant	$0.018
Labor and supplies	0.04
Power	0.0088
Motor rental	0.0012
Total cost per cubic yard of material moved, as measured in cut	$0.068

exceed 40 ft., and for the most part was about 30 ft. The greatest distance to which material was moved in the flumes was 800 ft. The flumes were carried on the ground to the edge of the bluff and then to the point where the material was discharged on light pole trestles. They were generally laid on 8 or 9 per cent. grades; but, on some of the longer flumes the grade was reduced toward the end to 5 and 6 per cent. With grades of less than about 6 or 7 per cent., trouble was always caused by stoppages in the flumes, which required one man to about every 50 ft. of flume to prevent. The yellow sand, common to all the pine country of northern Michigan, that was handled in the flumes, will run readily on itself at grades of 10 to 12 per cent. when forced along by the action of water running down a slope.

As the material was deposited at the end of the flume line it tended to form a cone, with the slope depending on the kind of material. The surface of this cone when made up of sand and gravel, seemed to be drained immediately so that it was possible to walk dry shod over the material while it was being deposited. In order not to completely drain the material as it was being deposited, two lines of flumes were used together in order to keep the center of the fill, low, arrangements being made to remove the water at the farther end. In this way a pool of water and soft material could always be maintained between the two points at which material was being deposited by the flumes. In other cases, the fill was deposited against a temporary dam at the end of the slope in order to prevent the water being drained away too quickly, thus giving the material a chance to settle more compactly by being placed under water. The finished slopes of the embankment at 2 to 1, or 3 to 1, were made by placing boards at the bottom of the slope as the latter was started, and by using straw to prevent the water from undermining these boards. As the work progressed the straw and boards were moved up the slope. Toward the end of the fill where the water to be removed was more concentrated, it became necessary to use brush and a crib work of small poles, 2 or 3 in. in diameter, to retain the soft material at the proper slope.

The detailed costs of building this embankment by the hydraulic sluicing method are given in the accompanying table, from which it may be seen that the total cost, including all expenses, averaged 6.8 cents per cu. yd. of material delivered into the embankment, as measured in the excavation from which it was removed. This exceedingly low cost of handling material, as compared with other methods, is one of the most favorable features presented in operating a sluicing plant. Mr. W. G. Fargo, under whose direction the work was carried on, states, however, that a plant of this kind is also particularly valuable as a means of moving material from a high to a low level, where it would be very expensive to handle teams on the steep return grade, and that it is quite satisfactory for depositing material in water, such as in filling a pool or a river channel.

(To be continued.)

THE JUNGFRAU MOUNTAIN RAILROAD in Switzerland will be extended from the Mer de Glace to the summit. The extension, including a 2½-mile tunnel, will be 4 miles long.

The Manhattan Bridge Pedestal.

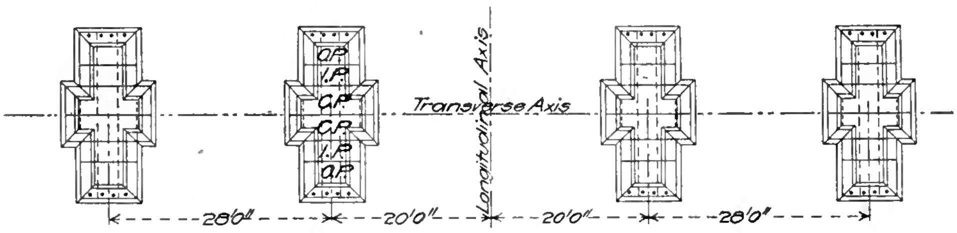
The Manhattan suspension bridge across the East River at New York, between the Williamsburg Bridge and the Brooklyn Bridge, will have, including approaches, a total length of 6,854 ft., and the steel superstructure between anchorages will weigh about 42,000 tons, nearly 19,000 tons of which will be comprised in the 1,470-ft. center span and the two 725-ft. side spans. The center span with a clearance of 135 ft. above mean high tide and the two side spans are double-deck structures 120 ft. wide over all, carrying eight lines of railroad tracks and trolley tracks, two side-walls and one 35-ft. roadway, and are proportioned for a regular live load of 8,000 lb. per lineal foot or a congested live load of 16,000 lb. per lineal foot. They are stiffened with two lines of riveted trusses 24 ft. deep, which are suspended at panel points about 18 ft. apart by four 1¾-in. steel suspender ropes from four main cables 21 3/16 in. in diameter, each composed of 9,472 parallel galvanized wires .192 in. in diameter. The cables are supported on massive cast steel saddles bolted, with 28 2-in. bolts, on top of vertical towers 281.89 ft. high.

Each tower consists of a single transverse bent with four vertical posts rigidly connected to the pier masonry and intended to spring 8 in. in either direction from the center line at the top parallel to the bridge axis with variations of temperature and loading. Each tower weighs about 12,500,000 lb., and each post is made in 14 lengths, each of which is shipped from the bridge shop in two or more pieces of 64 tons maximum weight. Each post has a closed rectangular cross section with 4 interior webs perpendicular to the bridge axis. The dimensions vary from 5 x 10 ft. at the top to 12½ x 33 ft. at the base, where it is seated on a riveted steel sectional pedestal 42 ft. 4 in. long, 21 ft. 10 in. wide and 5 ft. 5 in. high over all, which weighs 190 tons.

It was originally intended to make each of the eight pedestals of cast steel weighing about 380,000 lbs., and composed of six sections bolted together through vertical transverse webs. Owing to the difficulty and delay likely to be experienced in securing and finishing steel castings of these dimensions and shapes it was decided to substitute riveted steel for cast steel in the pedestals which were, however, to retain their original outline and dimensions. They were accordingly redesigned to have about the same weight and corresponding details to those of the castings and have been made by the Bridge Co., for the same pound price as was allowed for the original design.

The pedestal is proportioned to distribute uniformly over 695 sq. ft. of the surface of the pier masonry a maximum vertical load of 20,580,000 lb. produced by the congested live load of 16,000 lb. per lineal foot over the full length of the bridge. The maximum stress in the outer edge of the pedestal is produced when one-half of the main span and one of the side spans is entirely covered by the congested load and the remainder of the bridge is entirely unloaded. This corresponds to a possible deflection of 2 ft. at the top of the tower and although it is not considered probable that this will ever occur, the pedestals are designed to resist the extreme stresses.

The reaction of the masonry under one edge of the pedestal is a maximum of 64,000 lb. per square foot and the corresponding up-lift on the opposite edge may reach 9,000 lb. per square foot, equal to a total up-lift of 334,000 lb. In designing the pedestal it was at first arbitrarily divided into six sections for convenience of manufacture and shipment. The joints between them being located so as to most advantageously receive and transmit the stresses. The general



Location of Main Pier Pedestals of Manhattan Bridge.

outlines were adapted to cast steel construction and to conform with the architectural requirements.

The pedestal is finished on the upper and lower surfaces and on the abutting faces and the different sections are joined together by large horizontal bolts through their vertical webs. Section No. 1 has a maximum vertical load of 6,900,000 lb., which at an assumed coefficient of friction of 25 per cent. will develop 1,725,000 lb. friction with its base plate. The horizontal component of the maximum bending moment in the post produces a total horizontal stress of 3,700,000 lb. at the base of the pedestal.

In order to prevent the possibility of transmission of this stress to the masonry and consequent tendency to rupture the latter, the pedestal is seated on a bed plate made with three full-length longitudinal rolled steel plates 56 in. wide and planed on one side from a thickness of $1\frac{1}{8}$ to $\frac{7}{8}$ in. These plates are seated directly on the accurately dressed upper surface of the pier masonry to which they are connected only by eight $2\frac{3}{4}$-in. anchor bolts coarse-threaded their entire length and grouted in 4-in. holes 11 ft. deep in the pier masonry. These anchor bolts also pass through the base plates of the pedestals and the nuts at their upper ends engage saddle plates on riveted distributing members attached to the pedestal webs. Except for these bolts there is no connection or splicing between the pedestals and the base plates. Under maximum loading the bed plates act as outside splices to the base of the pedestal section developing the tensile strength above mentioned of 1,725,000 lb., which subtracted from the total horizontal stress, leaves a remainder of 1,975,000 lb., which is provided for by the eighteen $2\frac{1}{2}$-in. flange bolts.

The pedestal was designed with its main ribs in the planes of the post webs and virtually forming continuations of them with faced butt joints and splices generally made with double field riveted or field bolted cover plates. In addition to these webs there are provided exterior transverse longitudinal and diagonal webs or extensions to distribute the load over the entire horizontal surface of the wide long base plate. In all cases the connections of the pedestal webs to the webs of the posts were designed to take their proportionate share of the maximum post loads.

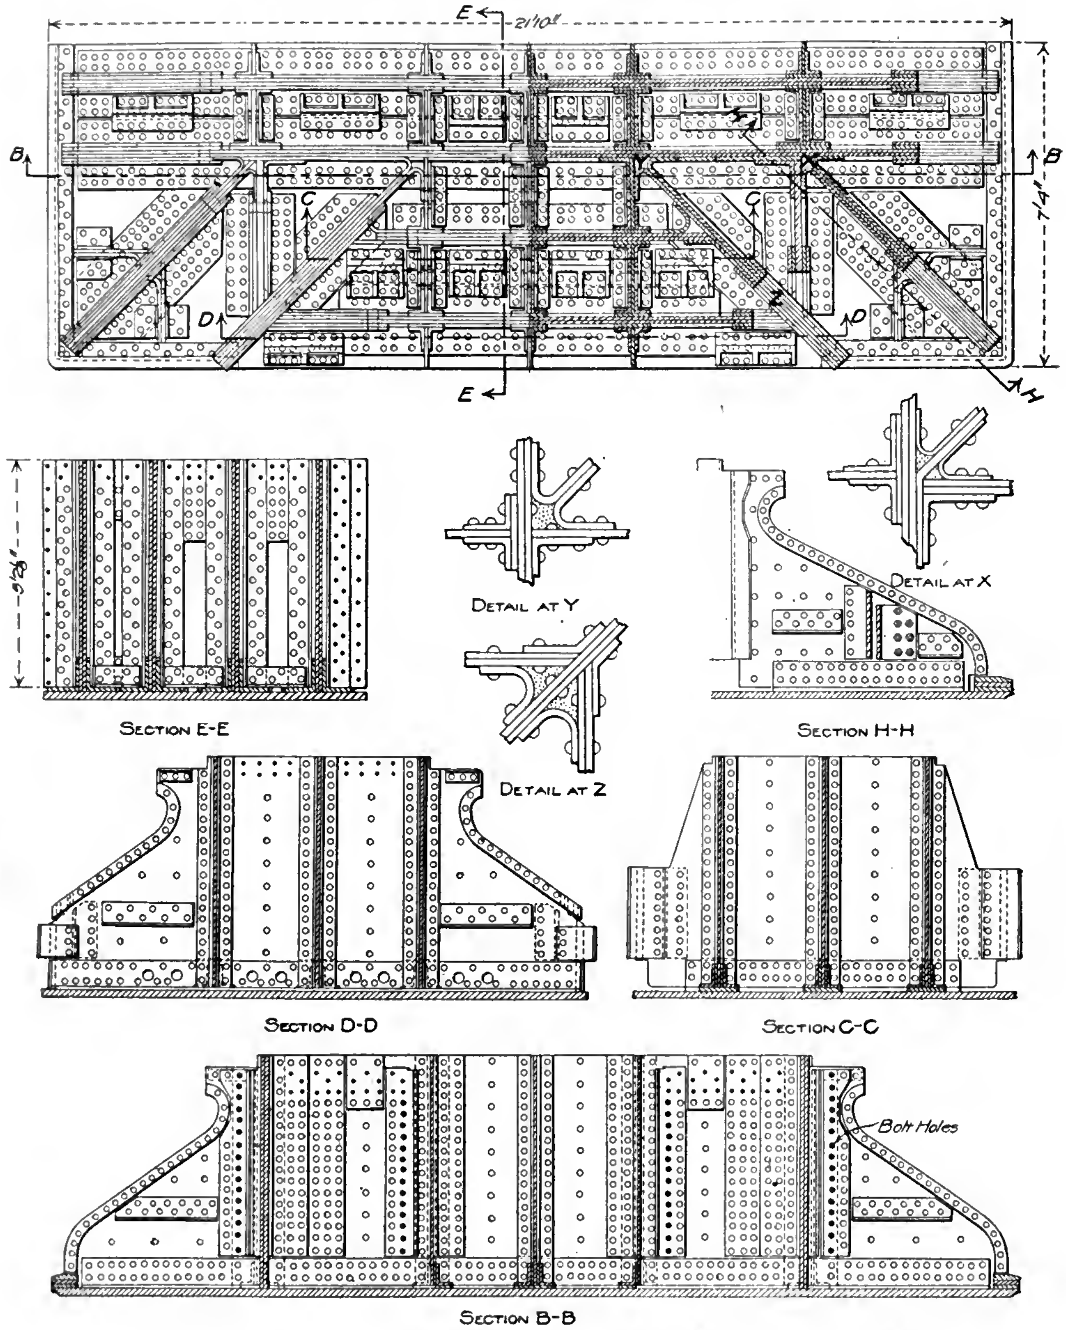
In the two end sections of the pedestal the ribs parallel to the bridge axis are made with continuous full-length webs and were treated in design and computation as simple T-shaped girders with flanges made by the sole plate. The intersecting ribs were made in short sections at right angles to and web-connected with these and are cantilevered beyond their outer faces. The tension in them is designed to be entirely taken up by the sole plate and the compression by the bearing on the web connection.

The diagonal ribs are made up with four web plates, 2 of which extend for a long distance parallel to the longitudinal ribs, riveted integral with them. The other two web plates are bent short to form oblique web connection angles. The rivets are proportioned to provide for all vertical shear and horizontal stress due to the maximum bending in the post. It was arbitrarily assumed that all rivets resisting bending stress were located within 12 in. of the tops of the ribs and it was assumed that the vertical stress is resisted by the remaining rivets in the whole area of the webs. By these assumptions the resultant stress in the upper rivets is reduced to a minimum of ordinary unit value. The remainder of the rivets, of course, receiving low unit stresses.

All of the ribs in the outer edges of the first section of the pedestal are calculated by the methods used for reinforced concrete beams, assuming that all tension is carried through the base plate and that the compression is received by the remainder of the cross sectional area of the member. All rivets are 1 in. in diameter and all rivet holes are drilled from the solid without punching. All spaces between the pedestal ribs will be filled solid with concrete extending up to the man-holes in the post webs. In order to relieve as much as possible the stress on the pedestal base plate and to assist in the distribution of stresses, horizontal angles are riveted to the faces of the webs with their horizontal flanges projecting into and embedded in the concrete.

The pedestal has no regular cap plate and the connection angles on the upper edges of the pedestal ribs, which are notched to receive it.

Each pedestal is divided into six sections by vertical joints transverse to the bridge axis as indicated in the general location diagram which also gives the position of the anchor bolts and shows the cornice and a corresponding stiffener rim around the base plate. The end, intermediate and center sections of each pedestal are symmetrical about its center line transverse to the bridge axis and have respective weights of 31, 19 and 41 tons. The center section has an 80-in. x 2-in. base plate 21 ft. 10 in. long and has in all 24 web plates from ⅝ of an inch. to 1 in. in thickness and 53 in. in maximum width which are riveted together in sets of 2 or 3 to form the



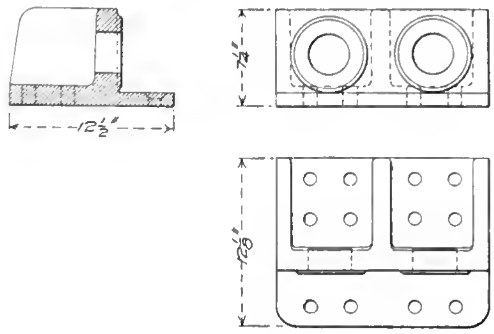
Center Piece C. P. of Manhattan Bridge Pedestals, Weight 41 Tons.

foot of the vertical post has no horizontal base plate. The spaces between the ribs are therefore unobstructed to give clearance for the vertical cover plate, splicing the post webs and pedestal ribs together. The upper edges of the pedestal ribs are, however, connected around the outside by a horizontal cornice of incomplete I-shape cross section made with a $15 \times 2\frac{1}{4}$-in. horizontal web, one $7 \times 5 \times \frac{3}{4}$ in., one $6 \times 6 \times 1$ in., and one $8 \times 6 \times 1$ in. flange angles as indicated in the cross sectional details. The web plate is bevelled for drainage on the upper face where the heads of the flange rivets are countersunk. It is made in sections up to 14 ft. long with mitered joints and is riveted to special flange rim. The flange angles are chiefly $8 \times 8 \times \frac{7}{8}$ in. The curved and inclined outer edges of the ribs are reinforced with double pairs of 3×1 in. flats and the spaces between the bent web connection angles and the ribs are filled solid with slow setting iron rust cement.

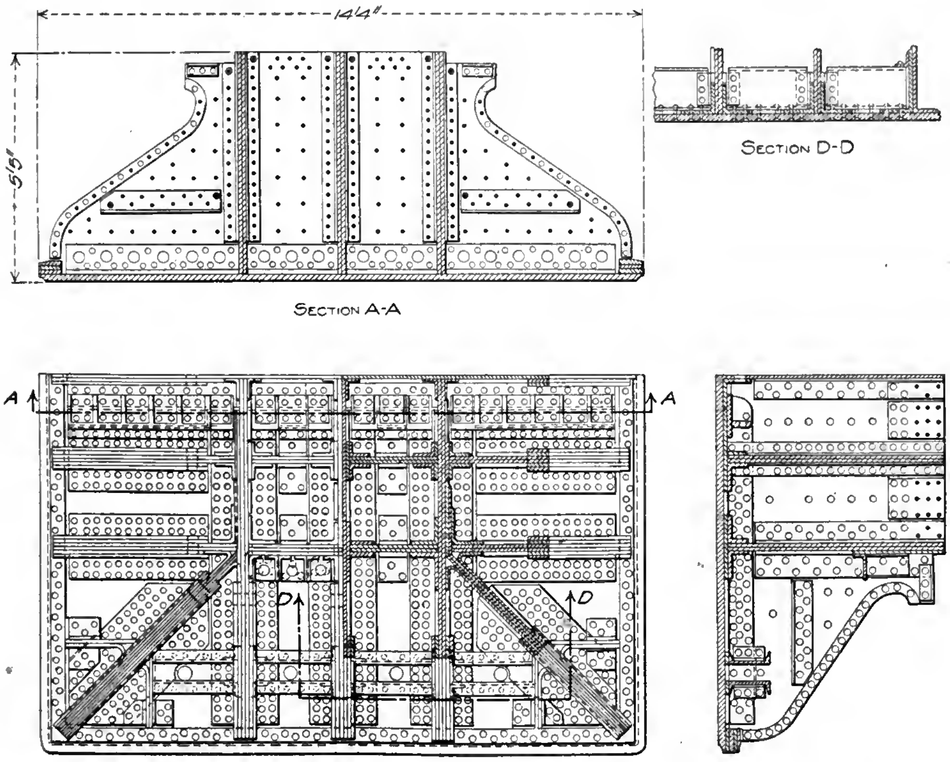
The intermediate section of the pedestal has a 59 x 2-in. x 14-ft. 4-in. base plate and is of comparatively simple and regular construction as indicated in the general assembled diagram. The end section of the pedestal is of complicated construction and has a 107 x 2-in. x 14-ft. 4-in. base plate with web plates 1 in. and ¾ in. thick riveted together in pairs to form the ribs except for the few horizontal bolts connecting the ver-

tical webs of adjacent sections of the pedestal which have nuts taking bearing on the faced surfaces of cast steel blocks riveted to the base plates of the pedestals. The blocks are made for 2, 3 or 6 bolts each, and all of them have unsymmetrical T-shaped cross sections stiffened by transverse webs dividing it into pockets for each bolt. They weigh from 145 to 475 lb. each.

The tower piers have long been finished and the anchorage piers are nearing completion, the 4,948,000 lb. of structural steel in them having already been delivered and set. The fabrication of the remainder of the super-structure has been in progress for several months at the bridge shop and when the erection was commenced in July, 12,887,000 lb. of steel for the towers and 3,770,000 lb. of steel for the pedestals had been delivered to the shops and 2,040,000 lb. of finished tower and pedestal sections had been delivered to the storage yards at Bergen Point, whence it is forwarded daily as required for erection in the super-structure which it is expected will continue simultaneously at both main piers. All of the pedestals have now been completed at the shops and erected. The separate sections were delivered by barges and unloaded by a floating derrick which places them on top of the masonry where they were rolled to position and set by hydraulic jacks.



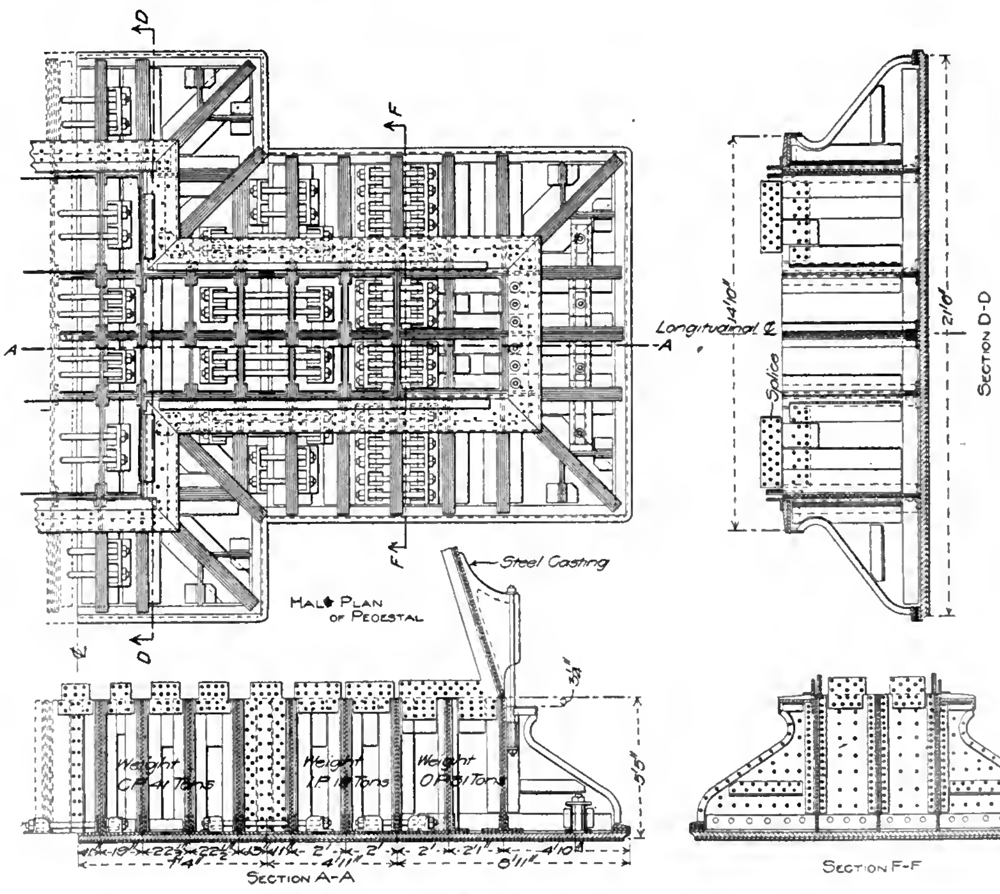
Casting for Splice Bolt.



Outside Piece O. P. of Manhattan Bridge Pedestals, Weight 31 Tons.

The cables are supported over the towers by eight cast steel saddles 11 ft. long 5 ft. 11 in. wide and 3 ft. 4½ in. high over the anchorage on eight sectional cast steel saddles, which are 30 ft. long, 5 ft. wide and 4 ft. high, seated on 60 segmental cast-iron rollers 9 in. in diameter. The saddles, rollers and 4-in. thick bed plates have to be planed, besides which there are 2,500 cast steel cable bands 3 ft. long made with flanged halves bored to a diameter of 21 3/16 in., 2,500 suspender sockets and as many 5-in. cast steel nuts, each weighing 50 lb., and all requiring to be faced or threaded or both. This makes an aggregate of about 2,000,000 lbs. of steel castings with single pieces weighing up to 31,000 lb., and involving a large amount of machine work. The contractors found that although it was comparatively easy to place the orders for the castings there was great difficulty in securing any promises to finish them within a reasonable time and that very high prices were demanded for the machine work. As the contractors already possessed a 50 x 150-ft. convenient and well-lighted machine and repair shop at their Crotch Island quarry in Maine, which was well equipped with steam, pneumatic and electric power, and with abundant ordinary tools, they decided to install there some special machine tools and finish all the castings themselves. They have accordingly purchased from Manning, Maxwell & Moore a 10 x 7 x 18-ft. Betts Machinery Company's planer and a 120-in. horizontal boring mill of the same make, a Dressers' radial drill, a large Cincinnati railroad shaping machine, a 22-in. Reed lathe, and a very heavy combination bolt machine for cutting threads on the 5¼-in. suspender sockets and tapping the nuts and a horizontal emery wheel grinder for spot facing small bearings. These tools have already been installed at the shops and the castings will be shipped to and from the shops by schooner at a freight cost of from 80 cents to $1.00 a ton for each 450-mile trip between the shops and New York City. Careful estimates indicate that a saving of at least $25,000 will be made on the cost of finishing the steel casting besides the great advantage of having the work under the direct control of the contractors and avoiding unnecessary delays and uncertainties.

Several plans have been devised for handling the work in such a manner as to expedite it and greatly economize the cost. Instead of boring the cable bands they will be clamped concave side up, in sets of 10 on the table of the planing machine and they will be dressed by high-speed steel tools with segmental cutting edges set to the exact radius and revolved transversely by a worm gear enabling them to finish the entire cylindrical surface with single cuts, moving at the rate of 22 ft. per minute and taking a chip about ¾ in. wide. The bands will be arranged in two parallel rows on the planer bed and while the concave surface is being finished, side tools will plane one set of lugs after which they will be reversed and the other set planed. A similar device will be used for planing the segmental surfaces of the 480 rollers. Twenty patterns have been made from the 2,500 suspender sockets and they will be finished after the cable saddles and rollers are completed. Over 300 tons of castings are now at the shops from whence the first finished lot has already been shipped back to New York.



Half of Assembled Pedestal; Weight of One-half 90 Tons.

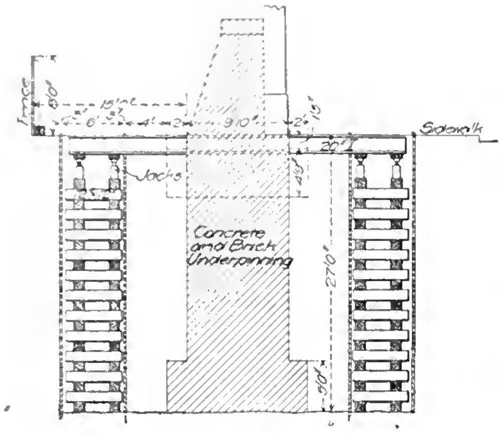
The bridge is designed and constructed under the direction of the Department of Bridges, New York City, Mr. James W. Stevenson, commissioner. Mr. O. F. Nichols, consulting engineer, and Mr A. Perry, assistant engineer, in charge of design. The Ryan-Parker Construction Co. is the general contractor, the riveted super-structure is fabricated by the Phoenix Bridge Company and erected by the Terry & Tench Construction Co.. The cables will be manufactured and erected by the Carbon Steel Co., Mr. Holton Robinson, chief engineer.

Water Purification at McKeesport.

The water purification works now under construction at McKeesport, Pa., are unusual on account of the necessity of softening as well as filtering the supply. The water is drawn from the Youghiogheny River, with a small additional amount from driven wells. Both river and well water contain a large amount of sulphates of lime and magnesia, requiring the use of caustic lime and soda ash, the former neutralizing the carbonic and sulphuric acid and the latter reducing the natural hardness and that added by the caustic lime. The plant has a nominal capacity of 10,000,000 gal. per day. It is a circular building 177 ft. in diameter in the basement, 92 ft. on the ground floor and 64 ft. on the second floor. The water is divided when it enters the plant, a large part flowing directly on its way, while a smaller part passes through lime saturators. This saturated solution is then mixed with the raw water in a channel leading to the mixing tanks, and the passage of the mixture through these tanks completes this part of the process. The water then flows to settling tanks where it is clarified, the stay of the water in the mixing and settling tanks being varied according to the character of the mineral matter. The various tanks and channels are arranged in a circular manner, the inner one being a waste channel from the filters and softening plant, the next one the channel for conveying water from the lime-saturating tanks to the mixing tanks, the next one being the mixing tanks themselves, the next one the channel for conveying water from the mixing tanks to the settling tanks, and outside of all the settling tanks. Outside of the settling tanks is a channel which carries the softened water to the mechanical filter plant containing six beds of 1,000,000 gal. capacity each. The plant was designed by Mr. Alexander Potter, and is being constructed under his supervision, all portions of it being of reinforced concrete.

Underpinning a 400-Ton Piet.

The portion of the double-track subway of the Philadelphia Rapid Transit Ry. located in City Hall Square, is very near the Pennsylvania R. R. Terminal Station, where the excavation was carried through sand and gravel to a depth of about 30 ft. adjacent to one of the piers supporting the train floor and side roof of the depot and estimated to carry a total load of about 400 tons on its 14 x 20-ft. base. The pier was of brick and granite above the surface of the ground and had a rubble footing about 9 ft. deep, seated in the dry earth.



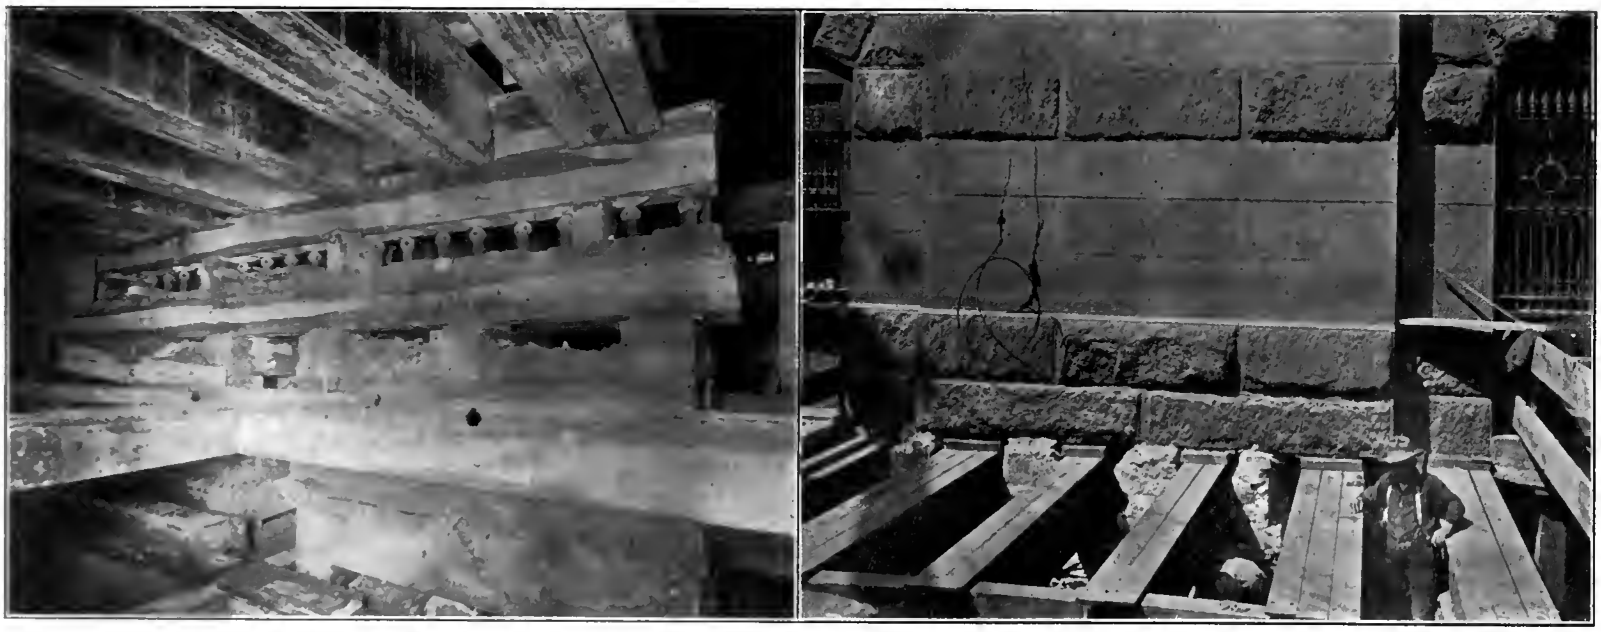
Method of Underpinning Pier.

A sheeted trench was excavated to 6 in. below subway grade on both sides of the pier and from it tunnels were cut through the footing wide enough to receive six groups of transverse I-beam needles and still leave sufficient rubble between them to support the load until it was transferred to the needles. Each needle beam consisted of two or three 20-in. 70-lb. I-beams, 26 ft. long, 16 in all. On the inside of the building the needle beams were supported on longitudinal sills on cribbing in the trench, 12 ft. on centers from the pier. The crib footings had a sufficient area to reduce the pressure on the surface of the ground to about 6,000 lb. per square foot. The opposite ends of the needle beams projected correspondingly about 12 ft. beyond the front of the wall and were seated on a 12x16-in. longitudinal sill supported by a similar cribbing.

About 20 jack screws were set under the sills at each end of the needle beams and were simultaneously operated to transfer the weight of the pier to the cribbing without perceptibly raising the pier. Alternate spaces left between the jack screws were filled with blocking on which pairs of wedges were driven as fast as the screws were operated so as to take up all slack and provide solid bearing competent to carry all the load and prevent any vertical movement should the jack screws fail under stress.

Excavation under the needle beams was carried down between the cribs to sub-grade and a new concrete foundation for the pier was built there clear of the needle beam supports and was carried up nearly to the lower flanges of the needle beams. Brick piers were built up between the needle beams nearly to the base of the masonry pier and engaged it in the usual manner with pairs of capstones separated by steel wedges and grouted in position. After their completion the jack screws were slacked off, releasing the needle beams, which were removed and the spaces they had occupied were filled with brickwork built up as here described. The new foundations contained about 90 yd. of concrete and together with the needling was built in about 22 days by an average force of 17 men.

The work was executed by Henry Sheeler & Sons, Chicago, as subcontractors to the E. E. Smith Contracting Co., general contractors for the City Hall section of the subway. The plans and operation were under the approval and supervision of the Philadelphia Rapid Transit Railway Co., Mr. W. S. Twining, chief engineer; Mr. Charles M. Mills, principal assistant engineer, and Mr. Frank R. Fisher, resident engineer.

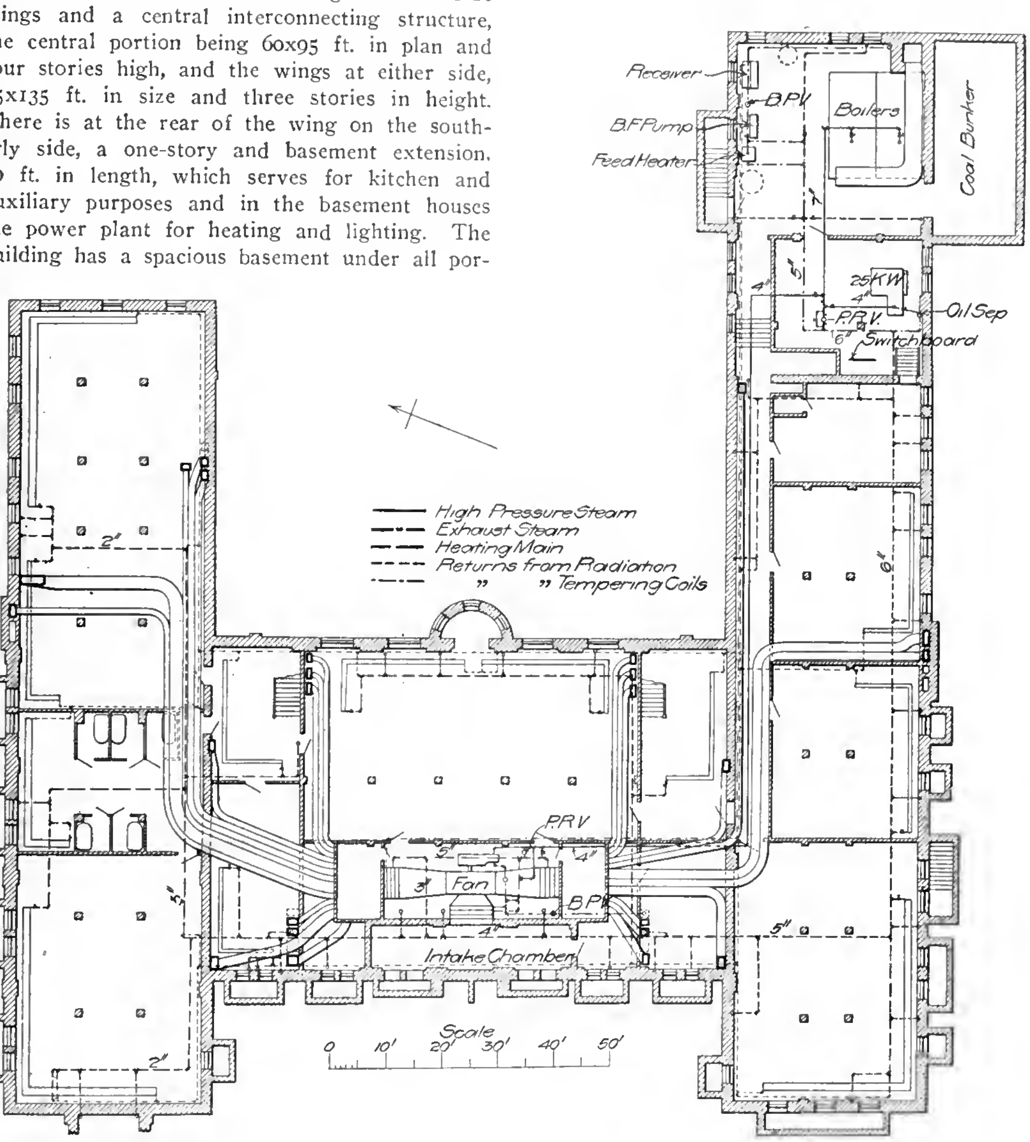


Needlebeams through Pier Footing and Jacks Used in Underpinning a 400-Ton Pier.

Coal Mining in Illinois during 1906 produced 41,180,100 short tons, or 7.9 per cent. more than in 1905, ranking second only to West Virginia. In anticipation of the suspension of operations which took place on April 1 the Illinois mines were operated to their fullest capacity for several months prior to that date, and the shortage due to the suspension was, to a great extent, provided for. After operations were resumed in June the intensity of labor among the mine workers was considerably greater than usual. This is shown by the fact that the average daily output per man was 3.13 tons in 1904, 3.29 in 1905 and 3.49 in 1906. According to the U. S. Geological Survey, a large part of the increased efficiency in labor was probably due to a greater use of machines for undercutting coal. In 1906 there were in use in the coal mines of Illinois 1,048 machines, and the machine mined product was 11,585,419 short tons, against 882 machines and a machine-mined product of 8,697,547 tons in 1905, and 643 machines and 7,110,902 tons in 1904.

Heating System of the St. Francis Home, Detroit, Mich.

The St. Francis Home for Orphan Boys is an orphan asylum that is being built near Detroit, Mich., by a Catholic organization of that city as a memorial to Bishop John S. Foley. It is located in a district known as Highland Park, about one mile beyond the northern city limits on Woodward Ave., where a large tract of land was secured for the grounds. An imposing structure of considerable size has been built of brick wall-bearing construction, with hollow-tile floors on steel beams and tile roofs, which provides dormitory and educational facilities for 300 orphans and the requisite number of teachers and attendants. The building has two side wings and a central interconnecting structure, the central portion being 60x95 ft. in plan and four stories high, and the wings at either side, 35x135 ft. in size and three stories in height. There is at the rear of the wing on the southerly side, a one-story and basement extension, 60 ft. in length, which serves for kitchen and auxiliary purposes and in the basement houses the power plant for heating and lighting. The building has a spacious basement under all por-



Mechanical Plant in Basement of St. Francis Home, Detroit, Mich.

tions, the first floor being from 3 to 4 ft. above grade, and there are attic spaces over both of the side wings.

The building occupies a particularly exposed location and has large areas of wall and window glass exposure, so that the problem of heating was one of considerable magnitude. In addition, ventilation is necessary in the greater part of the building owing to the number of dormitories, school rooms and other public rooms which will be occupied by large numbers of persons. Accordingly a scheme of heating arrangement was chosen which combines hot blast heating for all of the pubic parts and rooms which will, at times, be extensively occupied, such as the dormitories, the large dining-room, the chapel, etc., and direct radiation for the heating of all smaller rooms and for auxiliary heating in the larger public rooms. A feature of the installation is the use of hot blast heating in the dormitories to the entire exclusion of direct radiation, this being particularly feasible as the ventilation is essential at night when the large numbers of beds in them are occupied and, as the rooms are not occupied in the day time, no heating is required except at night time; the heating requirements are similar to these in the school rooms, no heating being required when they are not occupied, and they are accordingly fitted for indirect hot blast heating only, there being, in fact, no direct radiation above the second floor in the south wing and above the first floor in the remainder of the building, excepting in the toilet rooms in the central portion.

The heating installation is accordingly a simple one, insofar as direct radiation is concerned, there being but two radiators each on the third and fourth floors while the radiation on the lower floors is comparatively small in amount, excepting on the second floor of the south wing where a number of smaller rooms are individually heated. The total amount of direct radiation installed in the building is 4,450 sq. ft., comprising 3,600 sq. ft. in cast-iron radiation and 850 sq. ft. in pipe coils, while the total heating surface for the hot blast systems amounts to about 6,800 lineal feet of 1 in. wrought iron pipe. The distribution of the direct radiators is such that the greater part of those on the first floor and all surface in the basement, which consists of ceiling pipe coils, are supplied by convenient connections from the ceiling steam distribution mains in the basement, while the radiation on the second floor is supplied by 17 risers that are of comparatively small size and rise to the second floor level only, excepting two that supply toilet-room radiators of the two upper floors. The direct radiators, where depended on solely for the heating of the smaller individual rooms, are proportioned to counteract the heat loss from walls and windows upon the usual thermal unit basis, and are placed in the usual arrangements under window sills in all cases. They are of the Rococo and Perfection types of cast-iron radiation built by the American Radiator Co., and are fitted with Crane Co. supply valves and Monash air valves, which connect to a system of drain piping leading to the basement. The pipe coil surface for heating the basement rooms comprises a total of 1,700 lineal feet of 1½-in. wrought-iron pipe, which is distributed in 14 sections of sizes from 75 to 250 lineal feet each. These units are distributed along the outer wall lines of the basement rooms near the windows which rise to the ceiling line and are proportioned with regard to the rooms heated on the thermal unit basis similar to the other radiation.

The heating, both direct and indirect, is operated with low-pressure steam supplied partially from the exhaust of the steam-using machinery of the power equipment of the building, with provisions for supplementary live steam supply from the high-pressure system, when necessary. The steam-using machinery installed at the building consists of a 25-kw. electrical generating unit and two pumps for boiler feeding and condensation return purposes which are located in the power plant at the rear of the south wing and the engine driving the fresh air supply fan in the front portion of the basement. These units are all connected to a common exhaust main in the ceiling of the basement which serves as the source of heating supply for both direct and indirect radiation, relief to the atmosphere being provided by a 5-in. extension from the boiler room end of the main, through a back pressure valve, to an exhaust head above the roof of the power plant extension and through a 3-in. extension of the fan room division of the main similarly through a back pressure valve to a roof exhaust head. The three groups of machinery deliver steam into the main through oil separators to keep the heating system free from lubricating oil, that in the fan engine exhaust being a 4-in. separator while 5 and 3-in. separators are used in the generator engine and pump connections. This exhaust main is a 6-in. line throughout the basement of the east wing to the point of connection with the generator engine and reducing valve for live steam supplementary supply, beyond which it extends as a 5-in. line to connect with the boiler feed water heater, the pumps and thence to the atmospheric relief connections; near the front a 5-in. branch extends from the main across to the north wing of the building through which connection is made to the fan engine division of the system. The latter connection is, however, but 3 in. in size, as it is calculated that the fan engine will always, when running, supply all or nearly all of the steam that will be needed for the indirect heating coils and the 3-in. connection is intended principally for supplementary supply. This fan room main is a 5-in. line into which the 3-in. delivery connection and the 4-in. engine exhaust delivers, and there are also live steam supplementary connections at this point also for additional heating capacity if required.

The direct radiation is, owing to the short length of the supply risers, operated on the one-pipe system with a system of returns by gravity from a number of points in the supply main. The risers supply but 1 or 2 units on each floor level, and, owing to the comparatively small amount of surface required, are of but 1½ and 2-in. pipe for the 15 risers that are carried to the second floor level; only two of the risers, which are carried up to supply toilet-room radiation on the third and fourth floors, are of 2½-in. pipe. The connections from the risers into the supply mains are made for the greater part at an angle of 45 deg., with ample provisions

for expansion of the main and connections, and the risers are firmly anchored to the steel work of the building by clamps near their bases permitting expansion in an upward direction. In most cases the risers are run concealed in recesses or chases provided for them, and the radiation branch connections are run exposed above the floor except where the distance between the riser and the radiator is such that sufficient drop is not available above the floor, when the connection is made on the ceiling of the floor below. These connections are so arranged that there is a pitch between the radiator and the riser connection of at least ¼ in. per foot when the riser is hot and expanded, and the branch connections are so made that the riser may freely expand without moving the radiator. With this system of returns the risers drain directly into the steam supply main which is pitched in the direction of the flow of the steam and is drained at convenient points and at the ends, through hydro-static seals to the return main; these seals are return or U-pipe connections, 6 ft. in length, in which the condensation accumulates and prevents direct steam communication from the heating supply main to the return main, these seal pipes are fitted with flanges so that they may be readily disconnected for inspection and cleaning and also have drain cocks for drawing off the condensation accumulated. In addition to these at the ends of the mains and all branches there are similar water seals at the basis of all risers which are more than 20 ft. from the connection to the supply main so that drainage to the latter would be difficult, and all of the ceiling pipe coil heating surfaces in the basement are similarly drained to the return main.

The condensation from the direct radiation is, as above stated, returned to the boiler-room by gravity, a 3-in. return line being carried on the floor of the basement to all parts of the building paralleling the steam supply mains. Into this all of the drainage seals of the direct radiation system are connected, the heating coils of the indirect systems being connected into an independent return line with discharges through steam traps to permit of the use of high pressure steam in the coils if necessary. This return line from the direct radiation has a full size extension from its receiver tank end to connections with the two boiler units of the plant, permitting the direct radiation to be operated with the gravity return whenever the fan apparatus, the pumps and other high pressure machinery are not in use. The radiator air valves connect through ¼-in. lines to ½-in. risers paralleling the steam supply risers and the air risers in turn connect into a system of ¾-in. air mains in the basement which extends to the catch basin to discharge any water of condensation that may pass the air valve. All of the heating piping, both for steam supply and return, is covered with 85 per cent. magnesia sectional covering, canvas jacketed and banded, which ranges from ⅞ in. in thickness on the smallest pipes to 1½ in. on the larger pipes.

The indirect heating system is operated by a single large blower unit which is located in a 14x48 ft. room in the front portion of the basement, having a fresh air intake through the space under the porch of the front entrance and deliveries connected to numerous galvanized iron ducts leading into brick flues rising to the upper floors. The blower is a ¾-housed double-discharge steel plate fan of the centrifugal type, built by the American Blower Co., which is designed for a delivery of 22,400 cu. ft. of air per minute with a speed of the wheel of 200 r. p. m. The wheel is 7 ft. in diameter by 4 ft. in width, and is directly connected at one end with a simple vertical steam engine of the enclosed self-oiling type which was supplied also by the company building the fan. This engine has a 10x12-in. cylinder and is designed to operate the fan to its maximum capacity with steam at an initial pressure of 35 lb., and exhausting against a back pressure of 5 lb. per square inch, it being the intention to utilize the exhaust from this engine in the indirect heating coils at all times during the heating season when the fan is operated. Steam is supplied to the engine by a 4-in. line extended from the high pressure header in the boiler-room to the fan room where it has connections to the heating coils and a 3½-in. branch with steam separator to the engine throttle valve.

The fan has its intake through an 8x36-ft. space under the front entrance porch of the building which space may also serve to accomodate an air filter, if air filtration should at any later time prove necessary. Into this chamber two windows open from the outside, having free areas of about 20 sq. ft. each, and they are fitted with tight closing sash which may be shut in case it is desired to close down the fan system in cold weather. In the connection from this chamber to the fan casing, there is installed a tempering coil containing 2,250 lin. ft. of 1-in. pipe, which is disposed in three 4-row sections, in order to facilitate the adjustment of the surface to the heating requirements. The fan discharges through an arrangement of two plenum chambers, one at either end of the fan room from which the delivery ducts to either side wing of the building are supplied, a connection from each of the two horizontal discharge outlets of the fan leading to one of the plenum chambers with an enlargement of the casing near the latter containing a reheating coil. These reheating coils each contain two 5-row sections of 1-in. pipe having a total amount of surface equal to that of the tempering coil, the arrangement of pipes in these heaters as well as also in the tempering coil being such that a free passage for air between pipes 1½ times that of the cross-sectional area of the duct connections is secured. Air mostening connections are installed in each of the plenum chambers, consisting of ½-in. pipes, 10 ft. long, which are drilled with large numbers of 1-32-in. holes and connect with the low-pressure steam mains for delivery of vapor to the hot air blast.

Each of the three heating coils have two Monash air valves to prevent air binding, and they are, as above stated, supplied with steam from the exhaust steam system with returns independent from those of the direct radiation in order to permit of their operation with high pressure steam if required. The exhaust steam from the fan engine will always be utilized in the heating coils in cold weather, the fan engine exhausting through a 4-in. line with oil separator into a 5-in. low-pressure receiver-header in the fan room, into which is also connected a 3-in. branch from the low-pressure heating main from the power plant for purposes of reserve supply. This header has 3-in. branches to all of the heating coils and has in addition three 2-in. connections from the high-pressure steam main for live steam supplementary supply if required; two of these high-pressure connections lead direct to the header, one through a 3x6-in. reducing valve for low-pressure supplementary supply, and the other a by-pass direct, while the third is carried beyond and connects into the branch which feeds the tempering coil, this arrangement being made to permit of delivering high-pressure steam to the tempering coil independent of the supply to other coils. These heater coils have a separate system for condensation return to the receiving tank in the boiler room consisting of a 2½-in. line into which each of the coils discharge through a 2-in. Morehead trap. This permits an extra pressure to be carried on any or all of the heating coils without interference with the low-pressure direct radiation system.

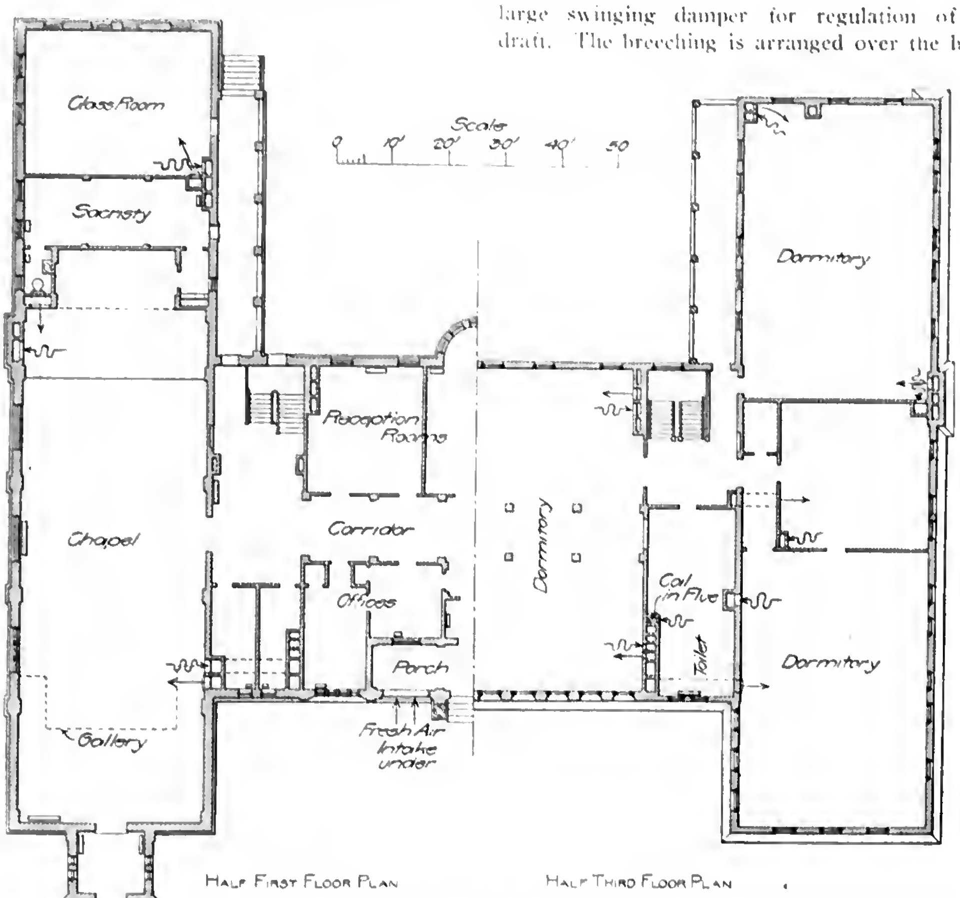
The plenum chambers are 8x12-ft. air-tight enclosures partitioned off in either end of the fan room, from the outer walls of which the air delivery duct connections are made. Of these there are 11 originating in the south chamber to supply rooms in the south wing and 13 from the north chamber to supply the north wing, making 24 delivery ducts in all. The chambers are built of 9-in. brick walls which are carried up to within 4 in. of the basement ceiling and there covered with tops of No. 16 black iron stiffened with angles. Each of the chambers has also a horizontal partition or diaphragm at a level of the base of the heater coil, the upper portion for the heated air from the reheating coils, and the lower portion for tempered air direct from the fan, suitable mixtures of the two being obtained by dampered openings in the diaphragms. The delivery ducts are for convenience of erection installed of a uniform depth of 20 in. for all widths, securing thus a uniform head-room throughout all portions of the basement, and range in width from 10 to 24 in., according to the capacity. Six of them are 10-in. width, 10 of them 12-in., 2 each 14, 16 and 18 in. in width and one each 20 and 24 in. wide. The ducts are all built of No. 24 galvanized iron, thoroughly braced and they are all laid out with easy bends of long inside radius, ending in a sweep sheets in the form of one-quarter circles at the bases of the masonry flues through which delivery is made to the upper floors; these sweep sheets are of No. 16 galvanized iron extending the full width of the flue with flanges securely driven into the joints. Every duct connecting with either of the plenum chambers is fitted with an air gate or damper by means of which the connection can be entirely closed off when the room supplied is not in use, the gate consisting of a No. 18 galvanized iron diaphragm so pivoted and mounted that it can be set for one-third opening, one-half opening or other adjustment as desired.

Ventilation is applied to all rooms on the downward system, the air supplied being delivered to outlet registers near the ceiling or at considerable elevation above the floor, while all exhaust connections have intake registers at or near the floor line. All registers both for fresh air outlets and exhaust, are fitted with screens of narrow flat wire of 1¼-in. mesh which are mounted on wall frames of the reverse bevel pattern, and all fresh air outlets have in addition diffusers attached which are adjustable and may be set to spread the air into any portion of the room desired. The amounts of air supply provided for each of the rooms served were designed with reference to the heat loss by both the exterior exposure and the change of air in ventilation, the amount of air required for ample ventilation being thereby secured. The duct lines are proportioned for comparatively low velocities, the average velocity of flow being but 500 ft. per minute in the duct lines and flue risers, which velocities are further reduced in the outlet register connections.

Provisions for exhaust registers have also been made in all of the rooms fitted for indirect heating in order that free circulation of air in these rooms may be secured for ventilation purposes. Systems of masonry flues are incorporated in the building construction in arrangement similar to that of the fresh air supply risers which have register openings into the rooms served at their bases and rise to hooded outlets above the roof. The flues have galvanized iron sweep sheets at their bases, similar to the fresh air supply risers, and the register openings are similar in construction and size to those for fresh air supply to the various rooms. No dampers are provided in these flue connections, closure, in case the

ventilating systems are shut down, being effected by the usual register dampers. The exhaust flues, connections and registers are similar in size to those of the fresh air supply system, for capacity of exhaust equal to that of supply, but no mechanical exhaust equipment has been provided, these vent flues operating by natural draft. Exception to this occurs only in the toilet-room vents, in which rooms positive changes of air were desired regardless of the operation of the fresh air supply system. For this purpose aspirating coils or stacks were installed in the flue from each of the large toilet-rooms at either side of the central portion of the building, the coils each consisting of two 9 sq. ft. colonial sections of cast-iron radiation which are placed in the vent flues just above the inlet openings.

The power plant of the Home is located in the basement of a 30x60-ft. one-story extension at the rear of the south wing of the building, the first floor of which accommodates the kitchen and culinary department of the building. The basement space is divided into a 34-ft. section accommodating the boilers, pumps and auxiliary equipment and a 25-ft. section for the engine and electrical generating equipment. The floor is depressed about 9 ft. below grade, giving a clear head-room of 14 ft. in both rooms and ample daylight lighting is provided by side windows above the grade line. A stairway opening on the inner court side provides for access to the boiler-room from the outside for machinery parts, etc., and on the opposite side there is an underground storage bin, 15x34 ft. in plan, built of concrete retaining walls alongside of the boiler-room with floor on level with that of the latter room and covered over the top with a 7-in. reinforced concrete slab. This arrangement of bin greatly facilitates the storage of coal, coal being delivered to the same by driving coal wagons directly on to the roof of the bunker and discharging through coal holes. The bunker has a capacity of about 150 tons if filled to the roof and coal is handled to the boiler room by wheeling from a door at the forward end conveniently located opposite the firing floor in front of the boilers.



Ventilation of Chapel and Dormitories.

The equipment of the power plant consists of two 70 h.-p. return tubular boilers with space available for a third unit, which supply steam for the heating of the building and for the operation of a 25-kw. electrical generator unit in the adjoining room. The boilers are set in a substantial brick setting on the side of the room adjoining the coal bunker with a 10-ft. firing floor at the front and a 5-ft. space at the rear for blow-off and breeching connections, while a space of 10 ft. is left at the opposite side for a possible future unit and the auxiliary equipment of pumps, feed water heaters, etc. The boiler furnaces are fitted with shaking grates for hand firing which were designed for operation with bituminous coal. The products of combustion are removed to the stack by a 34x40-in. iron breeching, built of No. 8 sheet steel and heavily covered with asbestos blocks and fitted with a large swinging damper for regulation of the draft. The breeching is arranged over the boiler fronts to facilitate extension to a future third boiler unit if additional capacity should be needed.

The boilers are of the fire tube type with 60-in. shells, 14 ft. in length, and each contain fifty-four 3½-in. tubes. They were built by the Gem City Boiler Works, and designed for operation with a working pressure of 125 lb. per square inch. They are without domes, but are fitted with 7-in. perforated dry pipes, 7 ft. in length, through which steam is delivered to the nozzles. Each boiler has three nozzles, one 2 in. in size for connection to an auxiliary steam line in the boiler-room, a 6-in. nozzle at the middle for the main steam header connection and a 4-in. nozzle at the rear for the safety valve. The outlet from the latter is piped to deliver into the stack through a 5-in. vapor line. The boilers are fed through 2-in. branches from a 2½-in. feed line carried over the boiler fronts and each has a 2-in. blow-off connection from the rear end of the shell connecting to a 2½-in. line which delivers into a blow-off tank in the rear portion of the boiler-room. The blow-off tank is a circular cast-iron receptacle 36 in. in diameter by 36 in. deep with a 3-in. vent pipe carried up through the roof and it has a 4-in. overflow connection to the sewer in the adjoining street with check valve and an auxiliary connection to a catch basin in the boiler room floor which may be used in case of water backing up in the sewer; this catch basin is drained by a 2-in. ejector which is installed to raise any water from this source or from boiler-room drainage into the sewer.

The boiler-room auxiliaries consist of two pumps and a feed water heater, one of the pumps a plain boiler feed pump and the other a receiver pump for the return of condensation from the heating system. The pumps are both brass-fitted duplex pumps with 6x4x6-in. cylinders and the condensation receiver is of the usual type fitted with float valve for the automatic control of the pump, the suction connection to the receiver pump being tapped for a cold water chilling or condensing connection to condense vapor and chill the returns if coming from the heating system too hot. This boiler feeding equipment is supplemented by an injector of 150 h.-p. capacity which has connections to the cold water supply and delivers to the main boiler feed header. The feed water is heated in a closed tube heater which is designed to heat 3,000 lb. of water per hour from 40 deg. F. to 200 deg. with exhaust steam at ½ lb. pressure; it contains 40 sq. ft. of heating surface, made up of 1½ in. brass tubes No. 13 gauge, and is so connected that the water heated by it may be delivered either to the boilers or to the hot water service of the plumbing system. Steam is supplied to the pumps and injector by a 2-in. auxiliary boiler-room main which connects with the 2-in. nozzles on the boilers, connections also being made from this line to the domestic water heater for use with high pressure steam to the exclusion of exhaust if desired.

The water supply from the boilers is derived principally from the condensation returns from the heating system, with make-up from the city water system.

The electrical generating equipment consists of a 50 h.-p. simple horizontal engine, direct connected to a 25-kw. direct current multipolar generator which is operated at 220 volts for lighting and power service in the building. The engine is a simple automatic engine of the heavy duty self-oiling type, built by the Atlas Engine Co., and is designed to deliver full capacity with an initial steam pressure of from 60 to 90 lb., and a back pressure operating non-condensing of 5 lb. per square inch, when operating at 300 r. p. m. It is supplied with steam by a 4-in. branch from the 7-in. boiler-room high-pressure header and exhausts through a 5-in. connection with oil separator into the 6-in. basement exhaust and heating main. The engine is fitted for close regulation and is capable of withstanding an overload of 25 per cent for an extended period. The generator is a 220-volt direct current multipolar machine, supplied by the Fort Wayne Electric Co., which similarly has an overload capacity of 25 per cent., for an extended period without overheating. The electrical system in the building to be operated comprises 850 16-candle power lamps, distribution to which is made on a wiring system having 87 circuits and 359 outlets in the various parts of the building.

The building was designed and the power plant and heating and ventilating equipment laid out by Stratton & Baldwin, architects, Detroit, Mich. Mr. F. F. Van Tuyl was consulting engineer for the power and heating and ventilating equipments.

Fly-Wheel Insurance Rates have been decreased 20 per cent. by one of the casualty companies in case the power plants are equipped with an approved engine stop and speed limit system. The company has found that such apparatus affords such a degree of protection from accidents that its use in any plant should be recognized by the reduced rate mentioned.

Granite-Top Macadam Pavement in St. Paul, Minn.

University Ave., in St. Paul, Minn., was paved with granite-top limestone macadam for a length of three miles last year, and the same pavement is now being laid on the portion of the street extending from the end of this work to a point near the city limits. This street is the main thoroughfare between St. Paul and Minneapolis, a large volume of all kinds of traffic being tributary to it. It has a clear width of 120 ft. from lot line to lot line, and is paved to a width of 69 ft. A double-track street railway is placed in a 17-ft. strip at the center, thus leaving a 26-ft. roadway on each side.

The cross-section of the street and a detailed cross-section of one of the 26-ft. roadways are shown in an accompanying illustration. The 6-ft. walk on each side of the street abuts against the lot lines, providing a parking, 19.5 ft. wide between it and the curb. The curb is of Kettle River sandstone, 5 in. thick at the top, when dressed, and is set on a sand foundation. The macadam has a total thickness of 12 in. at crown, and at the quarter points of the distance between curbs, and of 9 in. at the gutter. The soil on which the macadam is laid directly, after the grading has been done, is quite sandy and of considerable carrying capacity.

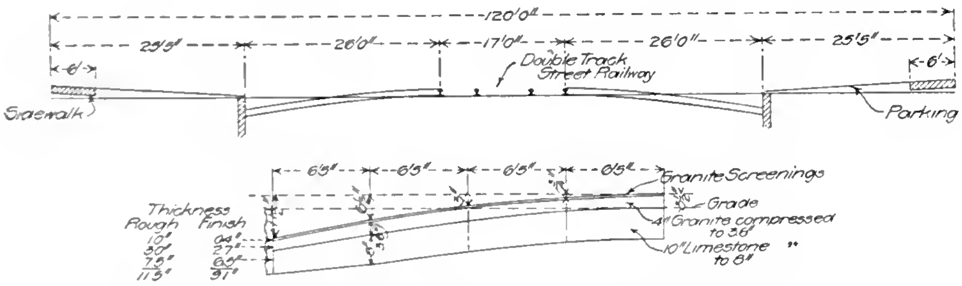
The macadam is laid in three courses, a footing course of crushed limestone, a wearing course of crushed granite and a finishing coat of limestone screenings. During the laying of each of the three courses of stone a quantity of Westrumite, a proprietory liquid preparation, is applied, the intention being to apply 1 gal. of the preparation to each square yard of pavement. This preparation is a liquid compound which makes an emulsion in water and has peculiar qualities for laying dust.

The limestone in the footing course of the macadam is required to consist of pieces which will pass a 2½-in. ring in their greatest dimensions and none of which shall be less than 1 in. in the smallest dimensions. This stone is placed to a depth of about 9½ in. at the crown and quarter points of the street and 7½ in. at the gutter. On it is spread a sufficient amount of limestone screenings to fill the voids. The stone is then sprinkled with water and rolled with a 10-ton roller until an even surface is produced. A ½-in. layer of limstone screenings saturated with a 50 per cent. solution of the Westrumite is then applied, after which the course is rolled until it is thoroughly compacted, sprinkling being done during the rolling with a 10 per cent. solution of Westrumite. The footing course finished in this manner is intended to have a full depth of 8 in. at the crown and quarter points and of 6 in. at the curb.

The wearing course consists of New Ulm, Minn., granite, crushed so all pieces will pass a 1½-in. ring, but none of them less than ½ in. in their smallest dimensions. This crushed granite is placed to a depth of 4 in. at the crown and quarter points of the street, and 3 in. at the gutter before rolling. Prior to and during the rolling the stones of the course are thoroughly sprinkled with a 10 per cent solution of the Westrumite.

Limestone screenings, saturated with a 50 per cent. solution of the Westrumite are then spread over the course to a depth of 1 in., or so as to fill all interstices, and are then rolled thoroughly. During this rolling the screenings are sprinkled with a 50 per cent. solution of the liquid compound, at least 2 quarts of the latter being used to the square yard of surface. The granite and the layer of screenings are intended to have a depth of fully 3.6 in. at the crown and quarter points of the street, and of 2.7 in. at the gutter, when finished. After the roadway is finished to the required thickness, it is sprinkled four times with a 15 per cent. solution of Westrumite. These sprinklings necessitate the use of about 1 quart of the liquid per square yard of surface; sufficient intervals are allowed between the sprinklings to permit the previous application to become thoroughly dry.

The space between the car tracks is paved by the street railway company according to plans approved by the city. In this work, however, no Westrumite was used, except in applying the top layer of crushed granite, and the limestone screenings.



Cross-Section of Macadam Pavement on University Avenue, St. Paul.

During the year it has been in service, the pavement built by the city has been very satisfactory under the heavy traffic which it carries. The surface has been sprinkled about once in 10 days during the summer, and is as free from dust as is a street regularly sprinkled with water several times a day. At the same time, this portion of the street is so far from the center of the city that it is impracticable to sweep it regularly.

The macadam was built at a cost of $1.40 a square yard, including the cost of the proprietary compound, but exclusive of grading, curbs, and so forth.

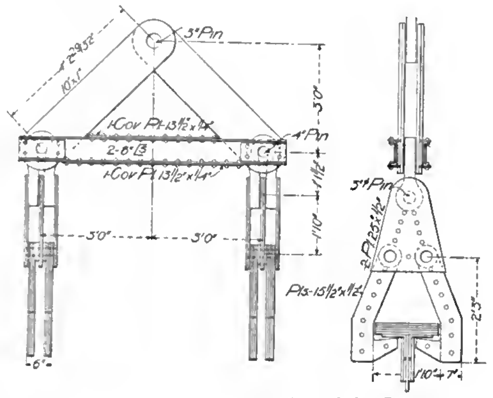
The plans for this pavement were prepared and carried out under the general supervision of Mr. L. W. Rundlett, commissioner of public works of St. Paul. Mr. A. B. Starkey, assistant commissioner of public works, who personally directed the execution of the work, supplied the data from which these notes have been prepared.

An Engineering College for Chinese Students is to be opened at Tongshan, China, by the Imperial Railway management in conjunction with the Chinese Engineering & Mining Co. Accommodations will be provided for about 140 students.

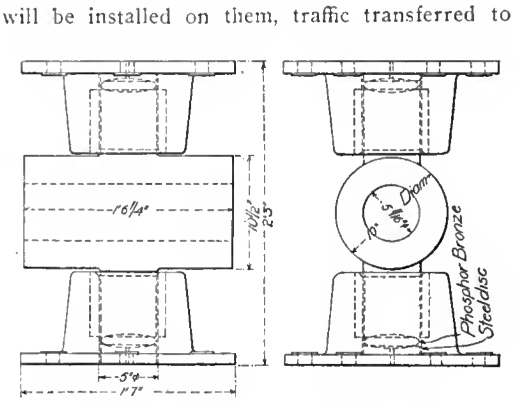
Erecting Six-Track Plate Girder Bridges With a Derrick Car.

Improvements now being made on the Harlem Branch of the New York, New Haven & Hartford R. R. include the abolition of grade-crossings at many points by the elevation of the two existing tracks, the addition of two new tracks and the building of sub-structures for these four tracks and to provide for two more tracks of the New York connecting railway which will hereafter be installed. In some cases the crossings are made with single spans and in more cases with a long center span over the street and two short approach spans over the sidewalks. The maximum widths of crossings are 100 ft., and the maximum length and weight of girders are 80 ft., and 60 tons respectively.

The concrete piers and abutments are built in two successive sections approximately symmetrical about their center lines. The first section includes about one-half of the substructure adjacent to the present low level double track and as close to it as will allow clearance for trains. These portions are made to accommodate three tracks and after their completion two tracks will be installed on them, traffic transferred to them from the low level tracks and the latter abandoned. The present low level tracks will then be removed and the remainder of the substructure completed on the side previously occupied by them. Finally, the super-structure for the third and fourth and for the fifth and sixth tracks will be erected on the completed substructure. The bridges are made with double track units, each of them consisting of three girders. Most of the girders have through floors and are 14 ft. 4½ in. apart on centers.



Lifting Device for Derrick Car.



Connection at Top of Mast.

A contract for the fabrication of structural steel has been awarded to the Pennsylvania Steel Co. Another contract for the erection of 18 spans has been awarded to the Lucius Co., which has designed and constructed a special derrick car intended to erect the girders with the maximum safety, rapidity and economy and to be suitable for erecting miscellaneous railroad girders after the completion of this contract. The car and its equipment weighs about 80 tons and has a boom 52 ft. long which can swing through a horizontal arc of 180 deg., with a capacity of 45 tons at a radius of 36 ft. 6 in., and of 60 tons at a radius of 23 ft. 6 in. In service it requires a vertical and horizontal clearance of 40 and 20 ft. respectively and when dismantled for transportation has a height of 12 ft. and a width of 9½ ft.

The car body is 9½ ft. wide by 55 ft. long and is of massive construction with six full-length longitudinal plate girders. A riveted pedestal about 7½ ft. long, 9½ ft. wide and 3 ft. high is seated on the forward truck to receive the mast and boom. It is of very strong cellular construction made with longitudinal and transverse web plates ½ and ¾ in. thick, reinforced by very heavy flange and web-stiffening angles. In the rear it has two horizontal pins 4

in. in diameter serving as pivots for the feet of two inclined posts 32 ft. ft. long on centers which are pin-connected at the top to form the triangular A-frame or mast.

The boilers, water tank and coal bunkers are installed over the rear truck and the hoisting engine is located between the trucks. The inclined posts of the A-frame are made with pairs of 18-in. built channels latticed, and are rigidly connected by a transverse horizontal strut at the bottom and by a riveted box at the top which receives the steel casting for the hoisting and topping lift tackles. The A-frame is maintained in vertical position by a pair of inclined struts and by a pair of 1¾-in. wire cable back stays with turn buckle adjustments, pin-connected to forged links engaging the top of the mast and the body of the car and the outside girders in the car body near the rear truck. The inclined struts are a pair of 12 x 12-in. timbers 25 ft. long with pivoted connections to the car body and to the mast about 12 ft. below its upper end.

At the top of the mast two flanged vertical cast steel cylinders are bolted to the riveted box and receive the trunnions of a horizontal cylindrical casting 10 in. in diameter and 18 in. long which is bored through its axis for a 5-in. pin engaging a pair of short links which connect to it the large special steel blocks containing the sheaves for the hoisting and topping lift tackles.

Special lifting devices are provided for handling the 60-ton girders; each of them consists of two pairs of riveted hooks suspended from the extremities of a horizontal beam 6 ft. long. Each hook is made with four thicknesses of 15½ x ½-in. sheared plates riveted together. The lower ends are slightly bevelled so as to take bearing at their extremities only where they engage the under sides of the top flanges of the girders between rivet heads which prevent them from slipping longitudinally. The upper ends are bored for 3-in. pins engaging three vertical connection plates, each of them made with two 25 x ½-in. sheared plates riveted together. The upper ends of the plates are pin-connected to a shackle made with a 3 x 3-in. steel bar, the loop of which engages a 4-in. pin through the end of the transverse beam. The beam, 7¼ ft. long over all, has a closed rectangular cross section made with two 8-in. channels and two 13 x ¼-in. flange cover plates and is suspended from the tackle by two links about 4¼ ft. long on centers which are made with pairs of 10 x 1-in. sheared plates engaging a single 3-in. pin which connects them to the tackle. This device weighs about 3,000 lb., is very easily and quickly adjustable and is considered to be very safe.

Derrick Car Ready for Service.

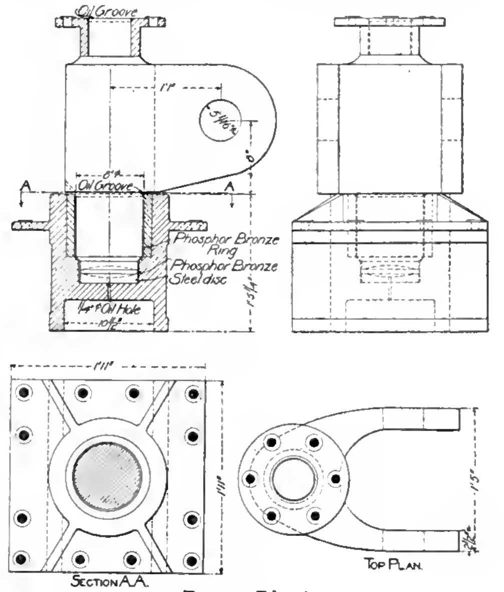
The 24 x 24-in. boom has a rectangular cross section made with two built channels having their flanges turned inward and latticed. It is field spliced in the middle with web and flange cover plates bolted on. Near the middle of the outer section it is provided with pin connections for transverse swinging tackles. The rectangular water tank has a narrow coal bunker on each side which partly enclose the boiler and carry about 2 tons of coal. The tank has a capacity of 500 gallons which with the coal is equivalent to about a 4-days' supply for the derrick engine thus making it independent of a tender car.

The cast steel foot block for the boom is made to offset it 26 in. on centers, from the mast, thus allowing it to revolve through a complete horizontal semi-circle. It consists, as shown in the detail, of three parts, the jaws, the pivots, and the bearings. The jaws have a 5-in. horizontal boom pin offset 13 in. from the center of the vertical pivot about 8 in. in diameter. The upper end of the pivot is secured by a horizontal plate in the pedestal and the lower end has a concave bearing on a double convex phosphor bronze disc seated on a hardened steel disc. The casting is secured to the riveted pedestal by twelve 29/32-in. turnbolts.

The hoisting and topping lift tackles respectively have ¾-in. and ⅞-in. steel ropes rove over six 24-in. sheaves in special steel blocks with self-oiling bronze bushing and ⅜-in. separating plates which were built by W. W. Paterson & Co., Pittsburg. The tackles are operated by a special 75 h.-p., 12 x 16-in. engine, designed by the Lucius Co., and built by the National Hoisting Engine Co. It is able to hoist a 24,000-lb. load on a single line at a speed of 100 ft. per minute and all of its operating levers are concentrated on a single quadrant rack so that they can be handled by one man.

When in service the derrick car is located on the end of the high level track near the top of one of the abutments of the span to be erected. The rear trucks are anchored to the track by ordinary hook clamps operated by adjustment screws. The front truck is blocked up and if necessary the rear end of the car floor is clamped to the forward end of a loaded flat car, thus increasing the stability. The girders are successively brought alongside, on the flat cars in which they have been shipped from the bridge shop, and are lifted clear by the derrick which swings them off from the car and lowers them to the ground in front of the abutment transverse to the railroad track. Afterwards the derrick car in the same position lifts the girders successively to the top of the abutment, revolves them 90 degrees and lowers them to their final position on the bridge seat. Ordinarily, one double track span is erected complete in about 1½ days with a total force of 8 men. The through spans have trough floors shipped in 5-ton sections field riveted at splices by Boyer pneumatic hammers using air from a Franklin compressor of 300 cu. ft. per minute capacity in an attendant box car.

It takes about half a day to dismantle the car for transportation, which is done by revolving the mast backward into an inclined position with the rear ends supported on blocking over the engine. The struts and back stays are disconnected and transverse braces are disconnected from the mast and are loaded on the derrick car. The boom is lowered to a horizontal position on a flat car in front of the derrick car and is disconnected from the mast and the middle splice unbolted if necessary. After transportation the car can be put in service in about half a day.



Boom Pivot.

The Inclined Railway at Lyon-Croix-Rousse, France, has recently been equipped with an electrical operating system to displace the original steam plant with which the cars were formerly operated. The incline is 1,500 ft. long, with a grade of slightly more than 17 per cent., and the cars are operated by a pair of 18-ft. drums, each working a single cable, which are now connected through a single-gear reduction drive to a 250-h.-p. direct-current motor supplied with current at 600 volts. The cable is operated at a speed of about 15 ft. per second and the train, consisting of a baggage and a passenger car, weighing about 20 tons net or 34 tons fully loaded, requires about 340 h.-p. to accelerate. An economic feature is the use of a storage battery of 275 ampere-hours capacity for emergencies and to assist in starting, and into this battery current is returned from the motor as the train is running down the incline, by connecting the motor as a dynamo and charging through a booster set.

The Rehabilitation of the Tracks of the Chicago Street Railway.

An ordinance passed by the city council of Chicago early in this year requires the interests controlling the street railways of that city to rehabilitate practically their entire systems within three years from the time this ordinance became effective. This immediate rehabilitation includes the complete reconstruction of the tracks of a large percentage of the total mileage in the city, the provision of an adequate number of modern cars to properly handle traffic, and the installation of sufficient additional electrical-generating equipment so power to operate the various lines satisfactorily can be furnished. After the expiration of the first three years, the remaining lines are to be similarly rehabilitated until the street railways in the whole city have been placed in a satisfactory operating condition. The same ordinance also covers a number of features concerning the franchises under which the street railways are to be operated and other relations between the street railway interests and the city.

The ordinance has been accepted by the Chicago City Ry. Co., which owns and operates the lines on the south side of the city, and this company has already carried on a large amount of work according to requirements set forth. The Chicago Union Traction Co., which operates the systems on the north and west sides, will doubtless also accept the ordinance as soon as the interests controlling that company can adjust their finances satisfactorily.

This rehabilitation of the three systems which embrace all the lines in the city is being done by, and at the expense of the street railway interests, under the direction of a board of supervising engineers consisting of Messrs. Bion J. Arnold, chairman, Charles V. Weston, representing the city, Harvey B. Fleming, representing the Chicago City Ry. Co., and John Z. Murphy, acting for the Chicago Union Traction Co. Mr. Arnold is chief engineer and Mr. George Weston is assistant chief engineer of this board.

The Chicago City Ry. Co. had rebuilt in the neighborhood of 6 miles of track on October 1, and had over 10 miles of track reconstruction under way at that time. An average of about one-third of a mile of single track is being laid each day by this company, and with favorable weather one-third of the total mileage to be reconstructed in the first three years will be finished in 1907, although the work was not started until late this season. The Chicago Union Traction Co. is also carrying on a large amount of track reconstruction according to the standards specified by the board of supervising engineers, in order that this work will be properly done in case the interests of this company are adjusted so the ordinances can be accepted by it, as will undoubtedly be done.

Three types of track construction have been adopted by the board of supervising engineers for use under different conditions. Although these three types have been practically standardized, a few minor changes are to be made in them, so the board has decided not to make public the details of the different types. At the same time, the general features of the latter have been supplied to this journal. A standard girder rail, the cross section of which is shown in an accompanying illustration, is used in all three types. In one type the rails are laid on steel cross-ties, imbedded in concrete, and in the other two types on wooden cross-ties, also imbedded in concrete; the difference between the two types in which wooden cross-ties are used appears largely in the construction of the sub-base on which the track is laid.

The steel ties are of the standard 4½-in. Carnegie girder section. They are placed on a heavy sub-base of concrete and are imbedded in a layer of concrete, which is continued 2½ in. above the base of the rails. In some of the work that has been done these ties were spaced 5 ft. apart on centers, but in most cases they are 4 ft. apart on centers, and it is probable that the shorter spacing will be adopted as the standard. Sawed wooden ties, 6 x 8 in. in cross section, and 7 or 8 ft. long, are used. They are also imbedded in a layer of concrete, which for one type of track is laid on a sub-base of crushed stone and for the other on a sub-base of concrete. These ties are spaced 4 ft. on centers.

The chief feature of all of the track construction is that the sub-structure is designed to be unusually permanent, and is built so the rails may be renewed with comparatively little difficulty and without disturbing the substructure. Tie plates are used on both the steel and the wooden cross-ties. The rails are attached to the steel ties by a special clip, which can be removed and replaced readily, and which was designed for use in connection with this work. Screw spikes are used to attach the rails to the wooden ties, with the belief that the life of the latter will thus be considerably prolonged.

The standard grooved rail used in all of the track reconstruction was designed specially for the conditions existing in Chicago. This rail weighs 129 lb. per yard, and is rolled by the Lorain Steel Co. Although the section of the rail is generally the same as that of several grooved girder rails which have been used in various cities in this country, it differs essentially in several important features. After making a long series of studies of the effect of wear on previous rails of this type, considerable metal was added to the outside of the head just above the top of the web, as these studies indicated that an increase in section at that point would add materially to the serviceable life of the rail. The thickness of the metal directly under the groove has also been increased for the same reason. The outer edge of the rail is beveled, and the pavement is finished ¼ in. below the top of the rail on that side. The head of the rail can thus be worn down until the flange of the car wheels ride on the groove before the treads of the car wheels reach the pavement. The slope on the outside edge of the head of the rail thus increases the permissible wear to a maximum, with a wheel tread not exceeding 2¾ in. The groove has been designed for cars with wheels having ⅝-in. flanges, with a possibility of an increase to ¾ in. While flanges of this width are scarcely suited for high-speed interurban cars, and some criticism has been offered against the adopted type of groove, the latter was designed strictly for traffic conditions in Chicago, where few, if any, high-speed interurban cars enter the city.

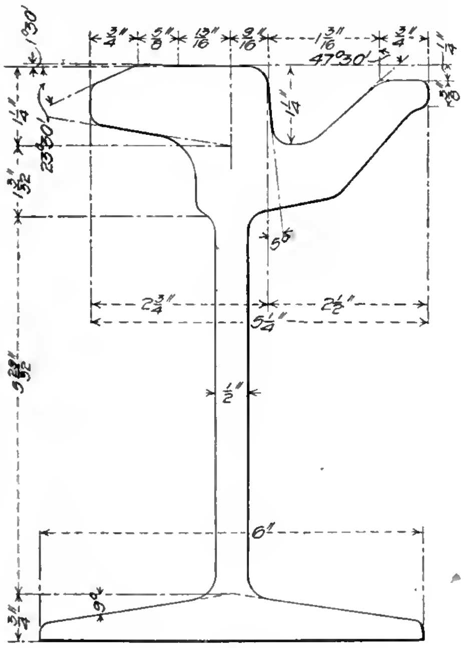
Two other conditions also had to be met in designing the grooved portion of the head of the rail, first, a groove which would prevent the wheels of vehicles entering it, and second, a groove which would be self-cleaning, was desired. As both of these conditions cannot be perfectly fulfilled by the same groove, a compromise has been made between them in this case. The rail is rolled so the extreme outer lip of the groove is ¼ in. below the top of the head of rail. The granite paving blocks used between the rails are laid so their tops are ⅛ in. higher than the outer lip of the groove, with the result that the paving will hardly wear below this lip. The wheels of behicles can therefore readily enter and leave the tracks, while the shape of the groove is such that it will be nearly free from dirt.

A Stretch of Track with Steel Ties Ready for Substructure.

Track Construction Methods.—The methods followed in the reconstruction of the two tracks of the line on Cottage Grove Ave. are more or less typical of the manner in which work has to be handled on the heavy traffic lines. This line is one of the most important in the system of the Chicago City Ry. Co., extending southeast from the downtown business district for about nine miles to a connection with a line leading to South Chicago. Throughout practically its entire length it passes through a densely built-up residence district and connects with numerous important cross-town lines. It was completed prior to 1890 and was operated as a cable road until last year, when an overhead trolley was installed. As is common with a very large percentage of the total mileage in the city, the old rails on this line had not been renewed for years and scarcely any repairs, other than those which were absolutely essential, had been made during the long period that the city held the settlement of the various street railway franchises in abeyance. These conditions, combined with the use of the long, heavy cars which were installed last year after the line was electrified, had put the tracks in very bad shape, so the track and the upper part of the sub-structure are being removed and replaced by the type of track having steel cross-ties that has been recommended by the board of supervising engineers.

The reconstruction work is handled in sections, a single track of each section being rebuilt at a time. On this particular line the traffic is so heavy that it is impracticable to divert it all over one track, even for short distances, so a third temporary track, laid on the pavement at one side, is used to carry the cars of the regular track that is out of service. On some other lines traffic from one track has been diverted over a parallel line, but on Cottage Grove Ave. several conditions combine to make that arrangement also impracticable, so the temporary third track is essentially necessary.

The cable formerly used to haul the cars over this line operated in a concrete conduit under



Standard Grooved Rail Section.

the center line of each track. The rails were carried by chairs on iron brackets, or yokes, cantilevered out on each side of the heavy concrete conduit. The rails, chairs and part of the yokes have to be removed and a considerable part of the conduit has to be cut away before the new track can be built. This preliminary work is handled with considerable difficulty, particularly the cutting out of the concrete, which has been done thus far by hand with cold chisels, picks and so forth. Arrangements have been made, however, to install a number of Little Jap pneumatic hammers for use in cutting the concrete, the power for these hammers to be supplied by portable compressor outfits.

The excavation for a track is made and the sub-grade is prepared for considerable distances, depending in length on local conditions, before any concrete work is done. The ties are then laid in the excavation and are blocked up to their regular positions, after which the rails are attached to them. The layer of concrete on which the ties rest and in which they are imbedded is then laid up to 2½ in. above the top of the ties, except at the joints, where it is stopped level with the top of the ties in order to permit the rails to be welded later without disturbing the concrete.

The concrete is produced by a mixer outfit mounted on a frame carried by two four-wheel car trucks. This outfit was built specially for use in this work by the Drake Standard Machine Works, of Chicago, and is operated over the rails as they are blocked up in place before the concrete is laid. The frame of the outfit is 48 ft. long and is built of structural steel. A standard Drake concrete mixer is mounted under one end of the frame where it can discharge the concrete directly into place under and around the ties and rails. Concrete materials are supplied to the mixer by a flight chain conveyor which runs the full length of the frame, the materials being shoveled into the conveyor from storage piles on the pavement on the roadway side of the track.

The concrete is made in the proportions of 1 part cement, 3 parts sand and 6 parts broken stone. These materials are piled along the track in such manner that as they are shoveled into the conveyor they are in the proper proportions for the concrete. This is accomplished by first placing a layer of sand of a predetermined depth and width on the pavement, and over that a layer

of broken stone and then a layer of cement. The sand and stone are delivered in wagons, from which they are dumped directly in place on the pavement, the layer of sand being kept considerably in advance of the stone. The required width and depth of the sand and stone is measured by templates, while the number of bags of cement to be used is determined by computation. By following this method the materials are readily placed in the piles in the proper proportions, with a minimum amount of rehandling after they have been delivered.

The materials are shoveled from the measured piles into the conveyor by from 10 to 15 men, depending on conditions. The frame of the mixing outfit was placed 51 in. above the top of the rail, in order to permit the men shoveling materials into the conveyor to straighten up each time they lift a shovelful, with the result that they can work at a higher rate of speed with less fatigue than though the frame was lower so they could not stand straight each time. A row of sheet metal deflectors, placed along the opposite side of the conveyor from the shovelers directs the materials into a trough in which the chain travels. These deflectors are arranged so they may be placed on either side of the conveyor, depending on the position of the shovelers.

The conveyor is a wide-link chain, which on its lower run travels in a cast-iron trough, carried by two Z-bars, attached to the main frame, and on the return run is carried above this trough on three loose spools. The conveyor delivers the materials directly into the hopper of the mixer and has operated with excellent results.

The mixer, which is of the pug-mill, continuous-feed type, is placed on the longitudinal center line of the frame. The concrete is discharged from it on an apron, which extends the width of the track just above the rails. It is distributed and tamped in place by six to eight men, who are required to work very rapidly to keep pace with the machine. The blocks on which the ties and rails are held up in position until the concrete is placed are removed under the alternate ties just before the concrete reaches them; the dead load of the track being carried by the remaining blocks gives the concrete an opportunity to set, as cars are not turned over the track for several days after the concrete has been laid.

The mixer is gear-driven by a 30-h. p. motor, which also drives the conveyor. While running 8 to 10 h. p. is fully sufficient for these purposes,

Concrete Mixing Outfit Used in Placing Track Substructure.

but on starting considerably more power is required for a short period. The car is propelled by two 75-h. p. street railway motors, placed on the rear truck, as a low-front truck, taken from an old trailer car had to be used under the front end, in order to provide room between the axles of the truck and the frame of the car for the mixer. Power for all three motors is obtained from the trolley.

The amount of concrete track substructure laid in a day by the machine depends largely on the rapidity with which the excavation and the sub-grade can be prepared. Under average condi-

tions, however, 750 ft. of substructure will be finished in a 10-hr. day, requiring about 250 cu. yd. of concrete. When the machine is delivering that amount of concrete 10 shovelers can supply it with materials. The machine has been in almost continuous service since the latter part of August and has produced such good results that the Chicago City Ry. Co. has purchased three more of the machines for work of the same kind.

The work that has been done on the other lines of this company is all handled in a manner similar to the methods which have been described, although on most lines traffic is diverted from the track under reconstruction to another street, or on lines with light travel the traffic is all turned over one track for short distances. The track reconstruction is carried on by separate gangs of men, about 2,500 men being employed in this work by the company. Each gang is under the immediate direction of a general foreman, thoroughly experienced in street railway track construction, and an assistant engineer has general supervision of the gang. These assistant engineers are all under Mr. W. F. Graves, who is division engineer in charge of track reconstruction for the Chicago City Ry. Co.

Each assistant engineer reports daily to the division engineer the general features of his work. One of the blanks used for these reports is shown in accompanying illustration, from which the method of recording the location of the construction gang on any street for any day and of indicating the amount and kind of work done each day is evident.

The organization of the board of supervising engineers is separated into several divisions, Mr. R. F. Kelker, Jr., being division engineer, and Mr. C. E. Thomas assistant division engineer of track and roadway. Under this division is a corps of engineer inspectors, who follow closely the construction and report daily to the division engineer the progress and other features of the work.

Although the track reconstruction, as well as all the other rehabilitation work, is carried on at the expense of the street railway company, the cost of this work is to be added to a previously agreed valuation of the whole street railway system, and the city will have to pay this total value if it eventually acquires the systems, as maintenance, depreciation, repairs and renewals are provided for in the meantime by special funds supplied from the gross earnings. The detailed cost of the reconstruction is therefore very carefully kept independently by the company and by the board of supervising engineers. A large amount of cost data is thus obtained, which, aside from its value as a means of arriving at the total outlay, furnishes an excellent basis for estimating the expense of future work and for checking operations from day to day.

AN UNUSUAL PIPE CONTRACT is now being finished for the Texas Co., of Beaumont, by the Youngstown Sheet & Tube Co. This contract calls for nearly 600 miles of 8-in. full-weight iron pipe, requiring over 50,000 tons of puddled iron plate. The line will cross a long stretch of alkali territory and accordingly every pipe has been heated to 350°, dipped in a bath of asphalt and then placed in a drying oven. The pipe will be used in carrying oil from Indian Territory to a Gulf refinery. The contract is interesting, not only on account of its size, but also because it has been filled with iron rather than steel pipe.

A Year's Experience with Gas Engines.

A paper presented to the American Street & Interurban Railway Engineering Association by Paul Winsor, Chief Engineer Motive Power and Rolling Stock, Boston Elevated Railway Co.

We have now been operating our gas-engine plants over a year. We have two of these plants, both of them generating direct current and feeding into our overhead system in multiple with our steam-driven power at stations. They have been operated most of the time by two 8-hr. watches from 7 a. m. to 11 p. m. and shut down from 11 p. m. to 7 a. m. The following figures and statements apply to our Somerville power station. I give no figures for our other plant as it has not yet been accepted. The Somerville power station has the following equipment: one pair of Loomis-Pettibone gas producers, with the usual auxiliaries; two 600-b.h.p. Crossley gas engines, each two cylinder, four cycle; two 350-kw. Crocker-Wheeler generators. This plant was started in May, 1906, and since then has given continuous, reliable and satisfactory service. There have been no shutdowns, no accidents, and no failures.

GAS ENGINE OPERATING CONDITIONS AT SOMERVILLE STATION IN 1907.

	Jan.	Feb.	March.	April.	May.	June.	July.	Total.	Average.
Kw.-hr. generated	204,080	175,200	192,250	202,870	118,640	35,770	60,170	988,980	....
Total lb. coal, including coke	391,223	364,817	405,050	401,150	234,705	90,991	124,452	2,012,388	....
Lb. coal per kw.-hr	1.917	2.081	2.120	1.975	1.979	2.542	2.065	....	2.034
Lb. coal per b. h. p. hour	1.322	1.436	1.426	1.363	1.365	1.755	1.425	....	1.404
Sta. load factor based on 16 hrs. per day and 7 days per week	58.8%	55.9%	55.3%	60.4%	34.2%	10.6%	17.3%	....	41.6%
Eng. load factor	84.2%	86.0%	87.4%	82.3%	78.3%	73.3%	82.8%	....	83.3%
Gen. load factor	99.3%	101.3%	103.0%	97.1%	92.4%	86.5%	97.7%	....	98.35%

The fuel has been soft coal, the same as used in our steam stations, mostly run-of-mine Pocahontas. The economic results are shown in the accompanying table.

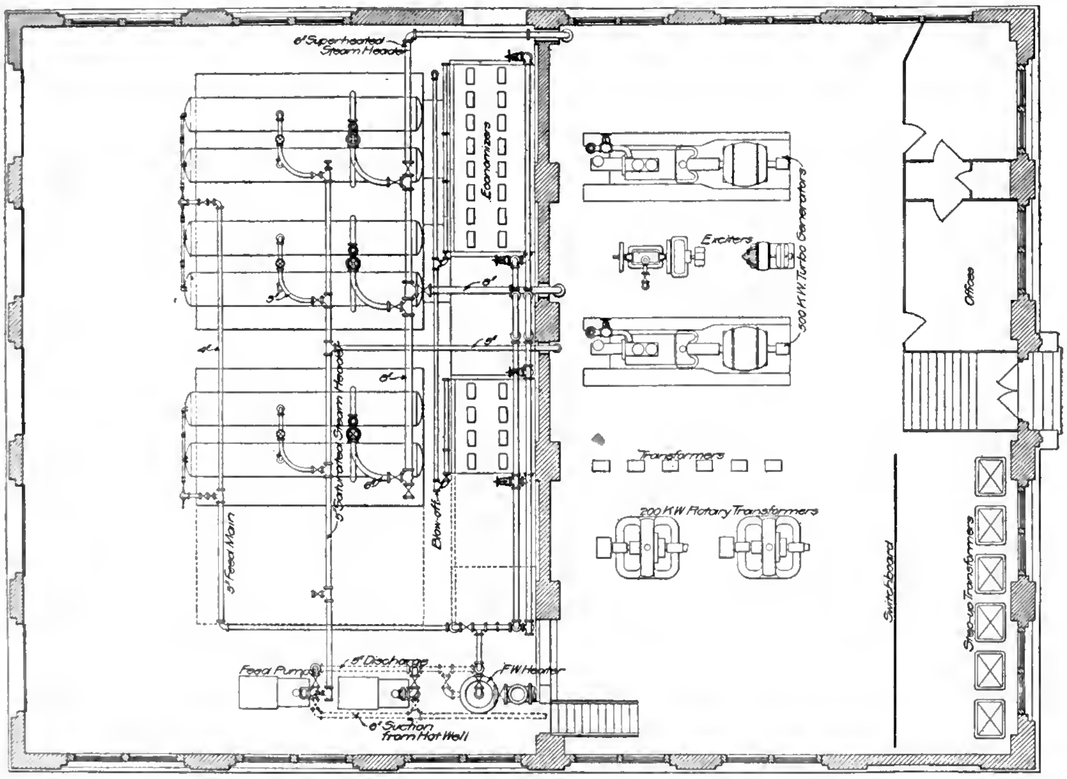
These are the results from actual service and include all the fuel used for power, heating, etc., and the auditor's usual 1 per cent. to make his books balance.

We have used a great deal of water for scrubbing the gas and for cooling purposes. The average amount has been 281 lb. per kilowatt-hour. When we bought this water, as we did for a few months, our water cost about twice as much as our coal. We have been, since Nov. 21, 1906, pumping this from a very dirty brook by means of two-stage centrifugal pumps, electric driven, and filtering it through a pressure sand filter. This outfit has been entirely satisfactory and has given us no trouble. The suction lift is 12 ft. and the pressure at the pumps, 30 lb.

The discharge of water from the gas scrubbers is very dirty, being full of floating lampblack, and is altogether too black to put back into our dirty brook. A sand filter basin 246⅔ sq. ft. in area and tile under-drained, removes all the lampblack, so that we are turning back into the brook cleaner water than we take out.

Our ignition current is from 14-volt motor generators and a floating storage battery and we have no trouble with the outfit. The igniters are make-and-break, two to each cylinder. These igniters had originally platinum tips, which cost a great deal and gave considerable trouble. We have been running now four months without any platinum and with less trouble.

During the first months, back fires and pre-ignitions were much too frequent, occurring almost every day. Lowering the compression on one of the cylinders, changes in the igniters, and experience have reduced these troubles, so that we now go two or three weeks without a single one.



Plan of Power Plant of the Gulfport and Mississippi Coast Traction Co.

This plant has proved absolutely reliable. It can be put into service any time in less than five minutes, much quicker than can our steam plants. It can carry good loads and do it continuously. Each unit has carried 450 kw. (652 b.h.p.) for an hour, with swings to 495 kw (717 b.h.p.).

For the first seven months of this year this plant used 2.034 lb. coal per kw.-hour, while our steam plants averaged 3.477 lb. per kw-hour, a saving of 41.5 per cent. One of our smaller steam plants, containing three 200-kw. compound condensing engines, used 4.414 lb. per kw.-hour; this gas station used only 46.1 per cent. as much.

Personally, I believe that a gas-engine plant, making its own producer gas, will operate at least as reliably as a steam plant and will use from 30 to 60 per cent. less fuel, depending somewhat on the size of the gas plant, but principally on the size of the steam plant.

The drawbacks to the gas plant are, in my mind: First, cost, approximating $200 per kw. when rated so as to have a 33⅓ per cent. overload capacity; second, small size of units, the largest gas engine now built being only of about 3,000-kw. capacity.

Power Plant of the Gulfport and Mississippi Coast Traction Co.

By Earl F. Scott, M. Am. Soc. M. E.

The power plant of the Gulfport & Mississippi Coast Traction Co. is located at Gulfport Miss., for the purpose of furnishing power for the interurban electric road connecting the towns along the Mississippi Coast, and furnishing light and power for the towns of Gulfport, Biloxi and Pass Christian.

The building is of fireproof construction throughout and designed to be pleasing to the eye. The exterior is stucco finish. The building is designed to give plenty of room around the machinery, and is well arranged as to the general mechanical lay-out.

The turbines are of the Westinghouse-Parsons type of 500-kw. capacity, and are direct-connected to three-phase 60-cycle, 2,300 volt Westinghouse generators. There are two machines in the original design of the plant, and sufficient room has been provided for future additions in both the turbine room and boiler room.

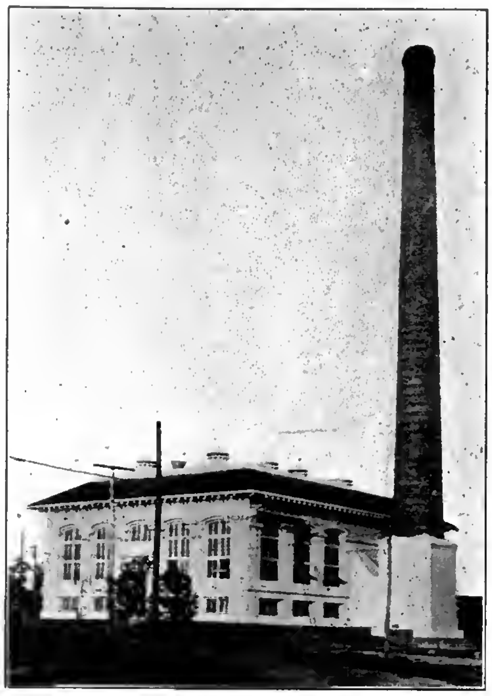
There are two exciters, one steam and one motor driven, each of 60-kw. capacity and arranged so that either may be used at will. The stream-driven machine is direct connected to a standard Westinghouse engine, and the motor-driven unit is direct-connected to a three-phase 60-cycle motor.

Under each turbine between the foundations is placed a Worthington surface condenser. Each condenser has 2,400 sq. ft. of cooling surface, in order to maintain 28 in. of vacuum with a 30-in. barometer, with condensing water entering at 80°. Each condenser is fitted with inner air coolers, to which the rotative dry vacuum pumps are connected. The vacuum pumps are Worthington make, 6 x 12 x 12 in., and arranged so that either pump may be operated with the opposite condenser.

Underneath each condenser and connected to the hot well, there is a Worthington 1½-in. two-stage turbine pump direct-connected to a three-phase induction motor for pumping out the condensed steam. These pumps discharge into a large hot well from which the boiler feed water is taken.

The salt condensing water is brought in from the sea through 20-in. cast-iron pipe by a 10-in. Worthington centrifugal pump direct-connected to a Westinghouse engine. The water after passing through the condensers is returned to the sea in a similarly arranged 20-in. pipe and discharged below low-tide surface in order to get the advantage of the syphon effect.

The condensing water is brought to within 200 ft. of the plant through an open concrete canal of about 80 ft. cross-section area, which begins at deep water, about 2,000 ft. distant, and terminates in a large circular basin from which the 20-in. pipe takes the water.



Gulfport Power Plant.

The present boiler capacity of the plant is 1,038 b. h. p., made up in three units of 346 h.-p. each, set in one double battery and a half battery with the necessary foundations and openings for a future boiler of the same type and capacity. The boilers are Babcock & Wilcox make, with wrought steel headers, and are capable of carrying 200 lb. steam pressure. Each boiler is fitted with the standard Babcock & Wilcox superheater arranged so that superheated steam can be taken off independent of saturated steam. The boilers are fitted with Roney stokers and arranged with overhead coal bunkers having a capacity sufficient for a 48-hour run.

The coal and ashes are handled by Jeffrey coal conveying machinery, fitted up with coal crushers and the necessary automatic machinery to reduce the manual labor to a minimum. The ashes are run from the furnaces by gravity through ash hoppers into the basement underneath the boilers and there taken up by the conveying machinery.

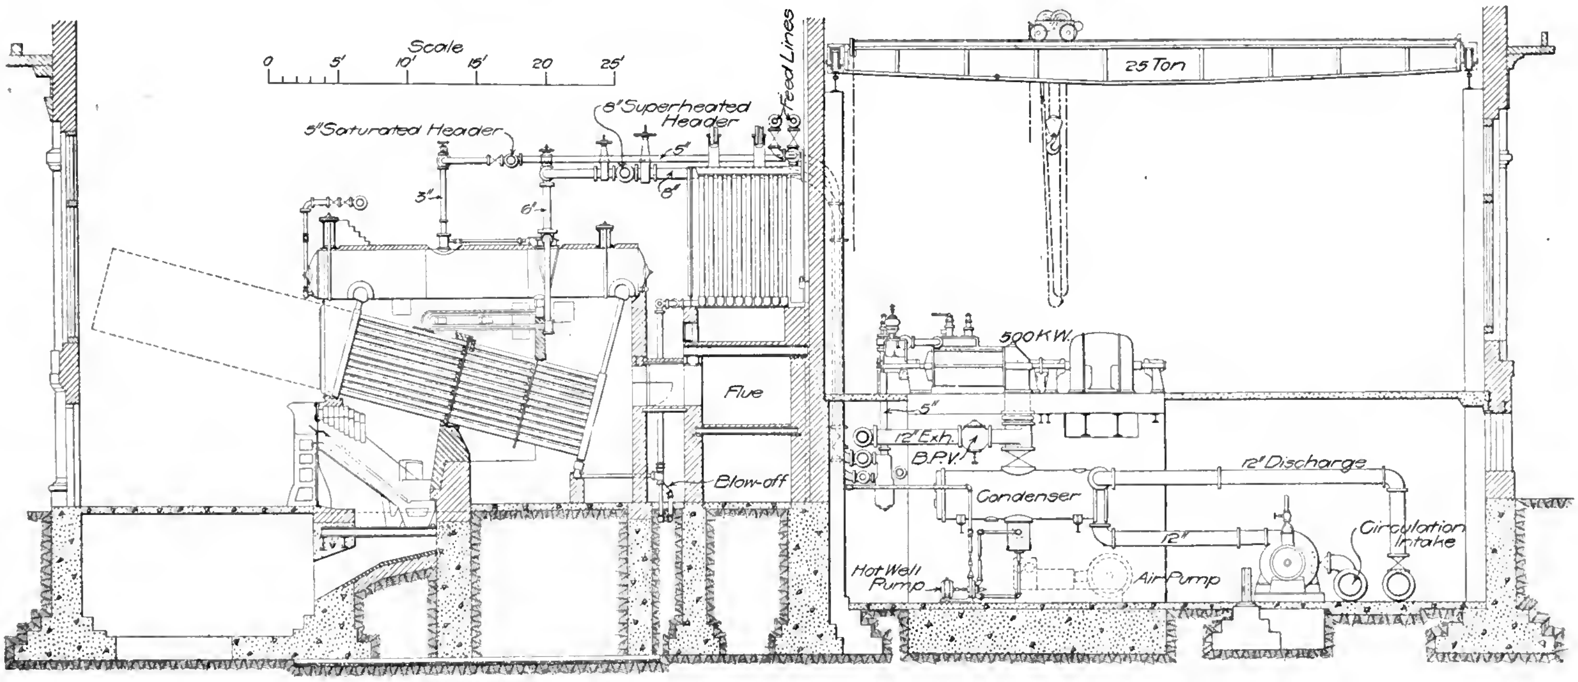
Back of the boilers are the Green fuel economizers. These are arranged so that the gases from each boiler can pass through or go around the economizers to the stack. The Custodis stack is 8 ft. in diameter and 175 ft. high and connected to the boilers with brick breeching.

There are two Worthington boiler feed pumps, 12x7x10-in., of the packed plunger pattern, and built for 200 lb. pressure. The pumps were selected of large size in order to be able to handle the feed for the total plant after it has increased to double its present capacity. The pumps are arranged in tandem and connected so that either may be operated at will.

In the pump discharge there is a Goubert closed heater of 1,800 h.-p. capacity. The heater is direct-connected to the main exhaust header and arranged so that the exhaust from the auxiliaries passes through it at all times. In case the turbines are running non-condensing, their exhaust will also pass through the heater.

The pipe system is laid off in two separate and independent lines for superheated and saturated steam respectively.

The superheated steam line is fitted at each boiler with a Foster automatic and hand stop emergency non-return valve, and these valves are so arranged that through a pilot valve they can be closed down instantaneously from either the firing floor or turbine room, making the steam lines absolutely under the control of the engineer.



Cross-Section of the Power Plant of the Gulfport and Mississippi Coast Traction Co.

From these valves the main steam header is connected by long radius bends. There is a large header running the full length over the boilers and near the center and at one end this header is branched off and run to the basement below the turbine room floor. The two branches run into a secondary main header which is hung from the basement ceiling and at convenient points the branches are taken off for the turbines. On each branch to the turbines is placed a Stratton steam separator to prevent any water of condensation from being carried over to the turbines on starting up. Both the main header and sub-header are arranged with fittings and blank flanges so that future extensions can be made without causing any serious delays.

All flanges on the superheated steam header

are Van Stone slip joints. One point regarding this line is of interest; the line is fitted up with Goetze corrugated copper gaskets and during one year's continuous operation, there has not been a joint that has required attention.

The saturated steam header is run similar to the superheated steam header, but not fitted with automatic stop valves. The same design of a main header over the boilers and a sub-header in the basement is carried out, and from the header in the basement branch lines are run to all auxiliary machinery which is placed in the basement. Steam for the boiler feed pumps is taken off the main header over the boilers. A reducing valve is placed near the main header, on the branch connecting the main and sub-header, in order to reduce the boiler pressure from 100 to 100 lb. for the auxiliaries.

From special tees under each turbine, the atmospheric exhaust branches are run. In each branch at the tees is placed a Blake automatic exhaust relief valve. Each branch runs into the main exhaust header, thence to the heater and outboard exhaust, terminating with a Swartout exhaust head.

The three main headers in the basement are suspended from the turbine room floor underneath each other. The hangers for these are made up with turnbuckles so that each header is independent of the other.

The feed pumps are piped up so that water can be taken from a large hot well placed in the basement, into which the condensed steam from the turbine flows, or through this hot well the boiler water can be obtained from a natural flowing artesian well, which furnishes an abundance of water if the plant should be run non-condensing. By means of a float valve, water from the well is added for make up.

The discharge for the feed-water lines is arranged so that the heater and economizers can be run at the same time or separately, or the pumps may deliver direct to the boilers cutting out both the heaters and economizers.

All fittings for steam lines and feed water lines are Crane's extra heavy flanged fittings, the valves are Chapman make, extra heavy where required, and designed for the different types of service. Live steam lines and feed water lines are covered with 85 per cent. Keasbey & Mattison magnesia covering, and exhaust lines with asbestos air cell covering.

All pipe work in the boiler room is suspended from the roof trusses by adjustable rods, and in the basement from the ceiling.

The circulating pumps are primed by the rotative dry vacuum pumps through a 2-in. pipe which connects to the highest point of the circulating system and runs to a point about 34 ft., above this and thence down to the pump. The priming pipe has this high loop in it to prevent salt water from being drawn over into the pumps. It requires about fifteen minutes to prime the pumps by this method when there is no water in the system. There is no foot valve on the 20-in. main suction pipe.

The only feature about the piping of the auxiliary machinery that requires mention is the by-pass connection on the rotative dry vacuum pumps. These pumps are connected so that either pump may be operated with either condenser.

The generators furnish 2,300-volt, 60-cycle, three-phase current. From the generators it is conducted to the main switchboard and through generator panels to the 2,300-volt busbars. Part of this current is then taken through step-down transformers from 2,300 volts to 380 volts and fed to the alternating current end of two 200-kw. rotary converters, being converted to 550 volts direct current. This 550-volt current is fed direct into the trolley circuit. Another portion of the 2,300 volt alternating current from the high voltage busbars is fed into the primary lighting circuit, extending through the city of Gulfport and also into the transmission line which extends both ways from Gulfport to Biloxi at one end and Pass Christian at the other end. This high-tension circuit is constructed of bare aluminum stranded wire of about 75,000 c. m. cross-section, and is designed to supply the intermediate lighting service along the coast between Pass Christian and Biloxi.

Another portion of the 2,300-volt current is conducted through step-up transformers and raised from 2,300 volts to 13,200 volts alternating current. This is conducted on a high-tension transmission line, constructed of three bare aluminum stranded wires of about 50,000 c. m. cross-section to the sub-stations located at Biloxi and Pass Christian, Miss., where it is reduced through step-down transformers to 380 volts and 2,300 volts alternating current. The 380-volt current is carried direct to the alternating current end of two 200-kw. rotary converters similar to those at the main station. The 2,300-volt current is used for lighting service in the two towns. Both the 2,300-volt and the 13,200-volt transmission lines are three-phase and constructed in triangular form with 36-in. separation of each leg.

The pole line is constructed of 35-ft. creosoted poles, with creosoted cross arms, 11-in. locust pins and Locke high-tension insulators. The trolley circuit consists of two 4/0 grooved lines in parallel with 6-in. separation between running wires and is hung on a 9-ft. Richmond flexible bracket, 20 ft. above the rail. This trolley circuit is designed to furnish ample capacity in the trolley wires without carrying an additional feeder to reinforce the line. High-tension transmission lines are protected at intervals and at both main station and sub-station with low-equivalent lightning arresters, manufactured by the Westinghouse Electric & Mfg. Co. The system is arranged with disconnecting switches at both sub-stations and main station, so that it is possible in case of emergency to feed the rotary converters at both sub-stations through the 2,300-volt line, this giving in a measure a duplicate transmission line.

The rotary converters to be used on this system are designed to start with a small motor mounted on the end of the main armature shaft, this doing away with the violent fluctuations in the line when starting the rotary converter from the alternating current end.

The plant has been in operation about twelve months and in every respect given entire satisfaction. The turbines have been run as long as four months continuous without showing any defects at all, and carrying 50 per cent. overload without trouble. The condensing apparatus has maintained 27½ and 28-in. vacuum at all times without the least strain and the boilers have given entire satisfaction, and in every case responded to over-load peaks without undue strain.

After twelve months of operation, the demand for electric current has exceeded the capacity of the plant so much so that at present the company has signed contracts for the installation of one 1,500-kw. Westinghouse turbo-generator, the necessary auxiliary condensing machinery and additional boiler capacity. The present building will accommodate all of this, anad the installation will be easily made, as all preparations were made for extension in the original designs.

The electrical part of the plant was installed by the Westinghouse Electric & Mfg. Co., under the supervision of Mr. F. D. Gatchell, and the boilers, auxiliary machinery and pipe work were laid out and installed by A. M. Lockett & Co., Ltd. of New Orleans, La., contracting mechanical engineers. The contracts for the new machinery have also been given to these companies.

Care of Electric Railway Tracks.

A paper presented to the American Street and Interurban Railway Engineering Association by George L. Wilson, Engineer, Twin City Rapid Transit Co.

Interurban Track.—The conditions of the interurban roads located, as all such roads should be, on a private right-of-way, approach closely those of steam roads. Many of the methods used in steam road practice, as the result of years of experience, are required for electric roads.

Grading, ballasting, construction of bridges, culverts and crossings, care of roadbed and track follow the same lines. The standard works of reference on these subjects apply with slight modifications to the care of electric roads and should be diligently studied by those in charge of permanent way.

The maintenace of the earlier and cheaply built electric roads has demonstrated that it is economy to have electric roads built with well-ballasted track; ties and rails put in as perfect condition, in regard to surface and alignment, as possible. Then the object in view is to preserve them in the same condition.

Following the purpose of keeping the track in perfect condition, which includes drainage, care of switches, crossings and side-tracks we come to the care of the right-of-way, cleaning from snow in winter, maintaining fences, public crossings and the making of the company's property attractive to the passengers.

It should be remembered that the principal business of electric roads at present, and probably for a long time, is the transportation of passengers, whose comfort and interest are constantly to be kept in mind.

The removal of rubbish, weeds and unsightly objects of all kinds, including advertising signs, from the vicinity of the tracks is a proper part of the care of the roadway.

Company property should be neatly arranged when stored, and the land owned by the company along the line and at stopping places ornamented with grassy slopes, vines and shrubbery.

At terminal or waiting rooms there should be flower beds and grass plots, instead of ragged grounds and piles of debris. Otherwise, waste grounds can be so improved that there is something of interest to attract the passenger's attention at every point.

This is looking some distance ahead for new lines, but it is practical to do a little, month by month, and year by year, until the right-of-way becomes a boulevard or parkway.

All passenger transportation lines find it desirable to make their routes as attractive as possible. A sloping hillside cut may, by the proper planting of shrubs, be made beautiful, with their flowers in summer, and gorgeous with the autumnal foliage. A rocky bank is not of itself attractive, but partly covered with vines it becomes an interesting feature.

Steam suburban roads have done considerable along this line, and the lot of the commuter has been cast in pleasant places thereby. The great trunk lines of the country are working to the same end. Through the Eastern States many of the roads pay a great deal of attention to the making of their station grounds attractive. The annual circular of a transcontinental line offering cash prizes to its station agents for the best station flower gardens is attractively illustrated and directed to "Our Fellow Workers among the Flowers."

The aim of every electric road must be to have its patrons attracted and interested along the way, that the route may seem both short and pleasant and the trip one to be repeated.

With the care of interurban track it is proper to consider the men as well as the roadway. The growth of railroads, both steam and electric, has required more men than are to be found in the

track crews. It is a fact that track labor has been recruited from the lowest paid classes, with the result that ambitious workmen have largely gone into other lines.

Our first railways and public works generally were built by the sturdy Irish immigrant, who rose soon to more remunerative employment. To-day the mass of employes have no apparent interest in, or regard for, the quality or amount of work they perform. In many cases the foremen and officials can only communicate with them through interpreters, and there is an absolute lack of loyalty to the interest of the employers. This must be changed if the best results are to be obtained.

It is not necessary that a track crew should be skilled mechanics, but if track, switches, frogs and all appliances are to be in the best working order men of a fair amount of ability and some mechanical skill are required.

To obtain this end the conditions must be such that an intelligent laborer can make a decent living and have a steady income. Work should be planned so as to be distributed through the year as far as possible, in order that there may be constant employment for a nucleus of good men.

Let the men from bottom to top have an interest in the results of their work and in the efficiency of the section or division where they are employed. Make them feel that it is their company and that they are a part of the whole machine. The question of keeping skilled laborers who will do good track work is at the bottom of the maintenance of track and the most difficult problem.

All interurban track should be patrolled daily, at least, and this brings us to the track-walker and his duties. This position is above that of laborer and next to that of foreman. A skilled trackman who is sober and industrious and who can be depended upon to see that splices and bolts are in adjustment, drains and culverts open, who will detect any spreading track or broken rails, see that farm gates are kept closed and stock off the track, in fact, be a general inspector and caretaker, is an important person. It is in a great measure to his fidelity that the safety of cars and passengers will be due.

City Tracks.—On city tracks the care of the roadway, besides the keeping of rails, switches and curves in good order, includes more or less of cleaning, sprinkling and snow removal. In order to determine the practice of different companies and for a guide for future operation, inquiries on these subjects were sent to fifty leading companies. From their reports the following notes have been prepared:

In the matter of cleaning the space occupied by tracks on paved streets the general practice is that the municipality bears the entire expense, as the theory is that the cars do not bring dirt onto the street, and the cleaning of the entire paved roadway would have to be done and the expense borne by the city if there were no tracks.

The fact of the tracks being in the street does not entail additional expense on the city. This view has been upheld in the courts, and it appears that refuse and things left on the streets by pedestrians, teams and by storekeepers, who often dispose of litter by throwing or sweeping it into the roadway, should be taken care of by the city authorities. Inquiries on this subject were made of fifty companies in all parts of the country, and of forty-six replying and operating 8,469 miles of track, with a tributary population of 13,241,000, it appears that forty-one, operating 6,706 miles of track, pay no part of the street cleaning expense.

In a few cities the railways bear a part of the street cleaning expense, this being done either voluntarily or by charter requirement. In these cases it should be considered as a contribution or a part of the amounts paid in by way of taxation.

The following are among the prominent companies which assist the cities in this matter:

Chicago Union Traction Co., Chicago City Railway Co. and South Chicago City Railway Co.; cost $123.60 per mile for cleaning and sprinkling in 1906.

Columbus.—On 79 miles of single track, within city limits, partly on unpaved streets, cost for cleaning and sprinkling was $13,000 in 1906; cost per mile of single track, $164.55.

Pittsburg.—Company pays for proportional part of street occupied by tracks.

New Orleans.—Pays for sweeping one street only.

New York City.—Pays for sweeping Broadway only, from Bowling Green to 15th St.

Twin City Rapid Transit Co.—Pays for sweeping its track allowance in St. Paul and Minneapolis; 86.12 miles of single track in 1906 cost $23,475.55; cost per mile, $272.56.

As street sprinkling is found to be carried on satisfactorily by sprinkling cars, it is believed that the cleaning of the track allowance can be done economically and satisfactorily with sweeping machinery which will take up the debris, place it in a receptacle and take it away to proper dumping grounds. This is an important subject for the companies which pay for cleaning their track allowance.

In the large majority of towns the street sprinkling is taken care of by the municipal authorities, without reference to the street railways, no part of the expense being paid by the companies. Returns from 24 companies, operating 4,768 miles and having a tributary population of 10,156,000, show this condition: Companies operating 3,356 miles sprinkle tracks only with tank cars; of these the practice is so mixed that it is difficult to know how much mileage is sprinkled. In general, it appears that the more important streets are the only ones sprinkled. This is done under requirement of state law or city ordinances. The cities are required to furnish water without charge, though in some places the company is obliged to pay for the water—in one case 6 cents per mile of track.

The business of sprinkling the whole of the roadway from tank cars has been developed to quite an extent; one outside company owning cars makes contracts with cities for sprinkling the roadways, and has 250 miles of streets covered. The railway companies operate the cars for a price per car-mile. The authorities of the cities report that the service is very satisfactory. The railway officials report that this plan gives good results and, while the returns are small, the conditions, on the whole, are satisfactory.

A number of cities pay the railway companies directly for this same kind of service. Prices received by the company for this work vary from 7 to 17 cents per car mile, 10 cents being about an average. The cost to the property owners per season is about 10 cents per foot of street, or 5 cents per front foot.

The tank cars used are of a variety of types, from the plain rectangular box to the cylindrical sheet iron tanks, operated either directly by gravity or as pneumatic sprinklers, having the tank under air pressure. The capacity is from 2,500 to 6,000 gal.

Four thousand gallons will sprinkle some six miles of tracks or three miles of entire roadway. Any statements of this kind are rather indefinite, depending upon so many conditions. A better idea of the work done is to say that in actual practice one car making four trips per day will care for eight miles of street.

While the returns for the service are small, the indirect benefits are of as much or more value. The freedom from dust not only decreases the expense of repairs to car machinery and gives a better contact between rail and wheel, but also, by more comfortable conditions for passengers, increases the pleasure of riding and other traffic so much that managers consider the expense more than met by increased revenue.

The use of oil for laying dust on some streets and for the roadbeds of railways has been extensively advocated. It has been tried by a number of roads. Some consider its use satisfactory, but the greater number have not put it into extensive use. The heavy asphalt oils of California appear to give the best results, while in the Central and Eastern States a so-called "roadbed" oil prepared by the Standard Oil Co. has been used more or less experimentally for ten or twelve years.

Among the steam roads that have used oil are the Boston & Maine, Boston & Albany, Central Railroad of New Jersey, Long Island Railroad, Delaware & Hudson, Santa Fé, Chicago, Burlington & Quincy, Oregon Short Line, Chicago & Alton and the Southern Pacific, the last the most extensively, having used it for five or six years on about 900 miles of road.

In practice the roadbed is sprinkled with about 2,000 gal. per mile for the first application. After the first dressing the quantity may be lessened to 600 or 1,000 gal. per mile annually, though some parties claim that two applications annually are needed. The sprinkling appliances used and the process are claimed to be controlled by a Chicago firm, which charges a royalty of $10 per mile for its use for the first application, no charge being made for subsequent sprinklings.

Few electric roads have used oil. The Los Angeles Pacific reports its use on unpaved city streets and states that three coats per year are desirable. At 60 cents per barrel, the cost per mile of double track is $100. San Francisco reports its successful use on macadam streets outside the city limits. The Brooklyn Rapid Transit Co. is experimenting with 20 miles of track on its suburban lines on private right-of-way where the pleasure riding is very heavy and the roadbed of sandy material.

From the reports of roads using oil it appears that managers of the steam roads, at least, do not consider its use profitable, and there is no general movement to adopt it. On electric roads on private right-of-way or on macadam outside of built-up sections of cities it may prove to be economical where the oil is obtained at a low price, especially on sandy roads leading to pleasure resorts. The accompanying memoranda in regard to the practice and cost may be of interest:

Boston & Maine R. R.—Has used oil in 1899; covered about 400 single-track miles; uses 2,000 to 3,000 gal. per mile; price of oil, 2.75 cents per gal.; average cost, $100 per mile.

Boston & Albany R. R.—Made experiments for three years, 1898-1900; used 2,000 gal. per mile first year, 600 gal. second year, 1,000 gal. third year; cost per gallon, 2.75 cents; cost per mile of track, $80.

Central R. R. of New Jersey.—Will use oil on Sea Shore Line for dusty season; uses apparatus constructed at its own shops; pays a royalty for the process.

Long Island R. R.—Use oil on crossings; cost, $125 per mile; use 600-gal. tank cars; oil costs 2.4 cents per gal.; 600 gal. used per mile; results on cinder and gravel ballast satisfactory.

Delaware & Hudson R. R. Co.—From 1896 to 1900 oiled road from Saratoga to Plattsburg, 188 miles; used roadbed oil prepared by the Standard Oil Co.; price, 2.75 to 4.75 cents per gallon; for 2,000 gal. per mile cost was $100; kept dust down, but its use has been given up; 1,000 gal. per mile every other year would be sufficient.

Oregon Short Line.—Reports using a little oil on a branch line, which kept down dust till track was ballasted.

Brooklyn Rapid Transit Co.—Reports that some track on private right-of-way has been sprinkled for two years; will sprinkle 20 miles in 1907; results satisfactory.

Chicago & Alton R. R. Co.—Use crude oil at 3 cents per gallon for sprinkling road crossings only; stone ballast on rest of road and does not need it.

Southern Pacific R. R. Co.—Has used oil for five or six years: 900 miles of track oiled; may use up to 4,000 gal per mile; pays $10 per mile royalty.

San Francisco Electric Railway Co.—Uses oil on macadam streets, but not inside city limits.

Los Angeles Pacific Co.—In Los Angeles on unpaved streets an occasional coat of oil is applied; generally, oiled streets are sprinkled three times per year; cost, $100 per mile of double track.

The universal practice with reference to snow is to keep the tracks open for service by the use of plows and sweepers during and immediately after each snowfall. The snow thus deposited on the rest of the roadway is left, as far as it can be done, without impeding travel. At crossings and congested points in business districts all companies assist in removing snow as promptly as possible by the use of car and team.

When it is necessary to remove snow from roadway the companies generally pay the cities one-third or one-half the expense incurred on the whole street. In some cases the cities and railway companies divide the streets, the railways taking care of a sufficient number of them to make up the same area as their total track allowance. One company takes one side of the streets and changes sides annually. This is reported as working well in a city of 60,000 people.

In many cities no separate account of this expense is kept, and, owing to the fact that conditions vary so widely between Southern and Northern locations, no satisfactory comparison of costs is practical.

Figures given show results of $17.41 per mile of single track in a city of 175,000, with 140 miles of track in the Central States for an average winter. In Chicago, 1906-'07, the cost was $41.13 per mile of single track for the Chicago City Railway Co., while in Milwaukee, 85 miles away, but a very small expense was incurred. Another lake city, Detroit, reports $35 per mile for an average winter. Duluth gives $45.45 for an average winter. Toronto reports on 98 miles of single track in 1904-'05 a cost of $102.04 per mile for one-third of street area. Providence, R. I., reports a cost of $148 per mile of single track in 1906 and 1907. Here all snow over 4 in. deep is removed.

Deflocculated or Acheson Graphite remains indefinitely suspended in machine oil, and in consequence some engineers are turning their attention to its special uses as a lubricant. Prof. C. H. Benjamin states in the "American Machinist" that he has found the effect of adding deflocculated graphite to oil to be very noticeable. He has made many tests with such a mixture and with the same oil used alone. With one or two exceptions, the addition of the graphite has at once reduced the friction and increased the life of the lubricant. The graphite improved all the varieties of mineral oils which were tried. One-third of 1 per cent. of graphite was tried with two grades of oil under different loads and reduced the coefficient of friction with the better oil about 20 per cent. and with the poorer oil about 23 per cent. One-sixth of 1 per cent. of graphite had a slight effect in reducing the friction of a standard engine oil, and this is apparently about the minimum quantity that can be used with any advantage. It also seems from his tests that the use of this grade of graphite with water has a tendency to prevent rust.

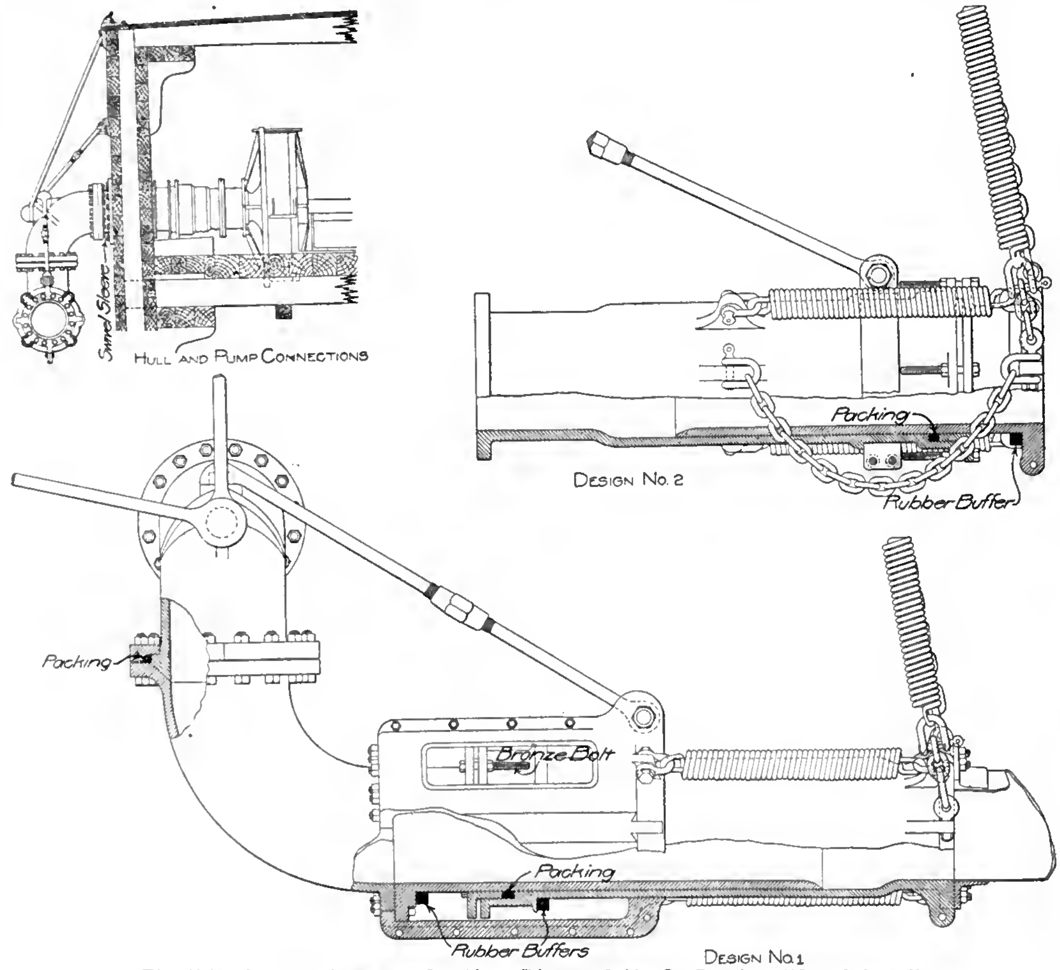
A New Flexible Connection for Suction Pipes of Dredges.

The expense, delays and inefficient service attending the use of rubber suction hose in the suction pipes of sea going suction dredges for the purpose of providing a flexible connection between the rigid portion of the suction pipes, which trail along the bottom being dredged, and the hull of the dredge, have been very detrimental to the successful operation of these vessels.

The rubber hose for an 18-in. suction pipe costs about $500, not including the cost of the flanged nipples and other fittings attached to the hose. While occasionally these sections of hose render service for several months they frequently fail within a few weeks. The inner tube or lining often becomes detached from the walls of the hose within a short time and the contraction of the hose, under the usual vacuum of 25 in., constricts the passage, and the usual irregularities increase the friction so much that the maximum efficiency of the pumps can rarely be attained. When the hose begins to leak it generally has to be replaced at once with another one. It often happens that several sections of hose fail within a short period of time, and unless an unusually large supply is on hand to replace them the work of the dredge may be delayed several weeks awaiting a new supply. The material of which the hose is constructed deteriorates rapidly, especially in warm climates, hence the inadvisability of keeping a large supply on hand.

The device shown in the accompanying drawing was designed to replace the rubber hose and obviate its disadvantages.

The usual swiveling sleeve in the line of the suction pipe leading from the pump, passing through the side of the vessel and made air tight by a stuffing box, is made use of in the customary manner. To the outer end of this sleeve is attached an elbow of 90 deg., which in turn is connected to another elbow of 90 deg. by a swiveling joint of special construction which is self-explanatory on the drawing. To the latter elbow is attached a telescopic section of pipe which may be arranged either as shown in Design No. 1, or in Design No. 2, on the drawing. The movement of this section of pipe within itself is under the control of springs as shown and responds to torsional as well as longitudinal stresses. The normal position of the pipe when at rest is as shown on the drawing. Under tension it has a maximum extension of 14 in., and under compression, as when the vessel retrogrades while the drag is on the bottom, as some times occurs, this section of pipe can collapse 8 in. from the position shown on the drawing, or a total of 22 in. from extreme extension. It will be seen that this device permits the drag to accommodate itself to irregularities of the bottom and to change its relative position with respect to the vessel as the demands of practical work require, without bringing undue stresses upon the several portions of the pipe or upon the vessel. In practice it has been found that it meets the conditions imposed much better than the rubber hose.



Flexible Connections on Suction Pipes of U. S. Dredge "St. Johns."

The dredge "St. Johns," which has two 18-in. dredging pumps, had one of these connections of Design No. 1, on her port suction pipe when she began work on the shoals at the entrance to the St. Johns River, Florida, Oct. 20, 1906. Another connection of Design No. 2, was put in service on the starboard side on April 12 of this year. No repairs whatever have been required to either connection and no delays have in any wise been occasioned by them. The swivel joints of both connections have required no attention since they were installed, and remain air-tight. The stuffing box of the telescopic portion of the first connection has been repacked once, the other not at all. During the time between the installation of the first connection and that of the second, four sections of rubber hose were worn out on the star-

board side. During the period from Oct. 20, 1906, to July 1, 1907, this dredge removed nearly 500,000 cu. yds. of ocean drift sand and carried it to sea an average distance of 3.6 miles. From May 16 to June 15 of this year, during which time the weather did not materially interfere with the work, the dredge removed 96,028 cu. yds. Work was done with one crew and was carried on during the daytime only.

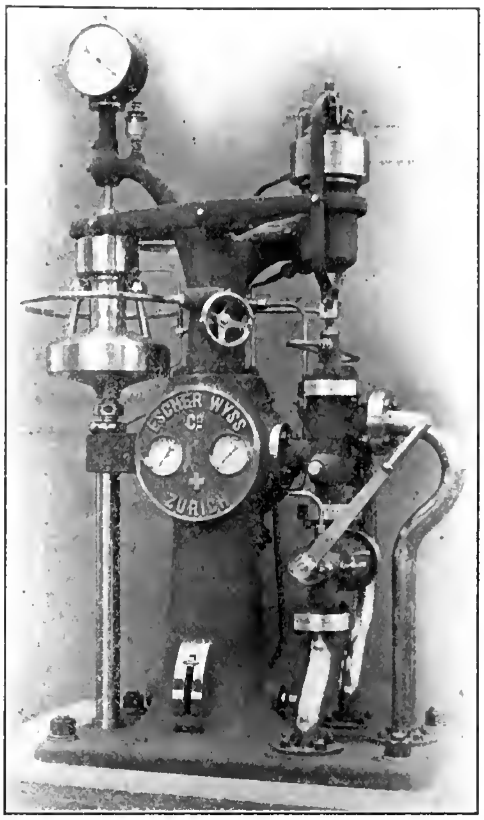
A ball-and-socket joint is now being used on some sea-going suction dredges in place of the rubber hose. As compared with the connection here described, the ball-and-socket joint appears to have the following disadvantages: The joint being rigid longitudinally, severe stresses are brought to bear upon the pipe and its connections when the drag encounters unusual obstructions in the bottom, or when the vessel settles backward in a sea-way while the drag is down. In order to provide the latitude of motion required in practice, as when transverse winds or currents prevail or when the vessel suddenly changes its direction for any reason, the ball-and-socket joint must be of large cross-sectional area or the passage will be constricted when the pipe is near its limit of transverse motion. This produces a considerable irregularity in the passage, causing an interference with the free flow of water through the connection If, through inattention, the pipe is permitted to swing, with respect to the vessel, beyond the limit afforded by the ball-and-socket joint, the joint or the pipe or both are apt to be broken. Such contingencies have occurred and the accidents mentioned have resulted in practice. The lower position of the suction pipe, where it connects with the swiveling elbows, in the device here described, permits the pipe to swing somewhat farther under the turn of the bilge of the vessel without damage than with the more direct alignment given by the ball-and-socket joint.

The device is original with Mr. J. A. Sackett, chief assistant engineer to Major Shunk, U. S. Engineer Officer in charge of the Florida district, and he designed all the details of the completed apparatus.

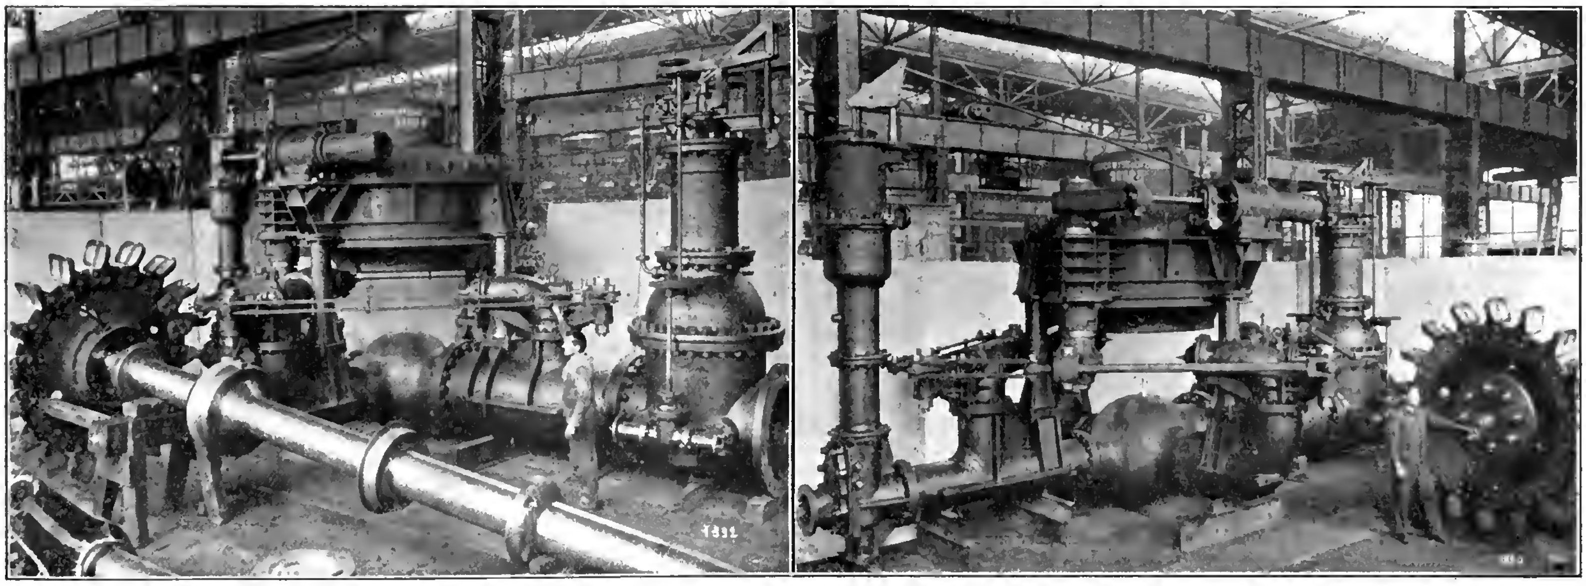
A Large Icebreaker has been recently launched at the yards of Sir W. G. Armstrong, Whitworth & Co., Ltd., England. This vessel, which was built for the Government of Finland, is 220 ft. long, 47 ft. wide and 28 ft. 2 in. deep. She has a propeller at the bow as well as at the stern. The forward propeller gives increased maneuvering power and assists in the breaking of ice by disturbing the water under it.

Large Impulse Wheels for a Brazilian Hydro-Electric Station.

The Rio das Lazes hydro-electric station of the Rio de Janeiro Tramway Light & Power Co., which is to have an initial installation of 54,000 h.-p., consisting of six 9,000-h.-p. units, was referred to briefly in The Engineering Record of Aug. 17, 1907. Since then, Mr. R. Weber, formerly chief engineer of the Escher, Wyss & Co., of Zurich, Switzerland, under whose direction the water wheels were designed and built, has furnished the accompanying views of one of the 9,000-h.-p. wheels set up in the shop, and of the automatic governor furnished for each wheel.



Governor for Impulse Wheel.



Two Views of Impulse Wheel of Nine Thousand Horse-Power Capacity.

A concrete dam, 115 ft. high and 92 ft. thick at the base, was built at a series of falls on the Rio das Lazes, 56 miles from Rio de Janeiro, to develop a storage reservoir for the station. Two 8-ft. riveted steel supply lines, about 6,000 ft. long, lead from this dam to a cross receiver near the power house; a 12-in. and six 36-in. pipes extend from this receiver to the station, at which the total head varies from 950 to 1,000 ft. These pipes are all of welded-steel plates; the thickness of the plates for the 36-in. pipe varies from 0.4 to 0.7 in. and that of the 12-in. pipe from 0.25 to 0.3 in., depending on the head. The receiver is connected with a small service reservoir at the same elevation as the main storage reservoir, this small reservoir acting as an equalizer to maintain and regulate the flow in the supply lines.

At the power house each 36-in. pipe line connects with the penstock of a 9,000-h.-p. vertical-shaft impulse wheel. The 12-in. pipe connects to the penstocks of two 500-h.-p. horizontal-shaft impulse wheels. The main wheels are each direct-connected to a revolving three-phase 50-cycle 6,000 h.-p. Westinghouse generator, the units being designed to operate at 300 r. p. m. The 500-h.-p. wheels are each direct-connected to direct-current generators, which supply excitation current to the main units and operate at 500 r. p. m.

Each main wheel has four variable-orifice needle nozzles through which water is supplied to the runner of the wheel. The operation of these nozzles is controlled by a special type of oil-pressure governor of the fly-ball type, which was designed by Mr. Weber. This governor is geared to the shaft of the unit, and actuates a valve in a pipe supplying oil to a cylinder that directly controls the position of the needle nozzles. Each wheel is also provided with a relief valve which is connected to the governor in such manner that it is only opened when all, or a relatively large percentage of the load on the generator suddenly drops off. Dependence for speed and pressure regulation is placed entirely in the governor and the relief valve, respectively, as the nozzles are not deflected. The whole arrangement is therefore water saving, since the relief valve is wasting water for a few seconds only when the load is decreasing rapidly.

The field of each 6,000-h.-p. generator being mounted on the same shaft as the runner of the wheel, each unit has but two steady bearings, the field being on an overhang of the shaft at the top and the runner on an overhang at the bottom. A maximum thrust of about 100,000 lb. is developed in each unit, and is carried by a thrust bearing of the oil-pressure type. This bearing is located between the two steady bearings, oil being supplied to it at a pressure of about 150 lb. The oil required for this bearing, and that necessary to operate the governing mechanism is supplied by a pump to each unit. These pumps are each driven by a small impulse water wheel.

The wheels of the main units have a guaranteed efficiency of 82 per cent. at full load. The

governor is guaranteed to prevent a speed variation of more than 10 per cent. when the full load is suddenly thrown off, the difference in speed between full load and no load being only 2 per cent. The relief valves will prevent an increase of more than 3 per cent. in the water pressure in the penstocks.

The runners of the impulse wheels of the exciter units are mounted on an overhang of the shaft of the direct-current generators. Each of these wheels has a single needle nozzle, controlled by an oil-pressure governor similar to those for the main units.

A Machine for Tunneling in Shale.

Numerous attempts have been made from time to time to build a machine which could be used to bore tunnels through rock without requiring explosives. While a small machine for this purpose has been reported to be operating successfully in Colorado, so far as this journal has been informed no such machines of any size have ever delivered satisfactory results in actual service. The latest attempt to perfect a machine to bore a fair-size tunnel has recently been abandoned, although the mechanical defects to be overcome were apparently not insurmountable. The Engineering Record has been supplied with considerable data concerning this machine, which are presented herewith, although no information regarding the place where the machine was tried can be made public.

This particular machine was designed to operate on the principle of a stone planer. The tunnel in which it was set up for a trial is being driven through shale rock. It has a finished diameter of 8 ft. and is lined with 12 in. of concrete. The machine consisted essentially of a 10-ft. cylinder, 48 ft. long and built of steel plates, carrying a revolving disk at the front end to which were attached the planer knives, or tools, the driving machinery being distributed through the cylinder. The disk at the front end of the machine was mounted on a hollow steel shaft, 4 ft. in diameter and about two-thirds the length of the cylinder, contained in the latter. This shaft was concentric with the cylinder and turned in two heavy bearings, one toward each end of the cylinder, which were carried by heavy frames attached to the steel shell.

Four 65-h.-p. electric motors in the cylinder, operating at 500 r.p.m., drove the shaft at a single revolution per minute through a set of gears. The front end of the revolving disk on the forward end of the shaft had six very heavy cast-steel arms radiating in the form of a flat truncated cone from a hub at the center. The planer tools were attached to these radiating arms. These tools were made of a special grade of tool steel and each had a cutting edge about 2 in wide. They were pitched about 2 in. apart so the 2-in. annular cuts made by them were separated by 2-in. rings of stone that were not planed off, but broke away as the cuts were made on both sides of them. The tools were so placed at different angles with the arms which carried them as to facilitate the cutting with the smallest amount of power. The face of the bore was taken out in the form of a truncated cone of the same pitch as the arms carrying the tools, and with a uniform diameter of 10 ft. 4 in.

The rock as loosened by the tools varied from a small amount of fine dust to pieces 6 to 8 in. in their maximum dimensions, the majority of the muck being about an average between these two extremes. The loosened material was picked up by buckets attached to the rim of the disk, and delivered to a traveling conveyor-belt that extended through the hollow shaft carrying the disk, to the rear end of the machine. These buckets radiated from the center and extended through the rim of the disk. Some of the rock loosened by the cutting tools fell directly into them, and the remainder was picked up from the bottom of the cut by them. The buckets were shaped to dump from their inner ends when they were in the highest position, the material falling through a hopper directly on the conveyor belt. As considerable dust was formed at the face when the machine was in operation, a fine spray of water was directed continuously against the face.

The conveyor belt was geared to the same shaft to which the shaft carrying the disk was geared, so it started and stopped with that shaft. The belt delivered to the boot of a bucket elevator at the rear end of the machine. This elevator raised the material and dumped it into a long narrow storage hopper suspended from the top of the cylinder. Enough clearance was made between the bottom of this hopper and a working platform in the cylinder so small cars could be run under the hopper and filled, four independently-operated gates permitting four cars to be filled simultaneously. Arrangements were made to carry cars to the surface by a freight elevator in the shaft from which the tunnel was driven.

The machine was arranged to make an advance of 2 ft. before it had to be moved forward. The shaft carrying the disk on which the planer tools were mounted was automatically pushed ahead by four positive-feed screws which bore through rollers against the rear face of the disk. These screws were geared to the 4-ft. shaft, so their rate of feed was controlled by the speed of the latter. Split nuts engaged the screws directly and could be released at will when the 4-ft. shaft was to be withdrawn into the cylinder. In order to provide for the travel of the shaft the various gears on the latter were made a little more than 2 ft. wide.

The machine rested on two pairs of high-power pneumatic jacks while in operation, one pair near the front and the other near the rear, both pairs being on the center line of the bottom of the tunnel. Eight pneumatic jacks, in two sets of four each were placed radially, to keep the machine in alignment while it is in motion. One set of jacks was placed toward the front end and the other toward the rear end of the machine, the four jacks of each set being placed one at each of the four 45 deg. points. The shafts of these jacks were all controlled independently so the course of the machine could be altered readily by manipulating them.

Two tandem-compound high-power pneumatic jacks were used to push the machine ahead. One of these jacks was placed along each side of the cylinder on the horizontal diameter of the cross-section of the latter, and toward the front end of the machine. The shafts of both jacks extended to the rear of the machine where they bore against a heavy built-up steel ring that is carried loosely at the end of the cylinder. This ring could be brought to bear against the sides of the machine with sufficient force to furnish a blocking base for the heavy moving jacks.

The motors driving the machine were operated from a switchboard at one side of the rear of the conveyor belt near the rear end of the machine. The various pneumatic jacks were operated by valves grouped together on the opposite side of the end of the conveyor belt. The operation of the machine could thus be controlled entirely by two men.

After the machine had been set up in the shop for trial runs, it was partially dismantled and shipped to the site, where it was re-erected in a chamber that had been built along the line of the tunnel adjacent to the bottom of the shaft. This erection was handled with less difficulty than might be imagined, although it had to be carried on in very congested quarters. The interior of the cylinder of the machine was almost completely filled with gears, jacks, shafts and so forth, a narrow man-way along each side of the revolving 4-ft. shaft being the only space not occupied.

The machine was arranged to cut at the rate of 1 in. a minute, but the rate of cutting could be changed quickly if materials of varying density were encountered. With ordinary tunneling methods the shale is of such nature that it would all have to be loosened by blasting before it could be removed, which would result in a large amount of breakage outside the lines of the tunnel as prescribed by the plans. This space would have to be filled with concrete, without pay, and it was considered that the saving of this extra concrete that could be made in the tunnel through the use of the machine would more than defray the cost of the latter.

A complete and exhaustive trial of the machine in the tunnel demonstrated that progress satisfactory to the engineers in charge of the work could not be made with it, so it was abandoned and removed, in order that the tunnel could be driven by ordinary methods. This journal has not been authoritatively informed to what cause the failure of the machine is to be attributed, but local reports indicate an inability to mesh simultaneously the sleeve nuts on the four positive-feed screws which bore through rollers against the face of the disk carrying the cutting tools, with the result that this disk could not be maintained normal to the axis of the tunnel.

The Para Harbor Improvements.

The Para harbor improvements, which have been undertaken under a concession from the Brazilian government furnish an instructive example of the valuable assistance private capital can render in the most important public works of a national nature, provided those furnishing it are assured of reasonable treatment. One of the notable commercial movements taking place today is the development of the great rubber district in the upper part of the Amazon valley and the improvement of transportation facilities so that the products of the east slopes of the Andes may be sent eastward instead of westward over the mountains and by a circuitous route to Europe. This development of the Amazon valley is a natural result of the growing importance of the Brazilian rubber trade, which has surpassed that in coffee of late, and has led to a better appreciation of the other resources of the valley. This has an area more than twice that of the Mississippi and discharges about three times as much water into the sea 65 miles to the east of Para, the port of this great district. The present port facilities of this city are admittedly inadequate for the existing business and would be a serious check on that of the future, so the government has granted a concession to parties with whom Dr. E. L. Corthell of New York is interested to build a modern port and collect port dues. In case the latter do not yield 6 per cent. on the investment, the government practically obligates itself to make up the deficiency. There will be a dredged entrance channel 1,000 ft. wide and deep enough for 10,000-ton vessels extending from deep water to the main quay, a distance of about 1.8 miles. The quay will have a rubble foundation and concrete superstructure, and will be equipped with fixed and movable electric cranes, warehouses, coal-handling plant, railway tracks and all other facilities needed to handle the business in the most economical and speedy manner. The construction will be carried out by S. Pearson & Son of London and Messrs. Schneider of Paris, and it is expected that the first section will be completed and put into service about 1912.

Book Notes.

The excellent collection of "Mechanics Problems for Engineering Students," prepared by Prof. Frank B. Sanborn, has been revised and enlarged. The book contains a great variety of problems drawn from regular engineering work to illustrate the principles of work, force and motion in a more interesting way than by the usual abstract exercises. It is a book equally useful to the teacher and to the ambitious student. (New York, John Wiley & Sons, $1.50).

The sixteenth annual edition of "Hendricks' Commercial Register" contains the names and addresses of over 350,000 parties covering the building, engineering, mechanical, railway, electrical, mining and metallurgical industries, classified under more than 31,000 headings. The publishers make no charge for fully classifying any firm's business, and the work is done solely with a view to answering completely all reasonable questions with which a reader turns to such a volume. Special attention has been paid to classifying the names so that the lists are equally useful to the purchasing agent or the catalogue distributor. For example, all parties having a machine shop or foundry are classified under the head of "Machinists and Founders" for the use of those desiring a mailing list of these trades, and each party is classified under heads covering every variety of its products, so that the names are available for the use of a purchasing agent. The book is the result of evolution from a list of the building trades which had only 1,648 classifications. From this small beginning in 1891 it has steadily grown in scope, size and accuracy, until it is recognized to-day as one of the best trade lists published. (New York, S. E. Hendricks Co., $10.00).

A new edition, the fifth, of Mr. Austin T. Byrne's "Treatise on Highway Construction" has been brought out, with about 120 pages of additional information. It has the same merits and defects as previous editions. Some of the information is practically obsolete, such as that relating to cement and concrete, and there are many sentences and paragraphs which are certainly not in harmony with the opinions held by some experienced paving specialists. On the other hand some of the chapters are particularly comprehensive and reliable. This inequality in the character of the contents can hardly be avoided, however, in a new edition of a book on a branch of engineering changing so rapidly as that under consideration. The great strides made during the last five years in the chemical technology in asphaltic cements, the progress in the construction of broken stone roads, the development of treated wood blocks and the improvements in asphalt blocks only recently undertaken, have rendered paving an interesting subject of study to those fortunate enough to become acquainted with what is taking place. As a result of this progress there is particular need of thoroughly revising books relating to paving work; Mr. Byrne would have done well, therefore, to have thrown away much more of the obsolete material in his book and to have condensed other parts. The book would have lost nothing of its encyclopædic character and gained in reliability; there is so much valuable information in the book, arranged so well for quick reference, that the next revision ought to be conducted thoroughly, so that the merits of the large amount of valuable matter are not overshadowed by the out-of-date or erroneous portions. (New York, John Wiley & Sons, $5.00).

Prof. Geo. C. Shaad, of the Massachuetts Institute of Technology, has written a good general manual of the engineering features of power stations and transmission. His purpose has not been to furnish a complete treatise, but merely to provide a general discussion which is accurate and at the same time not so technical that none but a graduate of an engineering college can read the book to advantage. The volume, which bears the title "Power Stations and Power Transmission," opens with a discussion of the location of the stations and the selection of the system of generating and transmitting the power. The general design of steam and hydraulic plants is then briefly outlined, after which the electrical equipment is explained. This section is followed by one on station buildings, records and office management. The whole first part is thus a well-balanced description of what may termed the generating end of the power plant. The second part is devoted to power transmission, and will be found particularly useful by those engineers who wish to obtain a general knowledge of the methods of designing this portion of a general power development undertaking. The author takes up in turn the methods of calculating the size of conductors, the various losses in transmission and the construction of the various parts of the line. This section of the book has been well prepared and may be profitably read in particular by those who have to take up for the first time such work. (Chicago, American School of Correspondence, $1.00.)

The young man who goes from a preparatory to an engineering school frequently finds the transition a disastrous one, largely because he has not been taught to make independent use of what he has learned. Hence there is a growing appreciation of the fact that the transition should be accompanied by training in the application of the knowledge gained in the preparatory school, in order to make the student realize that he has acquired an increased mental power, to review the work of the preparatory school in an interesting manner, and to give an outlook over the work of the engineering college. As a rule the preparatory work is least satisfactorily done in mathematics, and in order to remedy this defect, Prof. P. A. Lambert, of Lehigh University, has written a little book on "Computation and Mensuration," as a review of algebra, geometry and trigonometry and an introduction to their applications. The book assumes that the student has free access to his text-books on the branches mentioned and no attempt is made to prove formulas derived in such text-books. The book is an excellent introduction to a college mathematical course, particularly as it gives information concerning approximate and graphical methods of computations which are not ordinarily taught in preparatory schools. (New York, The Macmillan Co., 80 cents.)

Although the development of grinding and lapping in recent years has been one of the most interesting features of machine shop practice, very little has as yet been published concerning this and there is no general handbook on such work. Mr. Joseph V. Woodworth has accordingly rendered a distinct service in writing his manual bearing the title of "Grinding and Lapping." The book is in five sections. The first takes up the conditions, rules, methods, processes and attachments for accurate grinding and the use and preparation of abrasives. The second section is on laps and lapping; it discusses the construction and use of tools and processes for finishing gauges, tools, dies and machine parts to accurate dimensions. The third section is on the use and operation of grinding fixtures and jigs, for finishing repetition articles of metal, small hardened and tempered steel parts and special work. The fourth section is on hardening and tempering interchangeable tool-steel parts of delicate structure, which require to be ground and lapped afterwards. The fifth section is a table of the percentage of carbon that crucible steel parts of tools should contain, temper colors to which they should be drawn and degrees of heat for giving them proper tempers. In many respects the book is one of the most interesting contributions to our American works on machine shop practice, and the fact that almost all of it describes methods followed by the author or designed by him adds to the value of the text. Throughout the book there are references to experience with various methods of grinding and lapping which are decidedly instructive. (New York, Hill Publishing Co., $2.00.)

Letters to the Editor.

Cost of Hauling Farm Products to Market.

Sir: In the first article in your issue of Sept. 28, you mention me by name as having criticised some statistics published by the U. S. Department of Agriculture concerning the cost of hauling farm products to market, which reminded me of another investigation I partially completed some months ago and laid aside for lack of time; but as it is not likely to be completed soon, I will present a summary of it here, as it bears upon the matter to which you referred.

The Road Inquiry Office of the United States Department of Agriculture, under date of April 4, 1896, published in Circular 19, the data received from 1,061 counties. The conclusion is that in 1895 it cost the farmers $662,000,000 (70 per cent. of $946,314,665.54) to haul the crops of that year from the farm to the market.

Under date of Feb. 28, 1907, the same Department in Bulletin No. 19 of the Bureau of Statistics, publishes the data on Cost of Hauling Crops from farms to Shipping Points received from 1,894 counties. The conclusion of the later, and more elaborate, investigation is that in 1905 the cost of hauling twelve leading farm crops was $84,684,000. Of course, these twelves crops are not all that was hauled to market; but they must constitute the major part of the farm products. One of the points upon which I have been waiting for additional information is the magnitude of the other crops, but so far I have been unable to get any light.

On the face of the returns, the cost of hauling crops from the farm to the shipping point in 1895 was almost eight times as much as in 1905; but statistics of the same Department show that the weight of the seven leading crops in 1905 was a trifle more than double that of 1895. Therefore we may fairly conclude that the cost of hauling the crops to market as given by the first circular is practically sixteen times as great as that stated in the later Bulletin.

There are four serious errors in the last investigation, each of which tends to make the conclusion too large.

1. The question asked for the "usual medium load for each of the principal products." The mean between the heaviest and the lightest load may differ greatly from the average of the loads actually hauled, since the bulk of the products are hauled when the roads are in better than average condition. According to the U. S. Bulletin the average load of corn in Illinois is 2,754 lb., while the Illinois Agricultural Station in Bulletin No. 50 published the statistics for marketing 311,845 bush. of corn, which shows that the average of loads actually hauled was 62 bush. If this was all shelled corn, the average load was 3,468 lb.; and if it was all unshelled corn, the average load was 4,400 lb. As doubtless the most of the corn was shelled, the average load was probably only a little greater than 3,468 lb.; but even the 3,468 lb. is 21 per cent. greater than that stated in the U. S. Bulletin.

2. The cost to the farmer of a team and driver is assumed to be "the price for which teams are hired for any purpose." Of course there is a great difference between the actual cost to the farmer of a man and team hauling crops to mar-

ket, and the price paid for driver and team to work, say, at railroad grading, or hauling a highway bridge to its site. Judged by the estimates of 310 farmers in 76 counties in Illinois, reported in the Illinois Bulletin mentioned above, the price assumed in the U. S. Department Bulletin is about 24 per cent. too large.

3. The question asked for "the greatest distance of haul by any considerable number of farmers," and the assumption was made that the answer to this question represented the radius of the tributary area. This procedure overlooked the fact that for many places there is one direction from which produce is hauled much farther than from other points of the compass; in other words, this method measures to the end of the pan-handle to find the area of the pan. The U. S. Bulletin states that the average length of haul for corn in Illinois is 5.7 miles, while by the Illinois Bulletin referred to above the average length of haul in marketing over 300,000 bush. of corn as reported by 316 farmers in 76 counties was 3.2 miles. Apparently then for this reason the results in the second U. S. Bulletin are about 44 per cent. too large.

4. The amount of wheat hauled by wagons from the farm to the mill is not included in the statistical returns, but this item is estimated and then added. This esimated correction is distinctly equivalent to saying that a trifle more than one-third of all the wheat not used for seed is hauled in wagons to the local mill. The amount thus added is almost one-sixth of the total weight of all other crops, and hence any considerable error in this item will materially affect the final result. I have looked for statistics by which to check this estimate, but have found nothing of value. However, in view of the great quantity of wheat that is exported unground and also of the large amounts that are ground at Minneapolis and other milling centers, it can not be that more than one-third of the wheat not used for seed is wagoned to the local mill.

If we correct the results of the second U. S. Bulletin as stated in paragraphs 1, 2 and 3 above, the actual cost will be about 44 per cent. of that stated, not counting the error referred to in paragraph 4. The cost of hauling crops from the farm to the market stated in the first U. S. Bulletin is then about thirty-six times the value given in the last bulletin, provided we assume that the latter value includes substantially all the farm products. If we should allow 25 per cent. for the omitted crops, and should neglect the error in the opposite direction referred to in paragraph 4, the results in the first U. S. Circular would still be twenty-seven times too great.

Of course the above method of "correcting" statistics is not mathematically exact, but it is certainly sufficient to show the absurdity of the first circular referred to. Unfortunately that investigation has been largely used in discussions of wagon-road economics, and the only object of this communication is to show its utter unreliability. The hope is that with these very erroneous statistics out of the way, a more rational consideration of good-road problems may prevail.

Ira O. Baker.

Champaign, Ill., Oct. 4, 1907.

The New Waihee Canal.

Sir: The completion of the new Waihee Canal on Maui adds another important irrigation work to the sugar industry of the Island of Maui and the Territory of Hawaii. The new ditch provides first, for the irrigation of the several thousand acres of new land of suitable quality for the successful cultivation of sugar cane, heretofore arid and utilized only as pasture land; second, for a permanent supply of water for the cane lands already under cultivation; and third, for conveying the freshet water of the Waihee Valley to storage reservoirs where it is conserved for irrigation purposes, thus augmenting the normal water supply derived from the Waihee, Waiehu, Iao and Waikapu streams.

The division dam and head-works of the canal are located just below the famous Aliele Falls in the Waihee Valley, at an elevation of 649.5 ft. above sea level and 2½ miles up the valley. The cement-lined ditch from the dam and head-gates is located along the south bank of the Waihee Stream on a bench wall above the flood line, passing almost immediately through Tunnel O, 320 ft. in length. The conduit extends some 2,000 ft. to the portal of the next tunnel and thence continues, still tunneling the mountain spurs and high ridges forming the foot hills of the high mountain range of West Maui, spanning the deep gulches by flumes and skirting along and through the cane fields by open ditches to the north bank of the Iao Valley near the town of Wailuku, for a distance of approximately six miles. The original contour survey showed nine miles, making a saving of three miles of conduit by the present line as constructed. It next crosses the valley by pipe line and continues by easy curves and long tangents through the cane fields of the Wailuku Sugar Co. to the Waikapu Valley in open ditch, thence by tunnels and cutting under the Waikapu Stream, again following the grade contour through the new lands of Waikapu and Puuhele Plains, where many new reservoirs are located.

The conduit consists of 22 tunnels, having a total length of 16,539 ft.; 39 flumes aggregating 2,764 ft.; 35,549 ft. of open ditch, and 1,253 ft. of pipe, making a total of 56,105 ft. or 10.62 miles.

Of the 22 tunnels, the longest is 2,246 ft., located in the Waihee Valley, and the shortest is in the Waiehu Valley, making the average length of all the tunnels approximately 750 ft. The dimensions of the tunnels are as follows: Bottom width, 5.5 ft.; center height, 6.5 ft.; side height, 4 ft., with width of 6.5 ft. at the spring of the arch, making a cross section similar in outline to a horseshoe.

All of the tunnels are cut to a true line and uniform grade of 0.25 per station of 100 ft. or 13.20 ft. per mile, except the first tunnel, which is of a smaller cross-section and has a grade of 3 ft. per 100 ft. and is cement lined and arched with concrete. About 40 per cent. of the tunnels are lined with concrete and cement plaster to prevent loss of water by seepage and caving where the rock is soft and porous.

The cutting of tunnels was all done by Japanese labor, the contract prices ranging from 85 cents to $5 per foot, according to the material cut, the location and the length of the tunnel. Eighteen months were required in cutting the longest tunnel, 2,446 ft. in length. Very hard rock was found. Compressed air and percussion drills were used in four tunnels. The formation in the long tunnels was principally of lava rock of alternate strata of aa and pahochoe, with a slight dip to the sea.

The flumes, 39 in number, vary in size according to grades and capacity required, 3 x 4, 4 x 4, 4 x 6 and 4 x 7 ft. The waterways are constructed of redwood lumber with trestle and floor system of northwest lumber.

The open ditch varies in cross-section and grade to comply with the conditions of soil and capacity, being designed to carry the maximum capacity without cement lining. Approximately 20 per cent. of the open ditch has been cement lined on bottom and sides.

The steel pipe line crossing the famous Iao Valley is 1,253 ft. in length and 3 ft. inside diameter, conveying the water under the bed of the Iao Stream and delivering it into a cement basin 13 ft. in diameter, thence through a tunnel 439 ft. in length to a permanent weir, where the total flow of the canal can be accurately measured at all times.

Waihee Dam.

Weir on Main Canal.

Headgates.

The capacity of the conduit is 45,000,000 gal. in 24 hours, or 69.81 cu. ft. per second, after making liberal allowance for seepage and evaporation.

Construction on the canal was commenced in March, 1905, and completed in June, 1907. The construction of the canal was the result of an exchange of land and water rights on the part of the Wailuku Sugar Co. and the Hawaiian Commercial & Sugar Co. in settlement of their respective rights to the waters of the Iao Valley, which had been in litigation for years past. The cost of the canal in round numbers is $160,000.

The writer has been chief engineer of the works from start to finish, locating and designing and constructing the works of the Wailuku Sugar Co., of Wailuku, Maui, Brewer & Co., of Honolulu, Agents. Mr. George B. Sturgeon, now of Oakland, Cal., was assistant engineer, with location and the principal portion of the construction work.

Member American Society C. E., Consulting Hydraulic Engineer.

THE ENGINEERING RECORD

Published Weekly by the

McGraw Publishing Company

James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.

MAIN OFFICES:
239 West 39th Street, New York.

BRANCH OFFICES:

Chicago: Old Colony Building.
Philadelphia: Real Estate Trust Building.
Cleveland: Schofield Building.
San Francisco: Atlas Building.

London Office: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico............$3.00 a year
Canada ....$4.50 a year
Foreign subscription......................$6.00 a year
25 shillings. 25 marks. 31 francs.

Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of The Engineering Record on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

Remittances.—Remittances should be made by check, New York draft, or money order, in favor of The Engineering Record.

Changes of Address.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

Back Copies.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.

Date on Wrapper indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

Club Rate.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. The rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 14,500 copies are printed. Total circulation for 1907 to date, 626,000 copies, an average of 14,588 copies per week.

TABLE OF LEADING ARTICLES.

The Status of Wireless Telegraphy.

The other day, with a considerable and not unjustifiable blare of trumpets, it was announced that the Marconi transatlantic service was definitely established between the Port Morien and Clifden stations, the former near Glace Bay, the latter on the coast of Ireland. From this time on, it is stated, the wireless system will be in regular competition with cable service. At this point in the history of wireless it may be well to run over some past happenings to gain thereby some idea as to the real status of the art, and some notion of its usefulness in the immediate future. Far be it from this journal in any way to dim the lustre of William Marconi's achievements; he deserves well of the world as the practical pioneer in a new art. Yet it cannot be denied that wireless telegraphy as a whole has not yet fulfilled the promise of its beginnings and has at times been a grievous disappointment. The Engineering Record hopes that this latest effort marks the beginning of a period of uniform success and only occasional failure, instead of rather uniform failure enlivened by brilliant and inexplicable successes.

Wireless telegraphy has had in its short life a singularly checkered career. Nothing more uncanny and weird than this system of annihilating space had ever dawned upon the world save the lurid and cometary blaze of promotion which has followed in its trail. It is now more than five years since the first alleged transatlantic messages flashed across the speculative horizon. Just what really happened at this period few know and none are likely to tell for years to come. It seems to be well established that signals from shore to shore were actually transmitted and received, but there were disquieting rumors of the use of the old reliable cable for the messages of congratulation which have never been adequately disproved.

Whether connected messages via wireless were received at this time or not, it is certain that their transmission was little better than fortuitous. It is simply unthinkable that even a moderate regularity of success would not have promptly been followed by some serious effort at doing business, with a less delay than five years at least. Instead, there have been dismal failures of wireless transmission, at very moderate distances even over water, failures that do not of course score heavily against the future of the method, but merely show that the art is not yet upon a sufficiently sound theoretical basis to eliminate the frequent interference of the unforeseen. Mingled with these there have been brilliant successes, at times by all the varieties of the wireless systems in vogue. The cruise of the "Carlo Alerto" did much to restore the confidence that had been shaken by the first transatlantic fiasco, by proving that readable messages could cover distances at least comparable with the width of the Atlantic. Later installations on naval and merchant vessels have co-operated with shore station in some very long transmissions rising at times to a couple of thousand miles and more, although not with much regularity. It has not been unusual of late for an Atlantic liner to keep in touch with one shore or the other throughout her voyage. Most attempts at wireless working have been greatly handicapped by quite insufficient energy supply, and there is every reason to suppose that increasing the available power as Marconi has done in his recent stations will enable the reliable range of transmission to be greatly increased. Whether he has increased this range to the width of the Atlantic the trials now in progress will presently prove. When business men settle down to using the system as an ordinary means of communication its success will be firmly established, and that may be within a very short time.

It is hard to set a limit to the applicability of wireless in view of the distances that have already been covered. The most serious practical question at present is that of interference. Each wireless system has made its claims of syntonic operation, but The Engineering Record does no conscious injustice to anyone in saying that such claims have not yet been shown to rest upon any firm foundation. Interference has been the practically invariable rule whenever two systems have been within reasonable striking distance of each other. It would be interesting, for example, to know the truth about the colossal hoax which was apparently perpetrated on Marconi the other day in the alleged message intercepted from Manila announcing the safe arrival of the U. S. S. Philadelphia, which worthy craft has been securely moored in Puget Sound for the last three years. It is altogether reminiscent of the famous dispatch from Major Reflipe W. Thenuz perpetrated during the Spanish war. So long as the longest practicable waves are necessary to carry the energy sufficient for a long transmission, and everyone undertaking long distance work must push toward this limit of practicability, there seems to be no reasonable chance of avoiding interference. Something could perhaps be done were all wireless stations worked as a harmonious whole with spheres of influence connected in definite ways, but at present this unity is very far from being secured. This much is certain, however, that at the present time wireless telegraphy can, if systematically utilized, make all the seas familiar ground. It would be well within the range of feasibility to net the earth with international stations so disposed that no ship could be out of instant touch with shore. For instance, the Atlantic could be easily covered from Newfoundland, Bermuda, Barbadoes, the Cape Verde Islands, and the Azores in the northern waters, and Ascension, St. Helena, Trinidad and Tristan d'Acunha in the southern, co-operating with shore stations. Such a conquest of the waters would be of vastly greater solid benefit than any of the sensational feats which are so tempting to the imagination. Meanwhile success to Marconi in his present efforts and may he fully succeed!

Heating and Ventilation Tests.

It is doubtful if any branch of mechanical engineering practice offers a more fertile field for investigation at the present time than heating and ventilation. The design of an important installation of this character involves many assumptions as to the leakage coefficients, radiation losses, and aid friction expected; and while a great deal of excellent work is being done in this line, as the results in many installations show, there is certainly need of more definite knowledge of the conditions which insure success or failure in specific plants. Taken in itself the heating problem is much less difficult to solve in most cases than the securing of good ventilation, but the two are bound so closely together that they ought not to be considered separately either in designing or testing the performance of individual plants. Failure to appreciate the particular conditions of plants from both standpoints has injured the reputation of heating and ventilating practice not a few times in the judgment of the general public, which estimates the performance of an installation by its personal feelings and comfort rather than by quantitative tests.

In a branch of engineering where so many uncertainties are involved, or at least so many assumptions, the accumulation of a large quantity of test data is essential, beyond the usual extent, to the harmonizing of theory and practice. Many engineers are collecting this kind of information for their own private use, and of course much of it is rightly considered as personal stock in trade. At the same time, there is great need of bringing the technical considerations of the work down to a more generally available form, and the presentation at this time of two or three exhaustive paper by men in practice on specific problems in heating and ventilation, either in the technical press or be-

fore the engineering societies, would stimulate progress and be widely helpful in breaking down the eccentricities of a highly individualized practice. No matter how fully data may be published, on complex work of this kind, the value of judgment can never be replaced by the mere possession of formulas and constants. The right use of the latter with knowledge of their limitations must invariably be largely settled by experience. When these are supplemented by tests, real progress lies close at hand.

The range of tests possible in a heating and ventilating installation is very broad, and in many commercial instances only the fundamental issues can be determined. The quantity of air supplied per capita per hour, the quality of the supply and the temperatures obtained in the principal rooms are essential to any proper appreciation of the working of an installation. Combined with these factors in the comfort of the users of the premises is the question of operating economy, expressed more or less indirectly by the size of the coal bills. It is quite as important to keep a daily log of the heating plant as to prepare and submit regular operating records of a power installation to its owners, though in many quarters this is not yet fully realized.

As soon as one begins to measure the quantities required in a heating and ventilating test he must realize that scientific accuracy is a very difficult thing to secure. Temperature measurements can, of course, be carried to great refinement, if desired, but accurate determinations of air velocity and volume are not easy to make. An error of even 2 or 3 per cent. in the velocity measurement means the inclusion or exclusion of a large volume of air when multiplied by a considerable duct area in a building seating several thousand people. The calibration of anemometers is sometimes attempted by timing with a stop watch the speed of an observer traversing a known distance with an instrument in his hand, but it is a question if such a calibration can be relied upon to any considerable extent. Certainly for an accurate test upon a plant moving scores of thousands of cubic feet of air per minute, the anemometers used should be calibrated by physical laboratory methods. In some tests air velocities measured in one or two representative ducts have been taken as bases of operation throughout the entire installation, particularly where the ducts are not readily accessible. Such assumptions are dangerous to make if accurate figures are desired, and in any test carried out thoroughly as far as it goes, the data secured will show the velocity of air at every outlet which is essential to the proper operation of the system installed.

Fan speeds measured with a tachometer and not taken from the manufacturer's name plates are equally essential. One of the most important interpretations to be made from a heating and ventilating test when forced or induced draft is employed is the relation of fan speed to the volume of air delivered. Even if the exhaust from the fan engines be delivered to the indirect heating coils, the supply of the necessary quantity of air per capita per hour calls for the adjustment of fan speeds in relation to the external temperature and weather conditions; and in the case of variable speed motor-driven fans, the saving in power gained by not operating at abnormal speeds in relation to the requirements is well worth securing.

Air discharges in outlet ducts furnish helpful data in almost every case where the test is carefully made. The effect of damper adjustments, both automatic and manually operated, is interesting to study in a concrete installation, especially in plants where mixing dampers are in service. In this connection, the sensitiveness and speed of automatic themostat control deserve more attention than they ordinarily receive. In tests of refrigerating systems the response of the regulating valves to slight changes in temperature is almost always carefully watched, and no less of a working examination should accompany a heating test, whether the test be on a newly completed or a long established installation. Complete temperature readings in all the vital portions of a heating and ventilating system are imperative if correct deductions are to be made. The mean of several readings per duct or per room is none too good an index of the varying conditions to be expected in practice.

For the majority of cases the purity of the air can be sufficiently well determined by the phenoephthalein lime-water test, in which the time required to eliminate the pink color in a carefully prepared solution is noted when the solution and the air sample are brought into intimate contrast. According to Coyne's method, this time with a properly prepared solution is indirectly proportional to the amount of carbon dioxide present. Nothing short of a chemical analysis will show the accompanying atmospheric impurities in an air sample, but in the absence of any fixed standard of impurity other than the carbon dioxide figure, this simple test is doubtless acceptable enough for all but the most disputed cases. No heating or ventilating system can eliminate the dangers of atmospheric pollution from bacteriological causes, but in securing the presence of a low percentage of carbon dioxide the engineer helps to keep the standard of vitality at a high point per capita. Hence no test of the general value of a heating and ventilating system is complete without careful approximate measurements of the carbon dioxide present. The cleanliness of the air supply is well worth noting in such tests, by reference to scrubbing and washing apparatus when the installation contains such equipment.

On the heating side the most thorough study of a plant calls for an evaporation test on the boilers, with separate calorific determination of the fuel, and close checking of weights before the efficiency of steam application can be known. Given these boiler data and knowing the heat distributed in the steam supply, a fair check upon the efficiency can be obtained by weighing the returns and noting their temperature on the feed water side of the system. Where the run of piping through tunnels or walls is considerable before the direct radiators are reached, it may be necessary to make separate tests of radiation losses on known lengths of pipe in order to make the necessary deductions from the total heat units supplied to the distributing system. Where both direct and indirect radiation are tested at the same time it is necessary to separately measure the effect of changes in each system if the performance of either is desired in detail.

It is evident upon very limited consideration that the range of quantities and inter-relations open for actual research in heating and ventilating systems is almost unparalleled in the field of mechanico-physics. In the preceding paragraphs only the more important quantities and measurements have been mentioned. The working out of heat losses in detail, the study of the heat conducting and radiating characteristics of different types of apparatus, and of varying forms of wall, ceiling and floor construction, the analysis of resistance in ducts as affected by curves and elbows, the study of air leakage under different conditions of weather, and the consideration of fuel consumption in relation to the plant design and conditions of operation, furnish ample scope for research activities. Still another reason for the practice of heating and ventilating tests is to make sure from time to time that the installation is being handled as well as possible. It frequently happens, especially in school houses and other public buildings, that while a heating plant may start in economically, changes in the use of rooms, alterations in the buildings, or sometimes corrupt political practices place burdens upon the system which it was never designed to meet. The light which a test by a responsible engineer throws upon the conditions obtaining in a heating plant often points the way toward radical economies, either in the purchase and use of fuel, or the handling of the plant itself.

The Great Inland Waterway.

An unusual role has been played in the history of Chicago by zoological circumstances. For a considerable time many residents of the inland metropolis were accustomed to consider the proper representation on the city's shield to be a cow rampant, surmounted by a kerosene lamp. But it looks now as though this familiar blazon must be exchanged for an ursus couchant, for our honored chief magistrate, having at last found and slain that bear in the Louisiana canebrakes, has emerged from his seclusion, elated and happy, to tell the people of Vicksburg that no American president could spend his time better than by seeing for himself just what a rich and wonderful region the lower Mississippi Valley is. He has also acquired the "set purpose to do everything that in me lies to see that the United States does its full share in making the Mississippi River a part of the sea coast, in making it a deep channel to the Great Lakes from the Gulf." In the study of the subject which he evidently gave it in company with the engineering specialists who assembled to conduct the siege operations of bruin, he ascertained that with one-tenth of the effort spent by the people of Holland in taking two-thirds of their country out from under the ocean, the United States can remove the incomparably rich bottom land of the lower Mississippi from all fear of flooding by the Mississippi River, by a high and broad levee system. The matter is settled, moreover, that the deep channel and the high and broad levees shall be built. The president intends to start the project on principles that will prevent mistakes, extravagance and misapplication of effort. "I shall have no small difficulty in persuading some people," he stated at Vicksburg, "of the wisdom of a policy such as that I advocate, a policy that means the expenditure of money, a policy which must continue over a long course of years. If that policy is tainted in any way by jobbery or folly, it will be immeasurably more difficult to carry it through. What we must look out for is the action of the men, probably well-meaning, who in their anxiety to serve some particular district, will try to divert what should be a national effort to deepen a great national highway into a succession of efforts spread out so thin as to make all ineffective."

It is instructive, indeed, to observe the energy with which our honored chief magistrate has thrown himself into the cause of a deep waterway from the Great Lakes to the Gulf. The fact that the majority of leading engineers of the country are by no means convinced of the desirability or even the actual financial practicability of such an undertaking apparently has no influence in checking his unqualified support of the project. The mere fact that it seems to lack this support from those most competent by training to appreciate the problems involved and the

interests to be served by an enlarged channel will doubtless render the president's help extended to the advocates of the undertaking more vigorous and outspoken. We have all observed the great fondness he has displayed toward minority engineering opinions. And the fact that the desirability of a deep waterway from Chicago to the Gulf is at the present time advocated mainly by those who are least competent by training to express an opinion on the subject, or else by those who have an axe to grind, will doubtless be taken as merely an indication of the necessity of an educational campaign on his part.

In making these observations, there is no intention of asserting that an improved waterway from the Great Lakes to the Gulf will not be useful. It goes without saying that some use would be made of such a channel immediately upon its completion. The question at issue is whether the channel will be worth the expense, and, so far as The Engineering Record has yet been able to learn, there is no proof that money spent for a 14-ft. channel would not be about as well used in providing a game preserve near the White House. But this does not mean that a thorough study may not indicate the desirability of some kind of improvement. If the president's advocacy of a deep channel results in a thorough study, it will have been a national service. If that study is made by competent men, who are unbiased by the complications involved in the disposal of the sewage of Chicago by the method of dilution, the country will be thankful indeed. At the present time it seems hardly possible to differentiate between the people who desire to have a waterway for the purpose of navigation and those who believe that in some way or other the Trustees of the Chicago Sanitary District should be allowed to take a large amount of water from the Great Lakes for the disposal of the sewage of the community about the end of Lake Michigan.

Elsewhere in this issue will be found a summary of an important report made by Mr. Rudolph Hering, who designed the Chicago drainage canal, to the Trustees of the Sanitary District advocating the extension to the Calumet region of the method of disposal by dilution which the Trustees desire. He states that the anticipated lowering of the water lake level due to the diversion of the 14,000 cu. ft. per second from the lower end of Lake Michigan into the two canals for sewage disposal purposes will not occur, provided the works advocated by the International Waterways Commission are constructed at Sault Ste. Marie. This opinion is a direct contradiction of that reached by the members of the International Waterways Commission. The question is therefore thrown open to debate and the president is faced with the necessity of deciding between an international engineering commission representing the Dominion of Canada and the United States, and an individual engineer. Even assuming that the figures made by Mr. Hering are correct, and this journal does not attempt to pass an opinion on this disputed matter, the president must decide whether the desirability of permitting the city of Chicago to continue the use of a method of sewage disposal which is unnecessary although it may be financialy advantageous, is to outweigh the desirability of increasing the navigable depth of water throughout the Great Lakes, for if water is not diverted for the disposal of Chicago sewage, it will manifestly be available for improving the navigation from Chicago to Buffalo. The problem, therefore, is merely one of the relative interests served by the two methods of using the water.

Along with the disposal of the Chicago sewage, must also be considered the practicability of using for navigation this water turned into the drainage canals. It is fairly well recognized that the hope of sea-going vessels using the proposed waterway from Chicago to the Gulf is founded more on dreams than facts. The type of vessels which are best adapted for sea-going navigation and for use on inland waters are so radically different that the most to be expected from such a proposed channel is a growth of the fleet of shallow-draft vessels now using the Mississippi and its tributaries. Until more facts are ascertained than are now known, any arguments regarding the transportation possibilities of such vessels in competition with railway lines must inevitably be based on so many assumptions that the time spent in making or listening to them will be very largely wasted. Those who believe that a great waterway is needed from the Gulf to the Great Lakes will do more for this cause by securing all definite information bearing on the subject than by indulging in generalities. The cost of such a waterway is so enormous and its construction will extend over such a long period of years that the nation ought, under no circumstances, to be committed to it until every phase of the subject has been thoroughly investigated by competent, unbiased specialists.

The Engineering Record's New Home.

Elsewhere in this number will be found a brief description of the structural features of the new home of The Engineering Record. Many requests for information concerning this building have been received during the past year, but on account of the novelty of some of the details of the design and the special conditions which arose during the preparations of the plans for the structure, it was considered best to defer any detailed description for a paper for the American Society of Civil Engineers. This paper has been written by Prof. Wm. H. Burr, who designed the structural portion of the building, but there are certain comments which should be made in amplication of it. The structure, which is known as The Thirty-Ninth Street Building, was erected by a subsidiary corporation of the McGraw Publishing Company, the owner of The Engineering Record. Its primary purpose is to afford a home for the company and its affiliated printing corporation. Until the structure was erected and occupied, the printing of the company's various publications and books was done in three independent printing offices, and many difficulties are inherent in any such method of issuing large journals every week in editions equal to those of the McGraw publications. By bringing the printing, accounting, business, editorial and advertising departments of the company into a single building, the service that can be rendered by the company is materially bettered. To raise this service to the highest practicable degree it was desirable to have a structure readily reached from all parts of the city where engineers, contractors, city departments and manufacturers' offices are located, and it was equally desirable to have this building near the branch postoffices where second-class or "newspaper" mail matter is received. This narrowed the selection of a site materially and finally resulted in the selection of land on West 39th St., within about three minutes from Times Square, one of the central points of the city. This location is very near the new terminal station of the Pennsylvania R. R. now under construction, and also the Grand Central Station of the New York Central Lines, at both of which places mail matter of the second-class is either received now or will be received. The McGraw Realty Company has also arranged for the use of one floor and part of another floor of the new building as the "Times Square Sub-Station" of the New York Post Office, so that under its own roof there will be excellent facilities for expeditious handling of all mail matter other than that of the second class.

The site selected for the structure is an expensive one and the property in the vicinity is rising with great rapidity. In consequence of this condition ordinary business prudence made it advisable to erect a large building of an attractive appearance, well provided with the customary facilities of a modern office building. Three floors of the building must be occupied by the printing plant, and as the running of rotary presses is likely to cause vibrations, the design of the structure had to provide for the deadening of all such tremors. After an examination of many buildings containing printing presses, it was evident that a steel-cage structure of the height of the proposed building, about 150 ft., would probably tremble while the presses were running more than was admissible in a high-grade office structure, while a reinforced concrete building would probably be free from such vibration. A building of reinforced concrete, which is able to carry such loads as those imposed by printing plants on many of its floors, has to be of unusually heavy construction, and the mass due to the use of so much concrete acts in an efficient manner in absorbing vibration.

After the preliminary plans were worked out, it was found that a structure of the kind best adapted for the desired height could not be erected under the existing building requirements and be a good business proposition, so it became necessary to take up with the Bureau of Buildings the problem of designing columns which would be satisfactory to the Bureau and at the same time be of sufficiently moderate cross-section to leave enough room in the lower floors to render the latter useful for business purposes. Under the old regulations of the Bureau very large columns would have been required, and the proposed structure using such columns would have been a business impracticability. Probably the most interesting feature of the building is the type of columns finally adopted, which is fully described in Professor Burr's paper.

Another feature of the structure to which attention may be called is its exterior. Objections have been raised to the use of concrete in buildings on account of the impracticability of giving it a satisfactory exterior appearance. In some structures in New York this alleged defect has been avoided by using brick facings, and in buildings elsewhere the concrete surface itself has been treated in various ways more or less satisfactory. The Thirty-Ninth Street Building had to be as attractive as possible, and after a prolonged study it was finaly determined to use a sort of stucco of Portland cement and marble dust, which has been employed very successfully for several years in the vicinity of New York. This is a comparatively new proprietary process and the results of its application in The Thirty-Ninth Street Building are very satisfactory. At the present time the building is not entirely completed in some of the minor details, and it is undesirable in consequence to publish at this time illustrations of its appearance now. It may be stated, however, that the expectations of the company concerning it are fully met, and the many novelties, large and small, which were adopted on the advice of Professor Burr and his associates have proved uniformly satisfactory. While the structural novelties are explained in the paper in this issue, the general appearance of the building, the admirable lighting of the various floors on account of the unusual window space and other features which need not be mentioned at this time can only be appreciated by a personal visit, which the company cordially invites all its friends to pay to its new home.

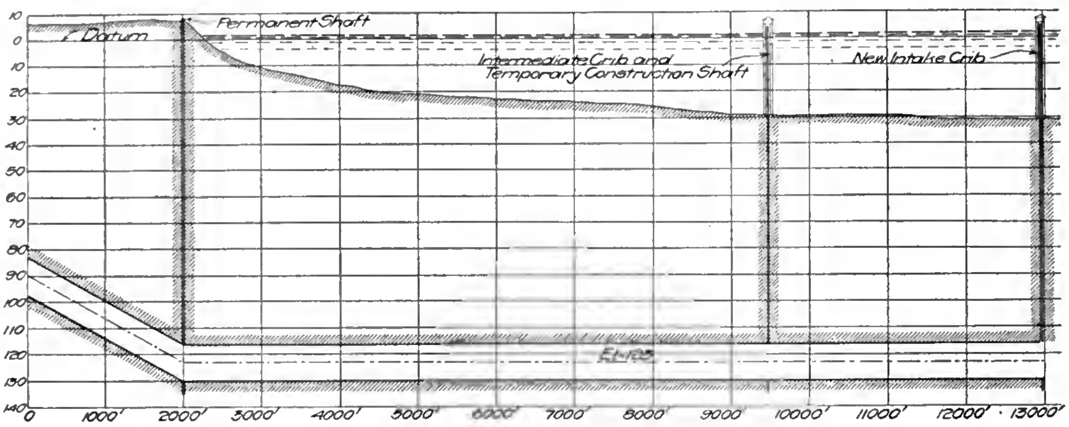
AN UNUSUAL PLANT FOR CONSTRUCTING A SUBMARINE TUNNEL AT CHICAGO.

A noteworthy installation of contractor's plant has been placed in service recently by George W. Jackson, Inc., in connection with the construction of the lake section of a new tunnel for the water-works system in Chicago. This tunnel, generally known as the Southwest Lake and Land Tunnel, is to have a total length of approximately 10 miles, extending from an intake crib about 11,000 ft. off-shore in Lake Michigan from 68th St. to the southwestern part of the city. The intake crib of the new tunnel is adjacent to the intake crib of an existing water tunnel which leads to a pumping station near the foot of 68th St., the shore end of the lake section of the new tunnel being at the foot of 73d St. Based on experience in the construction of the 68th St. tunnel, and on a number of borings made prior to the location of the new tunnel, it is expected that the latter will be entirely in limestone bed rock. The finished cross-section of the tunnel will be a 14-ft. circle for about 2¼ miles from the intake crib to a point where a 9-ft. branch is taken from it. From this branch the section will be reduced to a 12-ft. circle, which continues for some distance to a division of the tunnel into two 9-ft. branches. The tunnel is to be lined throughout with concrete, which is to have a minimum thickness of 1 ft., so the excavation for the lake section is required to be at least 16 ft. in diameter, and involves the removal of something over 125,000 cu. yd. of solid rock from the tunnel bore.

The center line of the land sections of the tunnel are 100 to 110 ft. below the ground surface, the latter being only 8 to 10 ft. above the mean water level in the lake. The tunnel drops on a 1.75 per cent. grade for 2,000 ft. adjacent to the lake, and then continues on a level grade in the lake section, the center line of this section being at a uniform depth of 123 ft. below the mean lake level. The section, which is being constructed by Geo. W. Jackson, Inc., has a total length of 12,180 ft., about 10,800 ft. of which is off-shore under the lake. A permanent shaft, 14 ft. in diameter inside the concrete lining, is placed at the point where the grade of the tunnel begins to rise, approximately 300 ft. from the shore of the lake. The intake crib at the outer end of the tunnel, which is also included in the contract, will be connected with the tunnel by a shaft, 11 ft. in diameter inside the concrete lining.

The lake section of the tunnel will be driven from at least four headings, one in each direction from the foot of the permanent shaft near the edge of the lake, and one in each direction from a temporary construction shaft, 7,500 ft. off-shore. It is also probable that some tunnel driving will be carried landward from the shaft at the intake crib. An unusually complete and extensive plant that has been installed to handle this tunnel-driving is expected to permit the work to be carried forward, day and night, practically without hindrance from the weather, or from rough water in the lake.

Aerial Tramway.—The unique feature of this plant is an aerial tramway, which is an adaptation of the type frequently used in mining districts to handle ore over considerable distances. This aerial tramway has a total length of 8,000 ft., extending from a head house over the permanent shaft on shore to a crib and head house erected at the top of the temporary construction shaft in the lake. It is carried at an average height of 35 ft. above the water by 24 four-leg steel towers, spaced approximately 300 ft. apart. This tramway will entirely preclude any necessity for tugs and scows that would be required to handle the materials excavated from tunnel, to transport men between the shore and the shaft, and to deliver supplies to the latter. The advantage to be gained by overcoming in this manner any dependence on floating equipment can scarcely be appreciated without a knowledge of the weather conditions in the locality and of the rough water which prevails in the lake along this shore during a large part of the year. Around the south end of Lake Michigan high winds are frequent at all seasons, even during fair weather, and in the winter these high winds often continue for several days, while in the summer local storms contribute an added danger. These atmospheric conditions, coupled with the comparatively shallow depth of the lake over the tunnel, cause much rough water, which renders impossible the operation of scows and tugs for considerable periods at a time. In fact, during at least five months of the year practically no reliance could be placed on floating equipment for the service required. At the same time, a very large saving in time, labor and power will be made possible by the operation of the tramway, as compared with the operation of tugs and scows, between the intermediate shaft and the shore. Furthermore, all of the limestone to be removed from the tunnel headings driven from the foot of the intermediate shaft can be saved, and after being crushed is worth $1 to $1.10 on the cars, whereas if an attempt was made to handle this rock from the intermediate crib on scows the rock could scarcely be unloaded at the shore at a reasonable cost, and would more economically be towed out and wasted in the lake. Although these are the chief advantages to be gained in operating the tramway, various others of considerable importance are presented, which in the aggregate render a successfully operated tramway a most economical installation.



Profile of Lake Section of Southwest Lake and Land Tunnel.

An elevation of one of the towers on which the tramway is carried is shown in an accompanying illustration, the towers all being the same. The controlling factors of the design of these towers were the rigidity and stiffness necessary to resist the force of the high wind and rough water to which the whole tramway will be subjected in the open lake. In providing for these conditions in the construction of the towers, a large factor of safety over the maximum load of 8,000 lb. that may be brought on each tower by the tramway is obtained.

Each tower has an extreme height of 30 ft. 5 in. and is 12 ft. square at the base, its four legs converging from the base to the top, as the corners of a pyramid, the tower being 1 ft. x 2 ft. 1 in. in plan at the top. Each leg of the tower consists of a 3½x3½x⅜-in. angle, the four legs of the tower being quite completely cross and sway-braced, as shown in the accompanying illustration, to obtain the necessary rigidity and stiffness.

Each leg of the tower is carried by an extra-heavy built-up steel pile, designed specially for this purpose. The tops of all of these piles are at the same elevation, 5 ft. above Chicago datum, which is about 1 ft. below the mean water level of the lake. The depth of water in the latter increases gradually from about 6 ft. close to the shore to 33 ft. at the outer end of the tramway, the average depth in this distance being 25 ft. The piles carrying the towers were built in lengths varying from 22 to 49 ft. and were driven by a floating pile-driver outfit practically to refusal in the hard blue clay which forms the bed of the lake over the whole site of the tramway, except near the shore, where an overlying stratum of sand and gravel occurs. The cross-section of each pile forms two sides of a hollow square, 12⅞ in. on a side. Two general sections of the piles were built, one for those from 22 to 43 ft. in length, and the other for piles up to the maximum length of 49 ft. Both sections are unusually heavy and are arranged to produce an exceptionally rigid column. The four piles of each tower are fastened together at the top by a pair of diagonal tie rods, and at the water level by two pairs of 2-in. rods, also placed as diagonals. A frame of 12-in. channels, 11 ft. 11 in. square, is also placed horizontally inside the four piles carrying each tower, 6 ft. below the surface, and is lashed to each of the four piles.

The tendency of the towers to tip, due to unbalanced loads on the tramway or other cause, is prevented by six inclined braces to each set of four piles for a tower. These braces are all attached at the water level, and each extend down to an anchorage set in the bed of the lake. Four of them are each at one end of the two diagonals of the square formed by four piles. These four inclined braces on the diagonal lines are 6x6x¾-in. angles, in lengths varying from 14 to 36 ft., depending on the depth of water at the different towers. Each of these angles is lashed to the pile for which it is a brace by a chain rove through holes punched in the angle and in two ½x6-in. reinforcing plates riveted to the upper end of the brace. Each of these four braces are placed at an angle, which brings its lower end 9 ft. from the base of the tower, where it is rigidly fastened to two short pieces of ½x6-in. plates, attached upright in a horizontal plane to two 6x½-in. plates, 15 in. long, which were set vertically their full length in the hard clay by a diver. This arrangement of plates at the base of each brace was provided more as a bearing for the brace to react against when a load is thrown on it than as an anchor.

The other two inclined braces to each set of four piles carrying a tower are on the axis of the tramway, on opposite sides of the base of the tower. These braces each consist of a 9-in. 21-lb. I-beam, reinforced by two 6-in. channels,

one on each side of the web. Each of these braces is attached loosely at the top through a 2-in. pin connection to a 12-in. I-beam placed horizontally between the pair of piles on the adjacent side, the connection being on the axis of the tramway. The lower end of each of these two braces to a tower is attached to a 6-ft. piece of 5-in. 6½-lb. channel, placed normal to the brace and imbedded in the bottom of the lake, to provide a reaction for the brace, the same as in the cases already cited. The lower end of each of these braces on the axis of the tramway is 12 ft. from the piles on the corresponding side of the tower, the length of the braces varying from 15 ft. to about 37 ft., depending on the depth of the water at the towers.

The construction of the towers and the arrangement of the piles on which they are mounted produce a structure for carrying the tramway cables that has already shown itself to be capable of withstanding the heavy seas and high winds which frequently prevail along the shore of the lake. No special protection against ice other than that afforded by the sub-structure of the towers as they stand has been provided, and it is not believed that any such protection will be required.

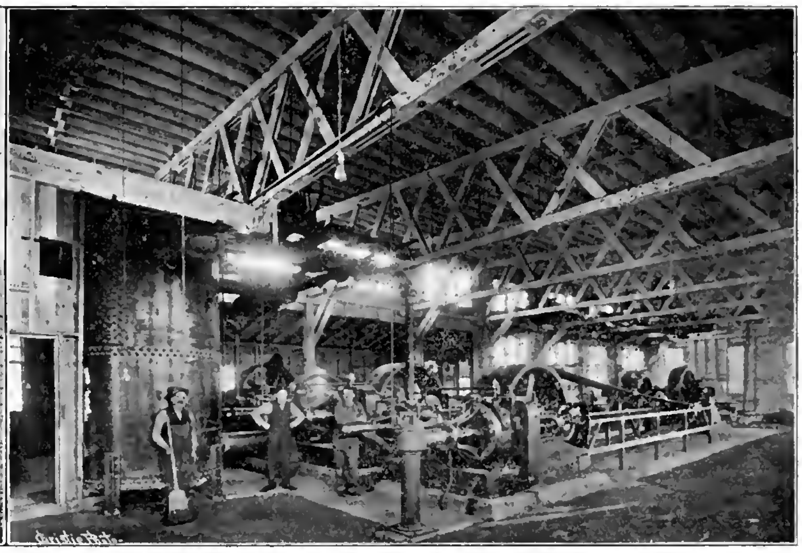
The tramway proper consists of a 1⅜-in. wire track, or carrying cable, and a ⅞-in. traction or trolleying cable on each side of the towers. Buckets are hauled out to the intermediate shaft on the carrying cable on one side of the towers, and back on the carrying cable on the other side by the traction cable. The carrying cable is of a special flat strand type, which permits the buckets to ride very easily, and has unusually good wearing properties. A saddle on each end of a 10-ft. cross arm at the top of each tower supports the carrying cable. The traction cable on each side of the towers runs normally on an 8-in. sheave wheel on the end of a second cross arm on each tower. This second cross arm is 9 ft. 2 in. below the upper cross arm, and rises in the space between the two arms when attached to a bucket.

The tramway buckets are built of steel, each bucket having a working capacity of 10 cu. ft., or 1,000 lb. of rock. They are each suspended on a carriage having two 16-in. grooved wheels, which run in tandem on the carrying cable. The carriage also has an automatic grip that clutches the traction cable, the latter having a normal traveling speed of 300 ft. per minute when the tramway is loaded. Under regular operating conditions about fifty of these buckets can be in service on the tramway and will be spaced 300 ft., or one tower length apart.

The rock excavated from the headings driven from the intermediate shaft will be hoisted to the surface in tunnel cars by a steam-driven 8,000-lb. freight elevator, designed specially for this service, and will be dumped from these cars into an elevated storage bin in the second story of a 76-ft. octagonal head house that has been erected on a large rock-filled timber crib, placed over the site of the shaft. The rock will be delivered from this bin, which has a capacity estimated to be equal to about 48 hr. output from the two tunnel headings, when in full operation, directly into the tramway buckets, and carried by the latter to a storage bin in a head house over the shore shaft. The terminal of the tramway at the shore end is in a second story of the head house there, the two carrying cables being connected by a loop telpherage track. As the buckets enter the building the grip on the traction cable is automatically released, so the buckets can be handled readily while on the telpherage track. The storage bin is in the first story of the head house, and the rock will be dumped from the buckets into a hopper in the floor over the bin. This dumping will probably be done by hand, although the carriages of the buckets are equipped so they may be arranged to dump automatically on reaching the hopper. The latter will be on the entrance side of the telpherage loop at the end of the tramway, and as the buckets are passed around to the opposite side of the loop, to be sent out again, the grip is automatically attached to the traction cable.

Passenger Car For Service on Tramway.

View Toward Shore From Intermediate Shaft.



Interior of Central Construction Power Plant.

The second story of the head house over the shore shaft contains switches connecting with the telpherage terminal loop of the tramway, which switches have sufficient capacity to store all of the buckets installed. The off-shore terminal of the tramway, like the in-shore one, is also a loop telpherage track, with switch connections for storing buckets. The tramway dips down to about 25 ft. above the water at the outer end to enter the head house over the crib at the intermediate shaft.

Several enclosed cars that are provided for transporting men between the intermediate shaft and the shore are also stored on these switch connections in either head house when not in use. These cars were designed specially for the service in which they will be used and will each carry four passengers. Their bodies are oval in cross-section, being 4 ft. long, 5 ft. high and 3 ft. 3 in. wide and have a light steel frame covered with sheet iron. The entrance is through a door in one side, which closes tightly, so the only openings when the car is on the tramway are two portholes in one side of the body; a seat for two people is provided at each end of the car, so the latter makes a comfortable conveyance in any kind of weather. The carriage by which the car is suspended from the carrying cable of the tramway is very similar to the one used on the buckets, except that it is much heavier.

The 1⅜-in. carrying cable is continuous, the two ends each being attached through a take-up to a separate anchorage at the shore head house. These take-ups each consist of a pair of triple tandem blocks rove with a ¾-in. wire cable, which is wound on a drum driven by a worm-gear that can be operated by one man. These ¾-in. cables are attached to the main cable, but the latter is also attached to the anchorage as a precaution. In the head house over the intermediate shaft the carrying cable passes around a heavy frame on a 4-wheel truck, which is safely anchored, but can be moved along the axis of the tramway as tension or slack is required in the carrying cables.

The tramway is driven by a 25-h.-p. alternating current motor, which runs at 600 r.p.m., about half the capacity of this motor being required when the tramway is in operation. The motor is geared to a large drive wheel for the traction cable, the wheel being equipped with automatic grips, which reduce the wear on the cable to a minimum.

The cables, buckets and special apparatus for the tramway were furnished by the A. Leschen & Sons Co., of St. Louis, Mo., and were installed under the direction of Mr. B. C. Riblett, chief engineer of that company, by the regular forces of the contractor. The steel towers and the piles on which they stand were all fabricated in the extensive bridge and steel shops of Geo. W. Jackson, Inc., on the north branch of

the Chicago River. The steel piles were also all driven and the towers erected by the contractor's regular forces.

Shafts.—The permanent shaft on shore, from which headings will be driven in both directions, will have a total depth of 145 ft., a sump, 5 ft. deep, below the invert of the tunnel, being placed at the bottom of it. Although the shaft is to have a finished idameter inside the lining of 14 ft., for construction reasons it was driven 21 ft. in diameter at the top, and will have a diameter of 16 ft. at the bottom before the lining is placed. Bed rock at the site of the shaft is at a depth of about 65 ft. The top 20 ft. of the soil overlying the rock is fine lake sand that runs like quicksand when wet and is very compact; under this sand is a 25-ft. stratum of blue clay, varying from quite soft at the top to fairly stiff at the bottom, where it grades off into a medium hard clay, below which is a stratum of hardpan and boulders directly over the rock.

The lake being only 300 ft. distant and about 10 ft. below the ground surface, the construction of a shaft of the required diameter in the running sand was a particularly hazardous undertaking, but was handled without difficulty, by using Jackson steel sheet piling. This piling consists of standard channels and I-beams, the channels being arranged in pairs, which are placed alternately with an I-beam between each two pairs. In this case standard 12-in. 20.5-lb. channels and standard 12-in. 31.5-lb. I-beams, all in 40 ft. lengths, were used. The webs of the I-beams were bent slightly to fit the curve of the shaft, but otherwise standard sheeting was employed.

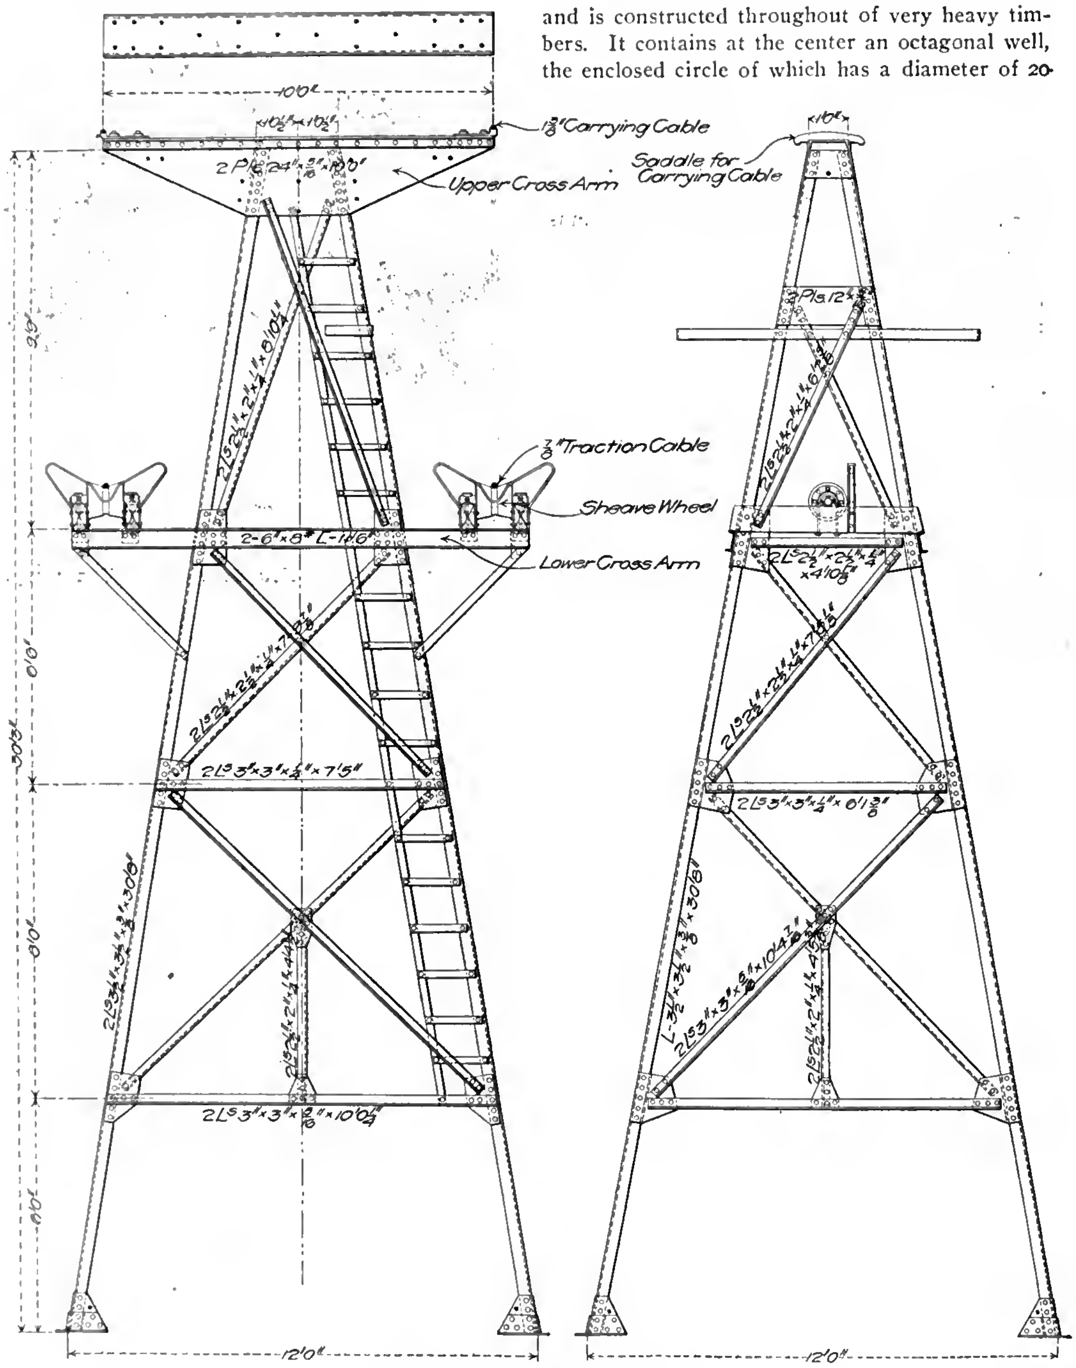
After the shaft had first been excavated to the ground-water level, at a depth of 5 ft., a template, 21 ft. in diameter and built of steel angles, was laid on the ground to serve as a guide for driving the piles. A portable turntable pile driver, having 80-ft. leads and a 5,000-lb. steam hammer, was used in sinking the piles. A stiff-leg derrick, with a 70-ft. boom, handled the piling from cars on a railroad switch that was laid along one side of the shaft, and also swung them into position for driving. The piles were first driven in a complete circle to a penetration of about 12 ft. The driver working on the outside then drove to the full depth enough piles on one side of the circle, so it could be moved inside the latter and sink the remainder from one position. The piles were all driven without any trouble, although in a few instances a water jet was used to assist the hammer. Seventy piles were required to make the complete 21-ft. ring, which has a circumference of 65.97 ft. It was contemplated that some difficulty might be experienced in closing the circle, but the last pile formed a perfect closure. The driving was done in three working days by five men, on an average, 131 lin. ft. of piling, or 1,600 sq. ft. of sheeting, being driven each day.

When the sheeting had been driven the sand, clay and so forth were excavated by hand from the area enclosed by it and were handled out in buckets by the derrick. Although the head of water on the sheeting when the excavation reached the stiff blue clay, which is practically impermeable, was at least 25 ft., only a few small leaks through the piling had occurred, and these were readily stopped by dropping clay and sawdust into the space enclosed by the pairs of channels of the piling. The excavation was carried to the bottom of the 40-ft. piling without any braces whatever, the piling having sufficient stability to maintain itself as the lining of this 21-ft. circular excavation against the heavy pressures brought against it. Below the bottom of the piling the excavation was sheeted with a steel casing, which was placed in 6-ft. sections, one telescoping inside the other, as the material was removed. The shaft was thus carried down to rock at about 65 ft. below the ground level and then left to stand for several weeks pending the installation of the balance of the construction plant. During this period a No. 2 Nye pump, working about one-sixth of the time, removed the seepage into the shaft, as the steel sheeting was practically free from leaks with the full head of water against it.

The two-story head house over this shore shaft is 46x65 ft. in plan and contains the terminal of the tramway on the top floor and a rock storage bin on the first floor, as has been stated. The rock from the tunnel headings driven from the shaft over which this house is built will be hoisted in tunnel cars by an electrially operated 8,000-lb. elevator in the shaft and dumped into the storage bin. An eletrically driven rock crusher is to be installed in the first story of the building to crush the stone for market. The crushed stone can be loaded directly into the cars on a railroad switch along one side of the head house, or the run-of-mine stone can be loaded into these cars. As more than 125,000 cu. yd. of rock will have to be removed from the tunnel and passed through this head house, the handling of the rock after it reaches the storage is alone a very large undertaking.

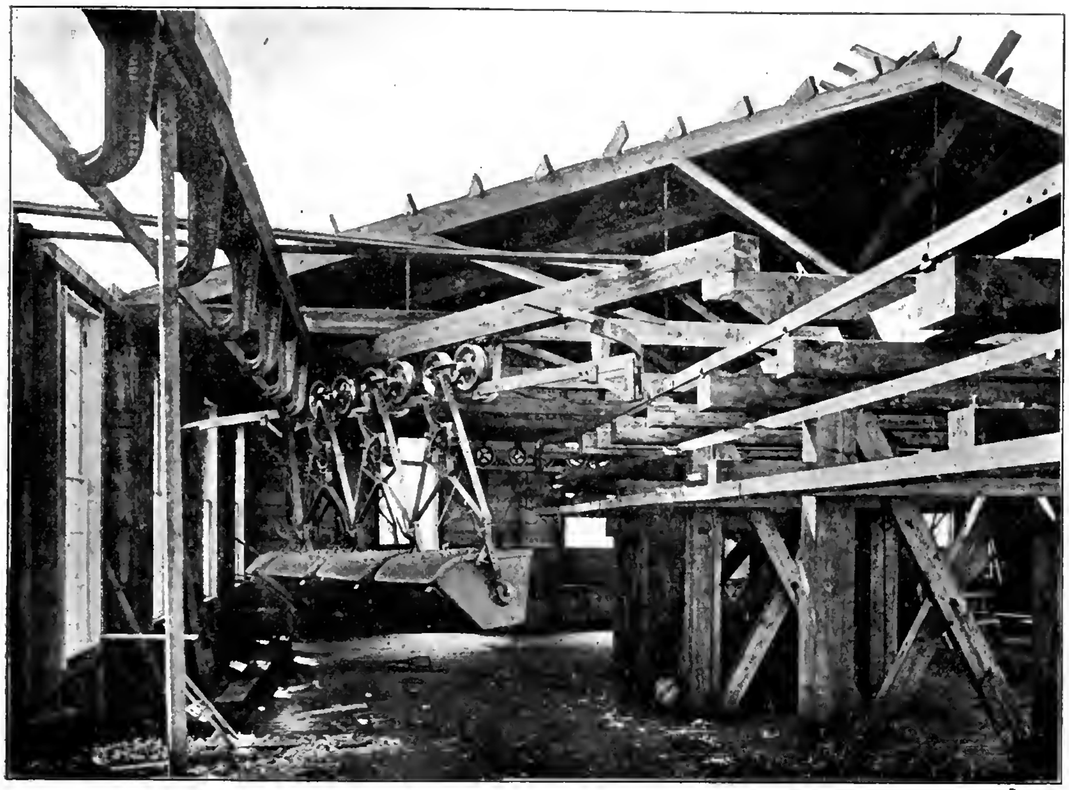
The bottom of the intermediate construction shaft in the lake is to be 137 ft. below the mean lake level, the water varying from 33 to 36 ft. in depth at this shaft, under different barometric conditions. Rock is at a depth of about 60 ft. below mean water level and is overlaid by 27 ft. of material varying from hardpan immediately over it to soft blue clay at the surface of the bed of the lakes. A heavy rock-filled octagonal timber crib, with an inclosed circle having a diameter of 76 ft., has been placed concentric with the shaft and carries the head house for the latter. This crib has a total height of 65 ft. and is constructed throughout of very heavy timbers. It contains at the center an octagonal well, the enclosed circle of which has a diameter of 20 ft., and around this well are the pockets for the rock fill. The sides and bottom of these pockets are made practically watertight to 12 ft. above the water level by 3-in. oak sheeting, thoroughly calked.

The shaft is to be encased down to the rock with Jackson steel sheet piling, which is carried up 9 ft. above the water level, making the total length of the sheeting 69 ft. The circle enclosed by the sheeting is 20 ft. in diameter to a depth of 46 ft. and 12 ft. in diameter below that depth. The large circle at the top is formed by sheeting of the same size and weight as that used in building the shore shaft, and is in 51-ft. lengths,



Details of Tramway Towers.

which have a penetration of 9 ft. into the clay bed of the lake. This sheeting has been successfully driven, and at the time these notes were prepared the space between it and the walls of the well of the crib were being filled with packing material, in order that the water might be pumped out of the area enclosed by the sheeting, and the excavation be carried down sufficiently to permit a second set of sheeting to be driven for the smaller circle. The top of this



Tramway Buckets on Telpherage Switches in Head House Over Shore Shaft.

second set of sheeting, which consists of 5-in. 6½-lb. channels and 9-in. 21-lb. I-beams, is to overlap the bottom of the upper set about 2 ft., thus forming, together with the material between the two, a joint that should be perfectly safe, as it is 7 ft. below the surface of the bed of the lake.

The crib was built in a slip in the Calumet River at South Chicago, about three miles from the site. After it had been completed it was loaded with rock until it drew about 20 ft. of water, and on a day when quiet water was practically assured it was towed to place by three tugs in about three hours. It was then guyed in position and the rock filling required to sink and anchor it was placed. About 500 cords of stone were placed in the ballast pockets by two derrick scows, which completed this work in two days, although the crib was safely anchored 11 hours after it reached the site. A foundation of piles had been driven previously in the bed of the lake at the site and were sawed off at the surface of the clay, and the crib settled into position on this foundation without a mishap.

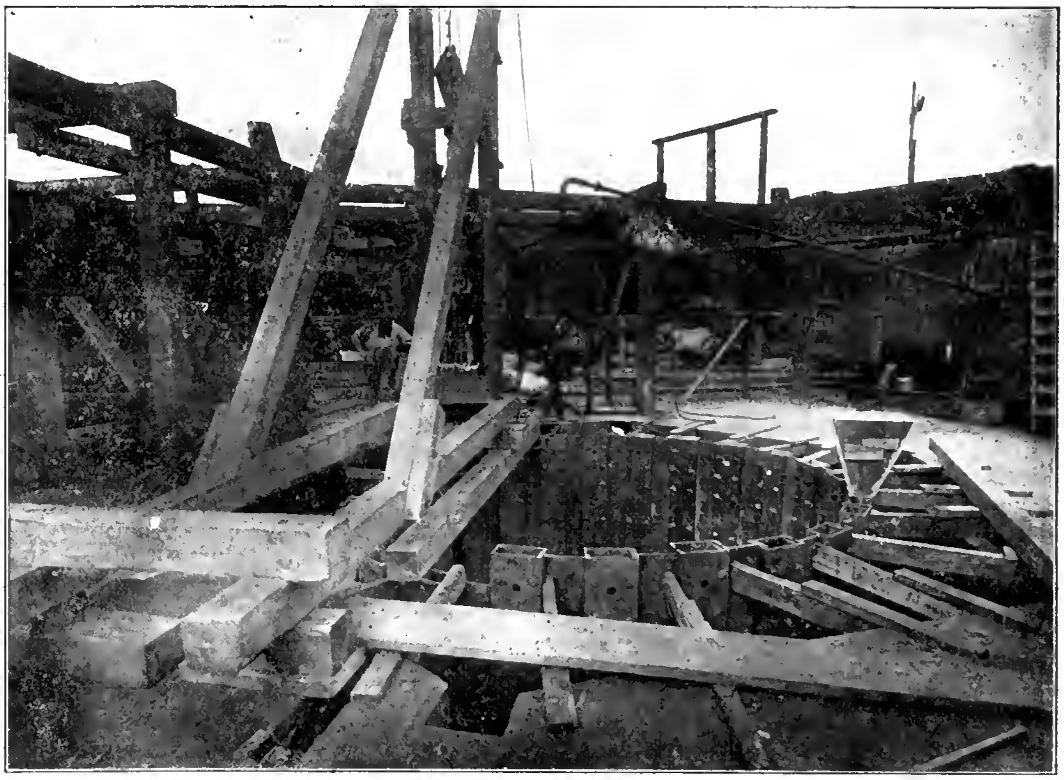
Central Power Plant.—A most complete central power plant, including a machine shop and a blacksmith shop, has been erected adjacent to the shore shaft, to supply power for operations in the tunnel and at the two shaft head houses, and for such other purposes as are necessary. The plant is in a 50x165-ft. frame building of unusually substantial construction for such purposes. A 25x50-ft. blacksmith shop is placed in the rear. In one corner of the front end of the main building is a row of four separate 12x21.5-ft. rooms, which provide a general office, an office for the contractor's engineers, an office for the city engineers and a bath and toilet room. The remainder of the building is one large room, which is free from columns, the roof being carried by light wooden trusses with a clear span of 50 ft.

These trusses are of quite simple and satisfactory construction. They are built entirely of 2x8-in. and 2x10-in. plank and 1-in. iron rods, without requiring any framing and very little cutting, all of the latter having been done with a hand saw. One truss was laid out so a complete set of pieces could be cut for it, then these pieces were used as patterns, from which the material could be cut for the whole series of trusses. The trusses each contain about 20 ft., board measure, of lumber to the linear foot and weigh approximately 3,500 lb. They were therefore easily erected with a light gin pole equipped with hand blocks.

All of the equipment in the power plant is driven by electric motors operating on power supplied from the commercial circuits of the Commonwealth Edison Co. This power is received as 3-phase 4,400-volt alternating current and is stepped down to 440 volts for use in the plant by a bank of transformers along one side of the building. A 250-kw. direct-current generator, direct connected to an alternating-current motor, is also installed to furnish direct current at 250 volts for operating the elevator in the shore shaft, electric locomotives in the tunnel headings, and so forth.

Four motor-driven Ingersoll-Rand air compressors, with a combined capacity of approximately 4,000 cu. ft. per minute, have been installed in the power house to furnish air to operate rock drills at the face of the excavation in the tunnel headings. These compressors are all compound duplex machines. Two of them, with 14¼-in. and 22¼-in by 14-in. cylinders, each have a rated capacity of 841 cu. ft. of free air per minute, when operating against 80-lb. pressure, and are each belt-driven by a 150-h. p. General Electric motor. The other two, with 16¼-in. and 25¼-in. by 16-in. cylinders, each have a rated capacity of 1,205 cu. ft. of free air per minute, when operating against 80-lb. pressure, and are each belt-driven by a 200-h. p. General Electric motor. These motors are each equipped with a starting device within the frame of the machine.

The four compressors all deliver into either of two 6 x 12-ft. upright receivers in the building. A 10-in. pipe header is extended from these receivers to the adjacent shore shaft, where a 9-in. line is taken off, and a 7-in. line, 8,000 ft. long, is continued out to the intermediate shaft in the lake. The 7-in. line is flanged spirally-riveted steel pipe from the shore line to the intermediate shaft and is placed on the bottom of the lake, with flexible joints to provide for variations in grade. This pipe is designed for a working pressure of 200 lb. per square inch and weighs about 9 lb. to the linear foot.



Steel Sheeting Driven to Form 20-Foot Circular Shaft at Intermediate Crib.

The entire compressor equipment has been placed in one central power plant on shore and a pipe line carried in the intermediate shaft, rather than to transmit electrical power to that shaft to drive a compressor there, for two principal reasons. First, no space was available in the head-house over that shaft. This head-house and the crib on which it stands are very large and expensive, but the provision of the addi-

tional space required for a compressor would have involved an increase in the cost of building a larger crib which would not have been in keeping with the advantage to be gained. On the other hand, the operation of two separate compressor plants would have occasioned double the expense for attendance that is required by a single central one. Furthermore, advantages for ventilating the tunnel headings which are afforded by the one central installation could not be obtained with two separate plants.

It is contemplated that 24 to 30 air drills will be worked in the two headings to be driven from each shaft, and on this basis the 4,000 cu. ft. per minute of air capacity that has been provided might appear to be more than is necessary. It was held, however, that the provision of more power than is generally considered to be required would preclude any possibility of shut-downs of the extensive plant due to one compressor being out of service. Another great advantage of the large amount of available air power is the ability to clear the gases from the headings after a blast. Arrangements will be made to deliver the full output of all four compressors at the face of the excavation in a heading directly following a blast. This will undoubtedly greatly reduce the delays which are occasioned under ordinary circumstances by waiting for the gases to disperse, and will also clear the atmosphere so thoroughly that the laborers at the face can deliver more efficient results when they return to work again.

Direct-current electrical power for operating the locomotives to be used in the headings driven from the intermediate shaft and for pumps in the latter is transmitted on two bare copper wires carried on insulators on the center line of the top cross arms on the tramway towers. The elevator for this shaft is arranged to be driven by a steam engine, in order that the men in the headings may be hoisted to the surface whether current is available or not. Alternating current for lights in the head house of the intermediate shaft, in the tunnel headings driven from the latter and for a light at each of the tramway towers is carried from the central power plant by a pair of insulated wires on the top cross arm of the towers. A regular nautical signal lamp is also maintained on each tower as an added precaution. A very powerful searchlight, mounted at such a position slightly to one side of the inshore end of the tramway that it can be thrown the full length of the latter, greatly assists in operating the tramway at night, as well as affording an additional safeguard to shipping.

A quite complete machine shop has been installed in the rear end of the power plant building. This shop includes a drill, a 12-in. 8-ft. lathe, a 22-in. planer, a radial drill with a 12-ft. arm, a pipe threader, a steel saw and a grindstone. All of this equipment is driven from line shafts by a 25-h.-p. motor carried on a bracket suspended from a roof truss. A smaller motor would have sufficient capacity to drive these various machines, but the larger one was installed in order to have enough power to start the motor-generator set. The equipment in this machine shop, and in the blacksmith shop, which contains two 6-ft. forges, a small air-driven trip hammer, an emery wheel and a radial drill, permits practically all repairs to the construction plant to be made at the work. Repairs that cannot be handled by this equipment will be made in the bridge and steel works of Geo. W. Jackson, Inc., so all dependence on outside sources for such work is avoided.

The Southwest Land and Water Tunnel is being driven under the supervision of Mr. John Ericson, city engineer of Chicago. Mr. G. F. Samuels is engineer in charge for the city. Mr. Geo. W. Jackson, president and chief engineer of Geo. W. Jackson, Inc., has personally directed the installation of the construction plant and will supervise the operation of it.

Harbor Work at Huron, Ohio.

The United States Government is at present making improvements in the harbor of Huron, Ohio, a small city on the south shore on Lake Erie near Sandusky. The Huron River was originally obstructed by a sand-bar at its mouth, which closed it to navigation, and in 1826 the first project for its removal was adopted. This provided for two parallel timber jetties 90 ft. apart, extending into the lake from the river bank. These jetties were lengthened and repaired from time to time, and the channels finally deepened by dredging to 16 ft. Altogether, up to June 30, 1905, the United States Government had expended $269,908.95 on the project, and in addition considerable dredging had been done by local authorities.

The existing project was authorized by the River and Harbor Act of March 3, 1905, and provides for a channel, with a depth of 20 ft. It utilizes all of the west jetty which was serviceable, extending it 240 ft. and terminating it at a pierhead 50 ft. square. A similar pierhead was constructed 300 ft. easterly from the extremity of the west jetty and is now being connected to the shore by a rubble mound breakwater, which extends from the pierhead to a point 1,200 ft. east of the present east jetty. Upon the completion of the work the latter is to be removed. The west jetty has a length of 1,741 ft., and the breakwater when completed will have a length of 1,756 ft.

The west jetty consists of 1,109 ft. of timber cribs, 582 ft. of timber crib with concrete superstructure and 50 ft. for the pierhead. The old timber cribs were used as far as possible in the improvement work. They were built at different times and differed materially in details of construction, varying in width from 16 to 24 ft. The bottom of the lake at this point is a stiff clay, and the cribs were sunk in trenches excavated in this material, without the usual rip-rap foundations. The cribs have settled considerably and lost their true alignment.

Where the old cribs were capped with the new concrete superstructure the cribs were cut down to 3 ft. below mean lake level, and a line of concrete blocks was set on both the river and harbor sides of the jetty. These blocks were aproximately 4 by 4 ft. and of sufficient length to span from one cross timber of the crib to the next, about 8 or 9 ft. To give a proper alignment to the superstructure it was frequently necessary to give these blocks irregular forms instead of the cross sections originally designed. The space between the concrete blocks was filled in with rip-rap and surmounted with concrete placed in mass to a height of 6 ft. above mean lake level. The pierhead of the west pier was given a height of 14 ft. above datum, to provide a foundation for a lighthouse.

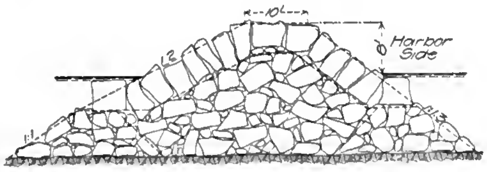
Anchoring the Construction Crib; and Passenger Car at Land Tower of Tramway.

The breakwater, or west jetty, consists of a rubble mound of quarry-run stones covered with large placed stones. On the harbor side the slope is one on one from the bottom to 12 ft. below mean lake level, and one on two to the top of the structure, which is 8 ft. above datum. The width of the top is 10 ft.

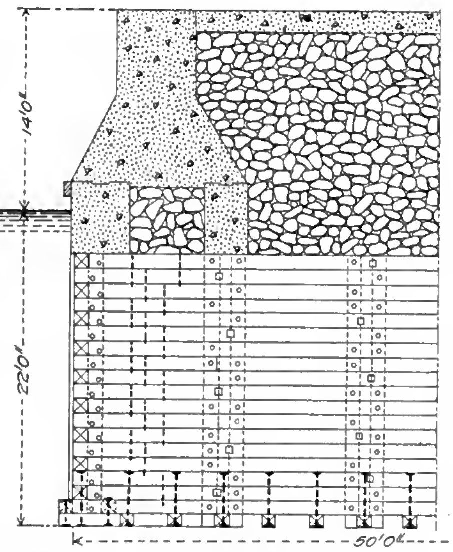
The average weight of the quarry-run stones of which the jetty is built is 1½ tons, running all the way from 200 lb. to 5 tons in individual pieces. The specifications required that no stones should have a thickness of less than 1-3 its greatest dimension. The placed stone is aproximately rectangular in shape, with no angle sharper than 60 deg., or more obtuse than 120 deg., weighing from 4 to 10 tons. The specifications require it to be set close with a derrick on the best and largest bed, adjacent stones not to be farther

apart than 18 in. The stones are set to break joints and tie the work together as far as possible, and on the slopes none vary more than 12 in. from the adopted outline. The lowest outside row of the placed stones on each side is set flat, with the tops of the stones as near as possible at mean lake level, while the remainder of the covering stone is placed edgewise.

In constructing the breakwater the contractor built a private storage yard near the shore end of the jetty and adjacent to the tracks of the Wheeling & Lake Erie R. R., and a track was laid from this storage yard out onto the jetty, being lengthened as the work progressed. An Interstate Engineering Co. 8-wheel locomotive crane weighing 65 tons and having an 80-ft. boom handles all of the stones from flat cars run out on the jetty behind it. For a time this crane also



Rubble Breakwater at Huron.

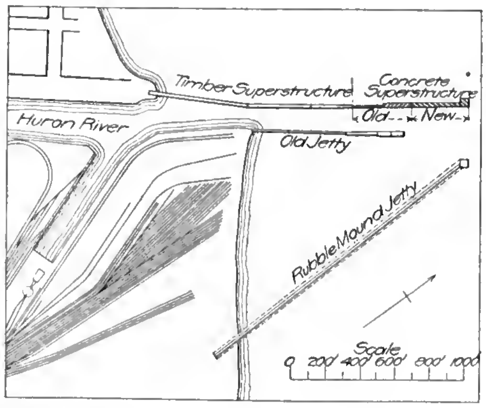


Half Section of Pierhead at Huron.

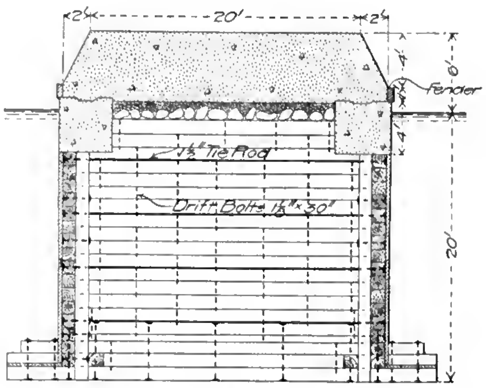
switched the cars back and forth from the yard to the jetty, but as the breakwater reached a length of 700 ft. a small locomotive was placed in service, to prevent the large loss of time due to switching by the crane. In extending the breakwater the crane throws the quarry-run stone into the water in advance of the work, until the rock is built up to about 1 ft. above the water for about 30 ft., sufficient to lay one section of track. The top of this new section is leveled off with small rip-rap, and upon it are laid track stringers carrying closely spaced ties. The top of rail is aproximately $2\frac{1}{2}$ ft. above the level of the lake.

About eight days are required to fill one of these 30-ft. advance sections of the breakwater. When the track is in place on the new section the placed stones are set on each side of the jetty, leaving the track clear. This method is being followed on the entire length of the structure, and after it is joined to the pierhead the crane will work backwards, setting the placed stone over the portion now given up to the roadbed. Some of the placed stones have weighed as high as 14 tons, while a great many have been used which weigh 10 tons, the average being about 5. The average day's work for 8 hr. is about 200 tons of quarry-run and placed stone combined, and the maximum tonnage for one day, consisting entirely of quarry-run, is 454 tons. The estimated weight of stone in the entire breakwater is 63,500 tons. The usual force required in filling the breakwater consists of a superintendent, a foreman, an engineer and a fireman on the locomotive crane, the locomotive crew and three laborers. When the riprap is being placed and the track laid an additional force of laborers is required. The contractor for the work is Hunkin Bros. Construction Co., of Cleveland. Most of the stone is limestone from Bellevue, Ohio, 26 miles from Huron, though a small quantity of sandstone has been obtained from North Amherst, Ohio.

While this work has been in progress the Wheeling & Lake Erie R. R. have constructed two basins near the mouth of the Huron River and propose to construct a third one opening into the harbor behind the breakwater. The basins have a depth of 21 ft. and are enclosed by timber retaining walls. The material excavated from the



Plan of Huron Harbor.



Concrete-Topped Crib at Huron.

larger basin was used to fill a marsh forming part of the company's property north of the tracks of the Lake Shore & Michigan Southern Ry.

The work is being carried on under the direction of Lieutenant Colonel C. McD. Townsend, Corps of Engineers, U. S. A.

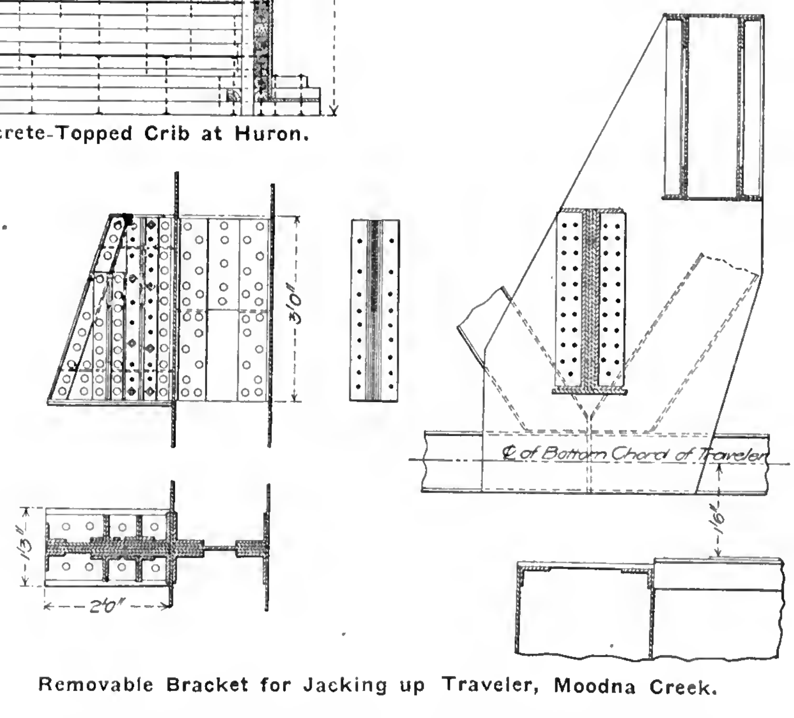
The Electric Locomotives being used in the Simplon Tunnel are troubled with excessive condensation, affecting the insulation, due to the difference in temperature in the tunnel and outside.

The Erection of the Moodna Creek Viaduct.

The Erie & Jersey R. R. viaduct across Moodna Creek, New York, is 3,200 ft. long and about 182 ft. high, and is composed of alternating 40 and 80-ft. plate girder spans supported on steel towers as described in The Engineering Record of July 6, 1907. As now under construction, it contains about 4,000 tons of steel and will carry a single track, but it is designed for future conversion to a double-track structure by the addition of two more lines of plate girders and column reinforcements amounting to about 1,750 tons of additional steel work.

The longitudinal girders $5\frac{1}{2}$ ft. deep and 9 ft. deep are of ordinary construction, web-connected at the ends to double transverse plate girders 10 ft. deep which are riveted across both faces of the battered tower columns. The end sections of the webs are shop-riveted to the columns and have field riveted cover splice plates, field riveted to the ends of the 13-ft. long center section. The maximum towers are 5 stories high with the panels X-braced in both faces but have horizontal struts at panel points only in the transverse plane. In the tallest tower one column in each bent has a roller bearing on the pier masonry. Expansion ends are provided for the 80 ft. girders about 240 ft. apart where they have a sliding bearing in a pocket attached to the web of the transverse girder, all other girder bearings are fixed.

The viaduct was erected by a steel traveler designed also for use in the construction of other extension works now in progresss for the Erie R. R. system. The overhead traveler is a simple rectangular framework 200 ft. long, 30 ft. high and $19\frac{1}{2}$ ft. wide on centers, which weighs about 100 tons. It is designed as a cantilever with an 80-ft. overhang and booms projecting from its extremities with sufficient length and capacity to handle tower members 120 ft., or 2 spans distant from the end of the completed structure. It is of special and rather peculiar construction, differing materially from ordinary travelers in the method by which it is supported from and advanced on the finished structure, in the provision made for handling through it unloading and lowering the members of the viaduct and in the plans for utilizing it for other purposes and realizing a heavy salvage after its work in erecting these viaducts is finished.



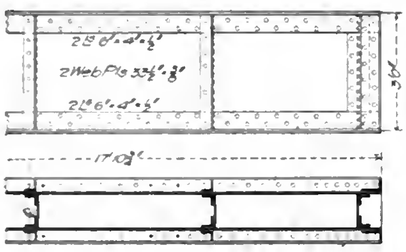
Removable Bracket for Jacking up Traveler, Moodna Creek.

It consists essentially of a riveted Pratt truss span with riveted members throughout and with

lateral bracing only in the planes of the top chord. There is no transverse connection between the bottom chords nor between the members of the trusses except what is afforded by the sway-brace frames, 12 ft. deep, and temporary wooden studs replaced and removed as necessary during erection. A clearance generally 18 ft. wide and 18 ft. high is thus provided through the traveler to allow for car service and the handling of material through it from end to end. This clearance is reduced to 15 ft. vertical by the overhead hoisting engine platform, 43 ft. long, built between the trusses at the rear end of the cantilever. It is not, however, diminished by the duplex-geared girder crane of 15 tons capacity and 16½ ft. span which runs on tracks made with I-beams 100 ft. long to the outer end of the traveler.

When in service the traveler is supported at panel points L0 and L6 at the rear extremity and on the last completed bent of permanent structure with pin bearings in ordinary shoes and pedestals, the latter being seated on the top flanges of the transverse girders of the viaduct towers. At each bearing the traveler is anchored by vertical bolts with nuts at both ends bearing against the bottom chords of the traveler and the bottom flanges of the transverse girders in the viaduct. When the traveler is advanced, temporary transverse plate girders are connected to vertical posts 1 and 6 a little above their lower ends and the traveler is lifted by jacking up under them and then lowering it to supports on special trucks that travel on the regular permanent track of the viaduct.

Each traveler truss consists virtually of a com-



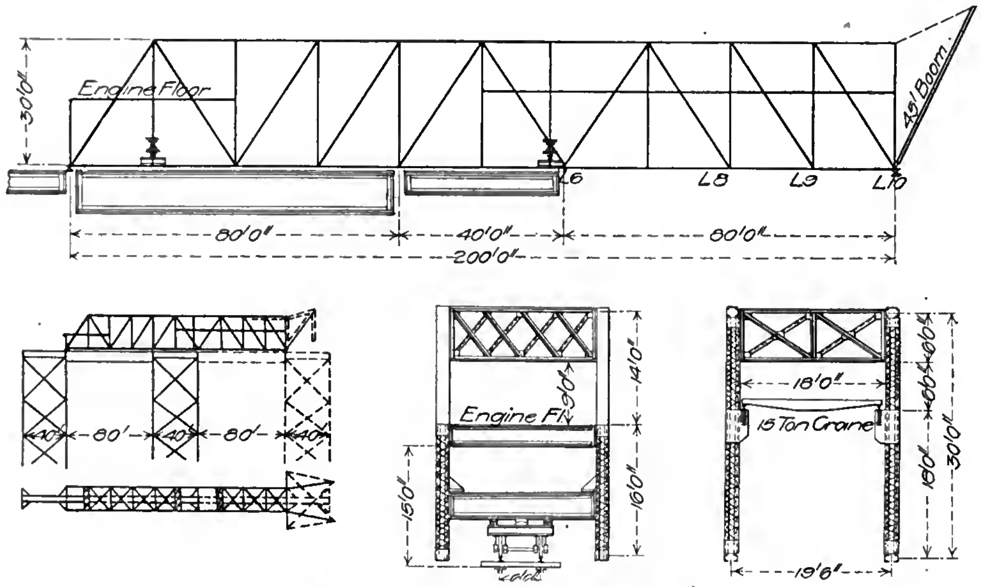
Detachable Lifting Girder.

plete 120-ft. truss and an 80-ft. truss, equivalent to four of the eight panels of the viaduct truss, with their bottom chords pin-connected together at panel point 6, the forward bearing over the last completed bent of the viaduct. The top chords of the two trusses are connected by a horizontal tension member U5 U7 taking the stress from the cantilever to the anchor arms. The trusses are designed so that after their service in the erection traveler is completed the 80-ft. trusses can be extended to make duplicates of the 120-ft. trusses and all together the four trusses will suffice to make two spans of ordinary 120-ft. highway bridges.

The traveler is of very simple construction with standard details and workmanship according to the Erie Railroad specifications. It is built with medium steel, all rivets are ¾-in. in diameter and holes are punched without reaming. The top chords and end posts are each made with a pair of 10-in. channels and a 17½ x ¼-in. cover plate. The bottom chords are made with a pair of 12-in. channels, latticed on both flanges, and the vertical and diagonal members are made with pairs of channels latticed and bolted at both ends between jaw plates shop riveted to the webs of the top and bottom chords. The transverse sway-brace struts are like lattice girders 6½ and 12½ ft. deep, the former being completely shop riveted and the latter having their members shipped loose and bolted together and connected in the field. The top lateral diagonals are single angles, one of which is continuous across the panel and the other is cut to clear it at intersection and spliced across and connected to it by a bolted flange cover plate.

Each main bearing is made with a 3½-in. pin engaging the double webs of a riveted shoe bolted to the bottom chord of the truss and having three alternating bearings in a cast-iron shoe with horizontal transverse guide strips engaging the edges of the top flange of the transverse header girder of the finished viaduct over the center of the viaduct column. Three bearings are provided for each truss, one at the rear end, one at the inner end of the cantilever and one at the outer end of the cantilever, to engage the advance bent of the tower as soon as it is erected.

At L1 and L6 the bottom chords of the trusses are spliced with web cover plates which project far beyond the top flanges to form jaws providing for the connections of the vertical and diagonal posts, and also receiving, on their inner faces, very heavy brackets to take the reactions of the hydraulic jacks used to lift the traveler from its bearings to the truck and from the truck to its bearings. These brackets are 3 ft. deep with a lower horizontal flange 2 ft. long and a very heavily reinforced web, and are each attached with 42 bolts.



Cantilever Viaduct Traveler Used at Moodna Creek.

The vertical posts at U1 and L1 have wide longitudinal vertical plates riveted to their inner flanges beyond which they project with open holes to receive the connection bolts through the transverse end plates of the carrying girders G1. These girders are 17 ft. 10¾ in. long, out to out, and have two 35½x⅜-in. webs 10¼ in. apart in the clear which are connected by five equidistant transverse diaphragms and have four 6x4x½-in. flange angles. The three intermediate diaphragms are set at the points where the girder takes bearing on blocking on the moving truck, and are proportioned to reinforce it for the concentrated shears at these places.

Each moving truck has six double flange wheels with their journal boxes bolted to the bottom flanges of two pairs of 15-in. longitudinal I-beam sills 7 ft. long and 6½ ft. apart on centers. These sills carry across their top flanges a single transverse girder 10 ft. long made with three 15-in. I-beams bolted together with cast-iron separators. Three pairs of longitudinal yellow pine cushion blocks on the top flanges of this girder give bearing against the transverse carrying girders G1. The vertical posts at the outer extremities of the cantilever trusses serve as masts for 45-ft. wooden derrick booms with fittings made at Erie Railroad machine shop. The total weight of the traveler is about 200,000 lb., and it is proportioned to carry a concentrated load of 30,000 lb. at the extremity of each cantilever truss.

After completing two panels of the viaduct the traveler is advanced until panel points L6 are centered over the last transverse tower bent completed. Hydraulic jacks are then set on the tops of the transverse girders with their upper ends engaging the lower flanges of the lifting brackets at panel points L0 and L1 and are operated until the traveler is lifted clear of the cushions on the trucks. The trucks are then withdrawn and the jacks are slacked off to lower the traveler to bearing on its shoes and pedestals and it is anchored to the viaduct by sixteen 1-in. vertical rods 6½ ft. long, engaging the bottom chord as already described. The two bearing girders G1 are then detached and placed with the trucks at one side, out of the way. The viaduct members are then brought inside the traveler by cars on the material tracks which deliver them to the girder crane, and the latter carries the material for the respective towers out to position and lowers it, to be swung into place by auxiliary tackles, and then while the bent is securely guyed brings out the 80-ft. girders and seats them on it.

After these are connected the bearing and anchorage for the extremity of the traveler at points L10 are adjusted on top of the transverse bents and the remainder of the materials are brought by the tower and the girder crane to the derrick booms on the end of the traveler, which completes the erection of the tower and sets the 40-ft. girders on it. The girders G1 are lowered and reconnected in their former positions, the trucks are brought out and placed under them and the hydraulic jacks are set under the lifting brackets again and raise the traveler clear of the trucks to which it is lowered, the jacks released and the traveler advanced 120 ft. as before and so on. The movement of the traveler is thus accomplished easily and quickly on the material track, and the bearings on the center lines of the trusses over the tops of the tower columns utilize the full width of the viaduct notwithstanding that the latter is only equipped with a single pair of girders close together for a single track.

The Erie Railroad construction department is under Mr. J. M. Graham, vice-president, and Mr. Francis Lee Stuart, chief engineer, under whose direction the viaduct was designed by Mr. Mason R. Strong, engineer of bridges and buildings, with the assistance of Mr. F. A. Howard, assistant engineer of bridges and buildings. The erection has been done by the Bridge and Building Department, under the charge of Mr. W. H. Wilkinson, inspector of bridges. The steel work was fabricated by the McClintic-Marshall Construction Company.

FUEL OIL ON LOCOMOTIVES is largely used in Mexico, where about 4,000 bbl. are now consumed daily, it is stated, on the Mexican Central Ry. alone. More locomotives are now being fitted with oil burners as a result of the satisfactory experience in the past. The oil costs about $1.10 per barrel, giving a material saving over coal.

A Favorable Report on the Calumet Drainage Canal.

On Oct. 19 Mr. Rudolph Hering submitted a report to the Trustees of the Chicago Sanitary District which will unquestionably be the leading argument they will use in their endeavor to secure permission from the Federal authorities to turn 4,000 cu. ft. of lake water per second into the drainage canal in addition to the 10,000 cu. ft. per second which the International Waterways Commission has approved. It will be recalled that Messrs. Hering & Fuller were retained by the International Waterways Commission to report on certain features of sewage disposal in the Calumet District lying south of Chicago, and that their report was in favor of septic tanks and sprinkling filters. As Mr. Hering was the engineer who designed the main features of the Chicago drainage canal, this report has been regarded by a good many people as indicating a change of opinion on his part concerning the methods of sewage disposal advisable for the district about the lower end of Lake Michigan. In order to counteract any such view, in all probability, the Trustees of the Sanitary District retained him to report on the most desirable method of disposing of the sewage of the so-called Calumet sub-division of the Sanitary District without causing a nuisance or any pollution of the lake water, irrespective of previous recommendations or legal restrictions. He was requested by the Trustees to take a comprehensive view of the problem, so that any recommendation he made would be in line with what appears to him to be the proper solution of sewage disposal problems in the distant future. He was also requested to furnish estimates of cost and any attending benefits that would be associated with whatever method he recommended. The conclusions in his report are as follows:

The Calumet Subdivision is the term used for that part of the Sanitary District lying south of 87th street, because for the territory north of that street provision for sewerage already exists or has been planned. The Calumet River passes through its southern part and resembles both in ordinary and flood discharges the Chicago River before its flow was reversed. There is also a low divide a few miles to the west, beyond which the drainage flows into the Desplaines River at Sag, and thence to the Mississippi River. Much of the territory is already provided with sewers, which take both sewage and rain water, except a small area at Pullman, where these waters are separated.

The lowness of most of the area makes it necessary for much of the sewage and rain water to be pumped. At 95th street, near the mouth of the river, there is a pumping station for this purpose. Under flood conditions sewage enters the lake, which in the future, and perhaps already, must endanger the wholesomeness of the water at the Hyde Park intake of the Chicago waterworks.

There are two methods available for properly disposing of the sewage in the Calumet region, so as to prevent the pollution of the water supply of the city and prevent any nuisance in the river or on land. One of these methods is purification by means of septic tanks and sprinkling filters, the other is by repeating the method now used in Chicago and building a canal from the Calumet River across the low divide to join the present sanitary canal at Sag, and by reversing the flow of the Calumet River to carry in it sufficient water to dilute the sewage properly. Whenever this flow is less than required, the deficiency is supplied from the lake; whenever it is greater, the excess flow goes to the lake. To guard against the sewage being carried into the lake at such times, it is necessary to build intercepting sewers to discharge it into the canal and not into the river.

At the request of the International Waterways Commission, the various "available methods of disposing of the sewage of the Calumet area, other than by dilution," were studied and sprinkling filters recommended as "being the cheapest, both in cost of construction and operation, and accomplishing an adequate degree of purification." Under the instructions of the Sanitary District Trustees, Mr. Hering has now compared this method with the dilution of the sewage in the Calumet-Sag canal.

The dilution method was studied by experience gained during its application in Chicago, since the sanitary canal has been opened. The canal was originally designed to carry 10,000 cu. ft. per second, sufficient to dilute the sewage of 3,000,000 persons. Above Summit provision for this population is being made; below Summit the canal is now capable of carrying 14,000 cu. ft. per second, but between Summit and Sag it is proposed to carry only 10,000 cu. ft. per second, and at Sag to receive 4,000 cu. ft. per second through the proposed sanitary canal from the Little Calumet River. This project will protect the lake water from receiving any sewage, Mr. Hering states. It will permit controlling the proper flow in the canal at all times and dilute the sewage of 1,200,000 persons in the same manner as the main canal now built.

In order to compare the two projects, it is necessary to know their true values, which must be based upon their cost and collateral advantages. A most important item for those who pay the taxes is the cost. This is obtained from a balance between expenses and receipts. The expenses should be stated as the total annual cost, made up of operating expenses and fixed charges for interest and other items. The receipts should be given as the returns from the sale of products. There is no money returned from the sprinkling filters, as their product has no value. But there is a return from the dilution project, because the flow of 4,000 cu. ft. per second can drop 66 ft. and develop 22,500 efficient horse power. This earning power produced by the money spent in building the canal to supply the water is an asset as much as if it had been built especially for water power purposes. It is an asset as much as the products yielded from mineral land originally bought from the government and as much as rent secured from a building.

Mr. Hering gives the accompanying table, showing the net annual cost of the two methods of disposal for a population of 300,000 in the Calumet region, and a future population of 1,200,000; these figures are based upon the use of sprinkling filters and upon the Calumet-Sag canal, first, for its actual cost, second, its cost with a return for power at Lockport, and third, with a return for power at both Lockport and Joliet. This table indicates that for an early population of 300,000, the canal project would cost annually about one-third as much as filters, and for a population of 1,200,000 about one-quarter as much, not considering any value which the canal may have for the purpose of navigation. The table further shows that when the population is 1,200,000, the presumable annual cost of the canal project, even without any returns from the sale of power, would be $136,600 less than that of sprinkling filters. Even a material variation in the cost would not alter the general conclusion that the canal is the cheaper project, Mr. Hering states.

The cost comparison alone would decide which project is the more desirable one for the citizens of Chicago, if there were not objections apparently more or less serious that have been raised against the Calumet-Sag project. These objections can be satisfactorily answered, Mr. Hering reports. The most important of them are stated below.

Annual Cost, Including Operating and Fixed Charges.

Installation for a Population of	Sprinkling Filters.	Calumet—Sag Canal. Cost of Canal Alone.	With power at Lockport.	With Power at Lockport and Joliet.
300,000	$360,240	$656,900	$384,100	$128,800
1,200,000	900,300	763,700	490,000	235,600

A question has arisen as to whether it would not be more economical to utilize the main canal and its feeders to their full capacity for the central district of the Chicago metropolis through which it runs, and to erect sewage treatment works for all the more distant parts, such as the Calumet region. The annual cost of works for carrying out this suggestion would be $122,000, considering an income from the additional flow of 4,000 cu. ft. per second. But this expenditure does not provide any relief whatever for the Calumet area, the cost of which, for filters, can be taken at $600,000 per annum when the population in the district is 700,000, while the cost of the Calumet-Sag project would be only $175,000 per annum.

The most important objection comes from the International Waterways Commission, which says that the diversion of 14,000 cu. ft. per second would lower all of the lakes from 6 to 8½ in., and that the cost of restoring the original depth would be about $12,500,000. It grants the diversion of 10,000 cu. ft. per second without further question for sanitary purposes, whatever the effect upon navigation may be, but recommends that the government of the United States prohibit the diversion of any further amount. Should the Sanitary Canal cause the lowering of the lake levels stated above, the prohibition would certainly be in the interest of Chicago no less than those of the entire lake region. It seems evident to Mr. Hering, however, from a study of the facts in the case, that whatever lowering would be caused by the diversion through the sanitary canal is already almost completely compensated by work partly done, or recommended to be done, by the Commission at Sault Ste. Marie.

The Commission has recommended the establishment of a low-water level in Lake Superior of 601.7 ft. above tide, to be held by regulating works, and a high water-level of 603.2 ft., or 18 in. higher. The lowest annual mean level of Lake Superior occurred in 1879, and was 601.43 ft. The most protracted low-water period since 1860 occurred between the years 1888 and 1893. During this period the lowest annual mean discharge at Sault Ste. Marie was 57,420 cu. ft. per second in 1892.

Computing from these facts the depth of storage necessary, after allowing this discharge to continue down the lakes, to furnish in addition a continuous flow of 14,000 cu. ft. per second to be diverted into the Mississippi Valley at Chicago, Mr. Hering finds this depth to be 21.6 in. If we add this depth to the lowest annual mean level of Lake Superior, which, since 1860 was 601.43, we get an elevation of 603.23, or but a trifle higher than the high water level recommended by the Commission. Therefore, its recommendations, if adopted, would create by storage during high water in the lake, Mr. Hering asserts, almost the entire flow of 14,000 cu. ft. per second desired by Chicago for its two sanitary canals, without lowering the lakes in the least, nor requiring any expenditure for restoring the original depths of the harbors, channels and canals of the lake system.

Other countries spend large sums of money for water storage to increase the flow of rivers. Our Great Lakes, Mr. Hering points out, are the most magnificient storage reservoirs of the world, high above ocean level and large enough to send, by gravity, great amounts of water to

the sea in two directions for the benefit of commerce. Assuming now that there cannot be an injury to navigation in the Great Lakes from the diversion in the proposed sanitary canals, a few collateral facts of the Calumet-Sag Canal over the use of sprinkling filters are mentioned by Mr. Hering

A final disposition of sewage by at once diluting it with a sufficient quantity of running water has the advantage, he states, of simplicity in operation, and is therefore always preferable to any method of treatment because it requires less attention, care and labor, and from a sanitary point of few, is quite as satisfactory, if the sewage is properly mixed with the diluting water and not used as a potable supply until actual oxidation has made it safe.

As yet the least expensive method of sewage treatment has not been developd to a final state. No municipal plant of sprinkling filters has yet been operated in America, although several are now under construction. We may, therefore, expect that experience, particularly in northern climates, may indicate some desirable modifications, Mr. Hering states, although we expect them to be only slight and in southern climates insignificant. On the other hand, the dilution method of sewage purification being the prevailing one and the oldest one in use, is thoroughly known as to what it can do and what it cannot do. We may, therefore, consider its works to be more permanent, Mr. Hering asserts. Even if the comparison of cost, simplicity and permanence, contrary to fact, had all indicated no distinct advantage for the dilution project, the present case introduces a feature which constitutes a decided advantage in favor of the Calumet-Sag canal. Its size, location and moderate current necessarily combine to make it available for a navigable waterway connecting Lake Michigan with the present sanitary canal at Sag. That there is already a marked tendency to concentrate heavy and bulky freight at the Calumet River is shown by the fact that, while the tonnage of the Chicago River has remained almost constant for 18 years, the annual increase of tonnage of the Calumet River has been quite rapid and is now more than half of that in the Chicago River.

If regulated for slack water navigation, it is well known that silt-bearing rivers have the disadvantages of perpetual dredging. If regulated for large quantities of lake water to materially augment the flow, such dredging will be much reduced and cause a permanent advantage. This view is endorsed and amplified by a remark made in Chicago in 1906 by General O. H. Ernst, Corps of Engineers, U. S. A., who said: "In a future not remote, larger amounts of water (than 10,000 cu. ft. per second) may be needed for sanitary purposes, and channels deeper than 14 ft. will then become practicable in the open alluvial portions of the Illinois River."

After weighing carefully all the advantages and disadvantages of the two propositions, it is Mr. Hering's opinion that the proposed Calumet-Sag Canal is not only the more economical one for disposing of the sewage of the Calumet region, but that it has still other advantages of more or less weight.

Sinking Viaduct Piers with Hydraulic Jacks.

The double track Market St. viaduct of the Philadelphia Rapid Transit Co., joins the Schuylkill River Bridge on a curve and the end tower, carrying a part of the approach span, has two piers, the most heavily loaded of which has about 13½ tons dead and 49½ tons maximum live load. They are located about 60 ft. beyond the water line and were sunk about 40 ft. through miscellaneous fill to coarse gravel with steel cylinders 4 ft. in diameter and 60 ft. long.

An excavation about 10 ft. wide and 30 ft. long was made adjacent to the masonry abutment, and was sheeted down about 10 ft. to water line on three sides with 2x10-in. vertical planks driven against horizontal rangers 5 ft. apart, strongly braced with transverse struts. An 8x12-ft. horizontal platform of 10x10-in. timbers laid on pairs of transverse 12x12-in. girders were set, one on each side of each cylinder pier center and provided with four vertical 1½-in. rods about 12 ft. long with their lower ends passing through the platforms and girders and bearing against the under sides of the latter with nuts and washers. The upper ends passed through 12x16-in. longitudinal horizontal timbers 10 ft. long and took bearing on their upper surfaces with double nuts and heavy cast-iron washers.

Between the rods a 16x16-in. transverse timber, 5 ft. long was seated across the tops of the lower timbers and connected to them with two pairs of 1½-in. bolts, engaging four 5-in. saddle plates on the tops and bottoms of the timbers. A pair of horizontal longitudinal 12-in. I-beams about 20 ft. long were set on the center transverse line of the bents with their top flanges between the pairs of 12x16-in. timbers with their top flanges bearing against the lower surfaces of the 16x16-in. upper timbers, and served as reaction girders for sinking the cylinders.

The platforms were loaded with more than 50 tons of pig iron, and a hydraulic jet was inserted in the cylinder, jacking beams were placed across its upper end and on them were seated a pair of 50-ton hydraulic jacks engaging the lower flanges of the reaction girders. The jet was moved around the interior of the cylinder close to the cutting edge and its scouring action combined with the pressure of the jacks, each operated by two men at its lever, gradually forced the cylinder into the ground while the sand and water overflowed its upper edge, was collected in a sump and drained by a steam pump.

When the first section was driven to the surface of the ground the jacks were removed, a second section was bolted to it through interior flange connections, the jacks were replaced and operations repeated until both cylinders were sunk 6 ft. farther, after which a third section was added, and so on until the continuous steel shell entered the gravel stratum and was pumped out. Men then entered, cleaned and leveled the bottom and rammed the dry 1:3:5 concrete with which the cylinders were filled.

The fill contained so many boulders and other obstructions that about two days were required for sinking each section of a cylinder, but the cylinders for both piers were sunk simultaneously. This method of sinking is, of course, not unusual in building construction, but in this case the conditions were difficult and it was believed that a considerable economy was effected by using this method instead of the ordinary pneumatic caisson method. The work was done by John Monks & Sons, New York, Mr. Chas. Deans, engineer, under the direction of the engineering department of the Philadelphia Rapid Transit Co., Mr. W. S. Twining, chief engineer, and Mr. Chas. M. Mills, principal assistant engineer, and Mr. Frank R. Fisher, resident engineer.

Jacking Down a Pier Cylinder for a Viaduct.

Reaction Beam for Jacking Down a Cylinder.

AFOKONIN is a new dust-preventing material described in a recent report from Consul Norton at Chemnitz. He states that it is a mixture of heavy residual oils obtained in the distillation of coal tar with high-boiling hydrocarbons. The product thus made is prepared for use by heating it in iron kettles, like those employed with asphalt, to temperatures ranging from 212° to 250° F. It is then sprayed evenly over the roadway with a special sprinkler, which operates under such high pressure that the liquid penetrates the upper layer of dust. As a result a compact shining black coating is said to be formed which has no odor and is dustless. This material has been used on the macadamized streets of Leipsic to some extent.

The Reinforced Concrete Work of the McGraw Building.

A paper by William H. Burr, in the "Proceedings" of the American Society of Civil Engineers for October, 1907, to be presented Nov. 20, 1907.

The McGraw Building is a true reinforced concrete structure—the latest type of buildings of that general class. It is on the north side of West 39th St., between Seventh and Eighth Aves., in the city of New York, in that district which has already felt the stimulating influence of the new Pennsylvania R. R. Station in process of construction a half dozen blocks to the south. This part of the city is undoubtedly destined to become a great business center, where substantial buildings of the highest type will be required in order to meet the demands of the development of that vicinity.

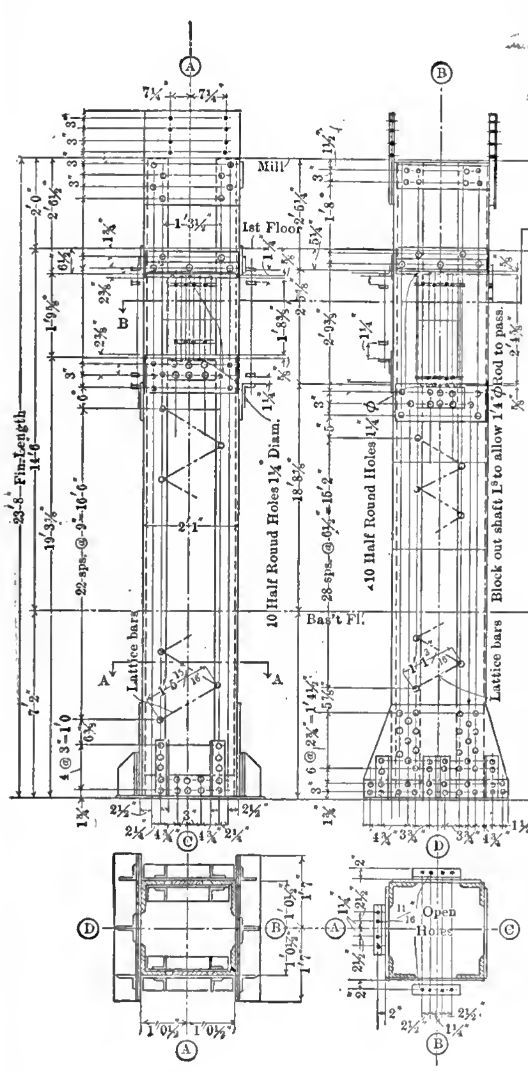
The building has a frontage of 126.3 ft. on 39th St., and a depth of 90 ft. It has eleven stories. The height of the roof is 145 ft. above the ground floor, or nearly 150 ft. above the street, or, finally, 159 ft. 6 in. above the basement floor. While, therefore, it is far from ranking among the tallest sky-scrapers of the city, it is to be classed among the high business buildings of Manhattan Island. Its height is much greater than has heretofore been considered practicable for a purely reinforced concrete building, i. e., a concrete building without iron or steel columns.

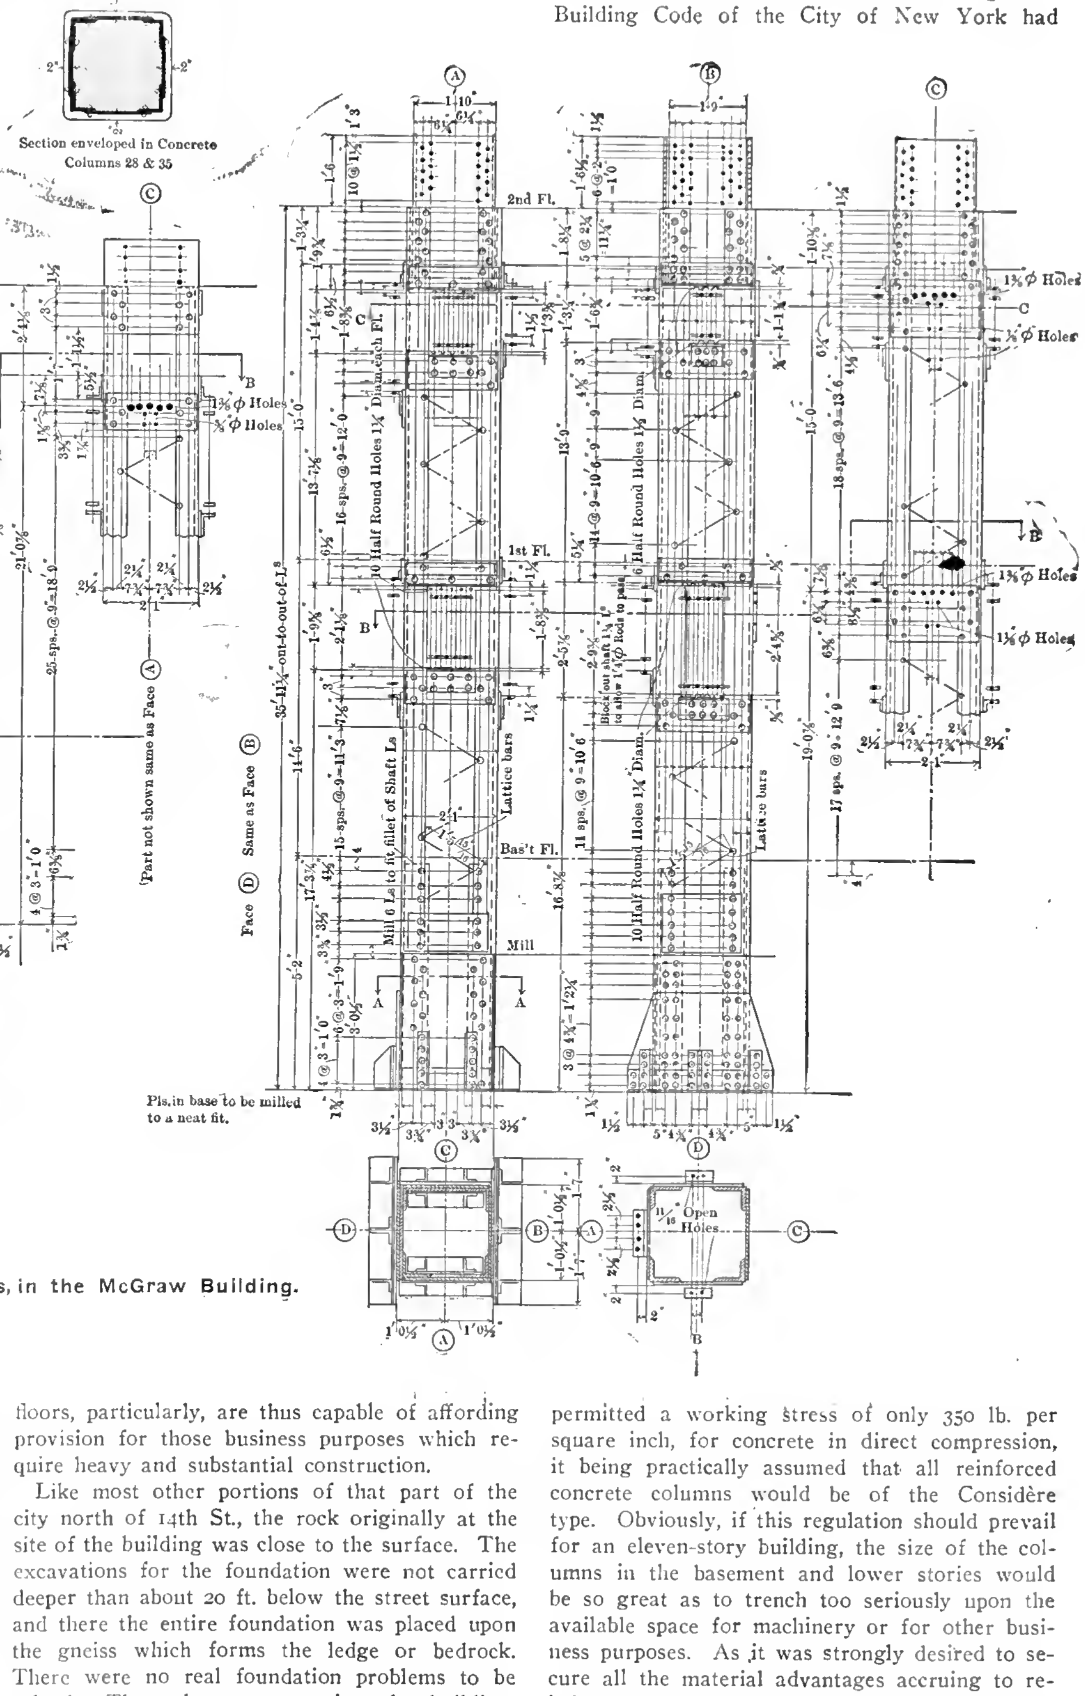
It has been constructed for the McGraw Realty Co. primarily to accommodate the business of the McGraw Publishing Co., whose publications include "The Engineering Record," "Electrical World" and "Street Railway Journal." At the same time is was designed to accommodate not only the printing presses of the McGraw Publishing Co., but any other similar business requiring the operation of heavy machinery or the storage of heavy goods in bulk. It was imperatively necessary, therefore, that the building should be designed and built so as to afford the greatest possible resistance to the vibration of heavy machinery, and possess to an unusual degree both rigidity and durability. It is also fireproof to such an extent that the McGraw Realty Co. may reasonably be its own insurer. While the building is admirably adapted to office use, its lower floors, particularly, are thus capable of affording provision for those business purposes which require heavy and substantial construction.

Like most other portions of that part of the city north of 14th St., the rock originally at the site of the building was close to the surface. The excavations for the foundation were not carried deeper than about 20 ft. below the street surface, and there the entire foundation was placed upon the gneiss which forms the ledge or bedrock. There were no real foundation problems to be solved. The columns supporting the building, and the retaining or area walls around the basement, were all founded upon the same ledge, under the requirements of the Building Code of the City of New York.

In order to meet the exacting requirements for the unusually substantial structure required by the McGraw Publishing Co., it was decided to design the building for a live load of 250 lb. per square foot for the first and second floors, 200 lb. per square foot for the third floor, 150 lb. per square foot for the fourth floor and 125 lb. per square foot for all the other floors above the fourth, and with a live load of 60 lb. per square foot for the roof. All parts of the floor beams and girders, therefore, and the columns, were designed to sustain, under the requirements of the Building Code, the actual weight of the structure and the live load specified above.

Prior to the submission of this design the Building Code of the City of New York had permitted a working stress of only 350 lb. per square inch, for concrete in direct compression, it being practically assumed that all reinforced concrete columns would be of the Considère type. Obviously, if this regulation should prevail for an eleven-story building, the size of the columns in the basement and lower stories would be so great as to trench too seriously upon the available space for machinery or for other business purposes. As it was strongly desired to secure all the material advantages accruing to reinforced concrete structures, it became necessary to design such columns as would be of much smaller cross-section than those of the type heretofore prevailing. Two procedures were available: one was to use a substantial quantity of





Steel Reinforcement for Typical Columns, in the McGraw Building.

steel in the form of an ordinary steel column suitably designed for this purpose, and the other was to use the concrete in such a way as to justify a much larger working stress per square inch than that prescribed in the Building Code. These requirements are met in an eminently satisfactory way by the columns of the type used. All columns throughout the building are composed of an interior filling of concrete combined with steel angles latticed in the ordinary manner of built steel columns. The interior columns and most of those in the exterior walls are built with four angles, with the usual riveted lattice or lacing bars on the four sides of each column. In the case of a number of the exterior columns it was necessary, for the attainment of unavoidable structural ends, to use a column of elongated cross-section with eight steel angles of the same general type as those in the interior, which, with the concrete filling, form a column of two cells, so to speak, rather than one. The plans accompanying this paper show fully and clearly this arrangement of the combined concrete with steel angles and lacing bars. In all cases the steel angles, with the corners of the angles turned out, were spaced as far apart as the extreme outer dimensions of the completed column would permit.

In accordance with the requirements of the Building Code, there is a thickness of 2 in. of concrete outside of the steel angles. This 2-in. shield of concrete is assumed to carry no load whatever; its function is simply that of fireproofing, i. e., to protect the steel against the immediate heat or flames of any fire that may start in the combustible materials at any time stored in the building, or of a conflagration in an adjoining building. The concrete within the exterior dimensions or outline of the steel angles is available for carrying a compressive or column load. As it is completely embraced or surrounded by the steel angles and lacing bars, it is steel "banded" in the most effective manner possible. Its enclosure in the steelwork of the column is so rigid, manifestly, that lateral strains under column loads must be greatly reduced—in fact, nearly prevented—within any ordinary limits of loading. Such concrete, therefore, is largely prevented from the usual yielding of that material under compression, and its compressive carrying capacity is increased. This is not only obvious from the condition of the concrete in these columns, but that view is confirmed by the comparatively few results of tests of concrete columns of this character. When, therefore, the plans of these columns were submitted to the Bureau of Buildings of the City of New York for examination and final approval, a special regulation was made permitting the concrete to carry a maximum working load of 750 lb. per square inch within the exterior limits of the steel angles, the exterior 2 in. of concrete, as stated previously, being considered simply a fire-protecting shield. This increased permissible load upon the concrete is coupled with the further provision that the cross-section of the steel in any column at any floor shall be sufficient to carry the entire dead load above that section without stressing the steel to more than 16,000 lb. per square inch.

The use of the steel, in load-supporting condition, as a long column independent of the concrete, and at the same time forming a rigid banding member for the latter, with the consequent increase of permissible working load on the concrete, reduced the size of the columns in the basement and lower stories to dimensions quite consistent with the desired convenient and economical use of the clear floor space. Columns of this general type combine with their high carrying capacity, great convenience in erection, for their steel sections may be erected ahead of the concrete work and afford convenient supporting members for the adjoining forms or for other erection work. The lacing bars, rivet heads, and other projecting column details act positively in creating a firm and complete hold or bond between the steelwork of each column and the concrete enclosed within it. This feature of these columns compels the steel and the enclosed concrete to act as a unit, and this action is enhanced by placing all the lacing bars in one direction inside the steel angles, the other set being placed outside, as shown on the plans.

The Building Code requires the ratio between the moduli of elasticity for the steel and concrete to be taken as 12. Hence, as the permissible compressive working stress in the concrete was taken at 750 lb. per square inch, the corresponding working stress in the steel would be 9,000 lb. per square inch.

The largest columns (in the basement) have exterior dimensions of 29 x 29 in., but, at the eleventh story, the exterior dimensions are reduced to 14 x 14 in. These columns were built in sections of a length equal to the combined height of two stories, i. e., 25 ft. The extra metal involved in this procedure was too small to be of practical consequence, and the expense of half the joints, if a change of section had been made at every floor, was saved. Much time was also gained in the erection of the steelwork. The abutting ends of the column sections were faced, and the joints were made by suitable splice-plates. Where there was a change in the exterior dimensions of the steelwork, full-strength splices were made by riveting suitable short-angle sections on the interior of the splice-plates of the lower part of the joint. These details are also shown on the plans.

The ratio of the area of steel section to that of the concrete for the various columns varied from 10 per cent. in the basement where the steel carries about 57 per cent. of the total load to 3½ per cent. in the ninth floor where 30 per cent. of the total load is carried by the steel. The requirements of the Building Code for a design of this type raises the percentage of steel to much higher values than in ordinary concrete-steel work.

Table 1 shows the number and sizes of steel angles used throughout the main columns of the building.

The design of the floors, in general, is quite similar to that usually found in buildings of this class, although there are certain important details which do not come under that observation. As the plans indicate, the spacing of the columns is such as generally to divide each floor into panels 21 ft. 9 in. by 14 ft. 8 in. between centers of columns, the clear span of the main girders between columns being 14 ft. 8 in. less the width or diameter of the column section. The clear span of the floor beams between the main girders is 21 ft. 9 in. less the width of these girders. These prevailing lengths of spans of the beams and girders were modified at a few points in each floor to accommodate such features of construction or details of floor space as stairways, elevator shafts and similar details.

As the plans indicate, all floor-girder and beam reinforcement was of round steel rods, of sizes running generally from ¾ to 1⅜ in. in diameter. These rods were grouped in one plane on the tension side of each beam or girder. As a rule, every alternate rod was bent upward at the end of each span so as to rise within about 2 in. of the top of the concrete, from which point it continues through either the main girder or the adjoining column, as the case may be, into the adjoining span well toward the quarter point of the latter. By these means, true continuity of beams and girders was secured in every case. In addition to this, the end of each rod was bent down, forming a right-angled turn, with an arm from 2 to 3 in. long, thus insuring a rigid bond or connection with the concrete. This main detail, formed by carrying the rods through the girders and columns, is an important feature in securing continuity and rigidity in the general construction of the building. It is believed to be one of the most important details of the best design of reinforced concrete building construction, and it should be secured either in the manner adopted in this building or by some other procedure of at least equal excellence.

The proper spacing of these reinforcing rods was secured by suitable supporting details throughout the length of the beams and girders themselves and by notches cut in angle-brackets riveted on the columns where they joined the latter members. At the columns, rigidity of connection was secured by bolting clamps through the angle-brackets just named and jamming the rods by tightening the nuts against those brackets. This secured an exceedingly strong metal connection between the reinforcing rods and the steel columns, aside from the further rigidity produced by the concrete mass of the intersecting columns, beams and girders. These details, shown on the plans, were designed with care for the purpose of securing the strongest possible steel connections between the beams or girders and the columns, it being one of the main purposes to attain rigid continuity between floors and columns, and floors and outside walls. It is believed that unusual stiffness and strength have been given to this building by these means.

All beam and girder computations required by the floor designs were made in accordance with the provisions of the Building Code of the City of New York, the usual common theory of flexure formulas for concrete-steel beams being used.

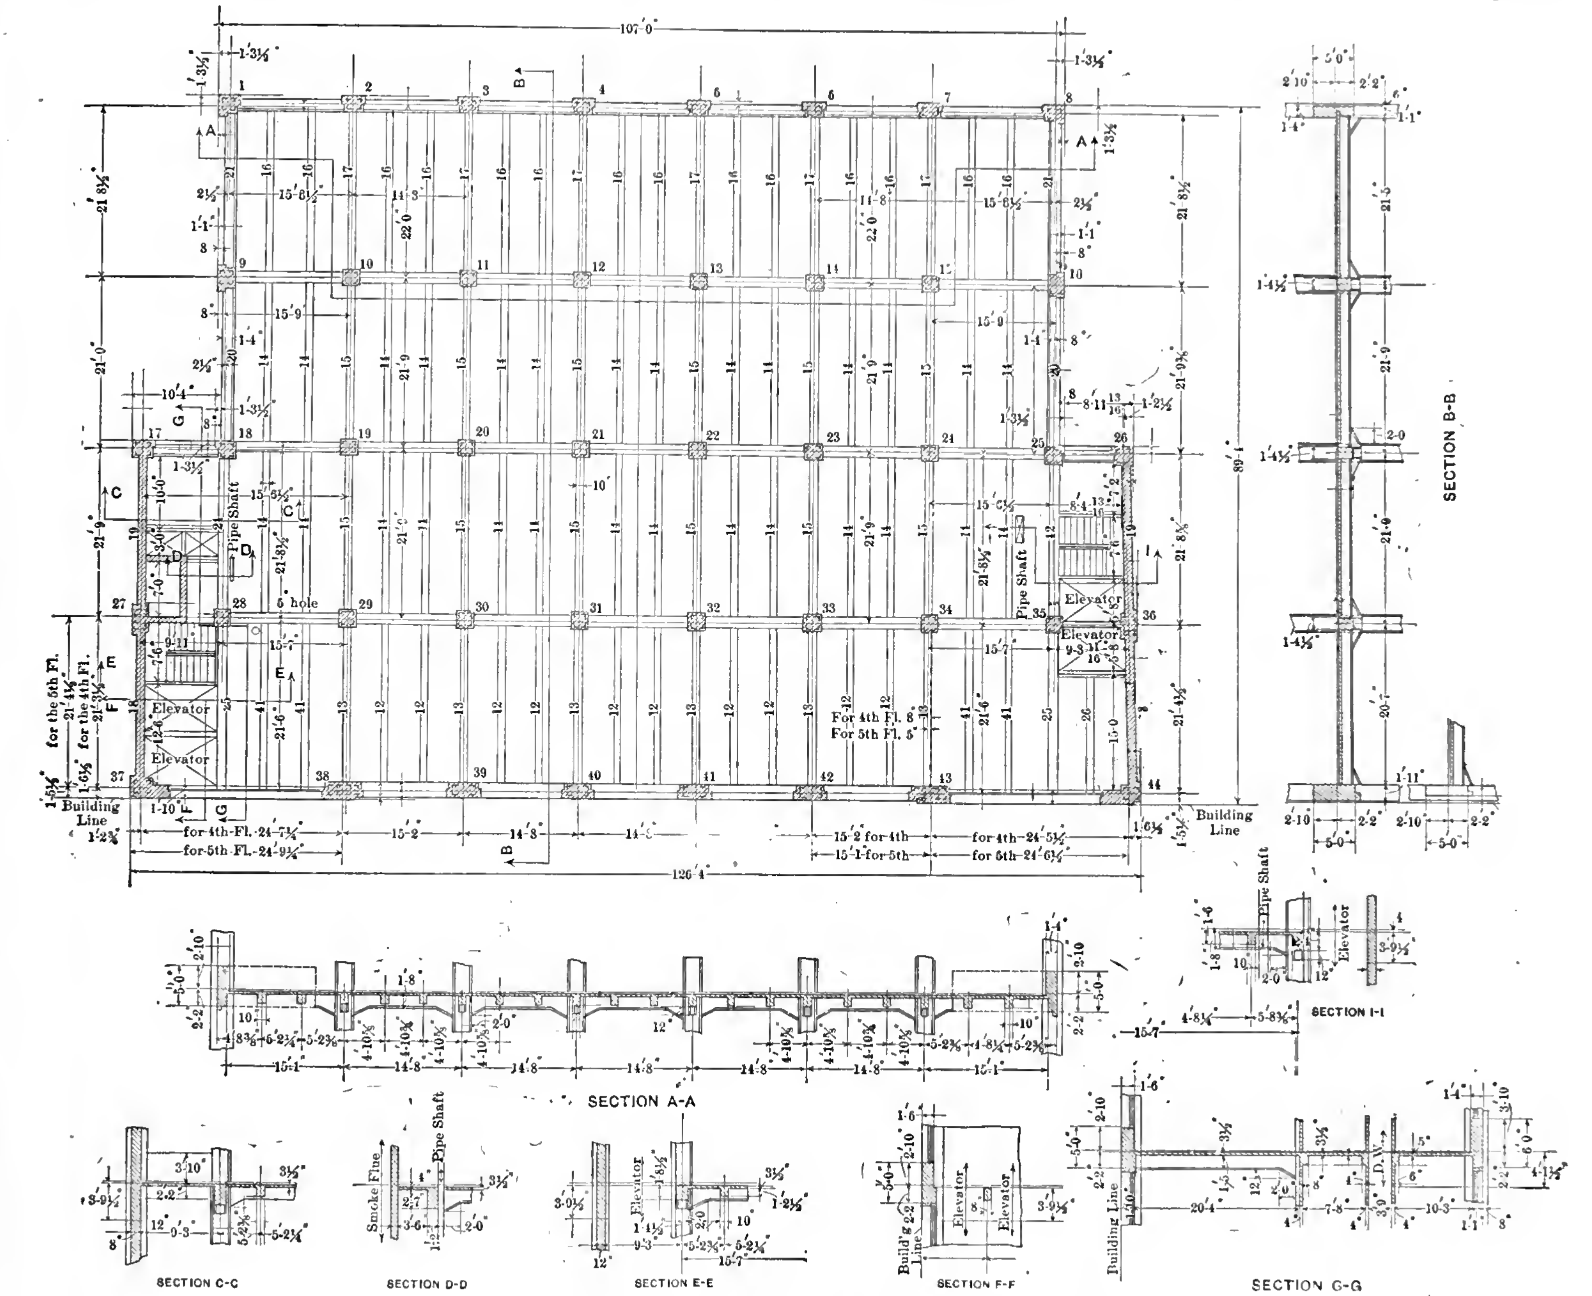
While the parabolic law of variation of intensity of stress in concrete beams results in a trifling economy of material, it is less rational and simple than the usual straight-line law of variation, and the latter is more nearly accurate.

The Building Code of New York does not permit the condition of perfect continuity of beams to govern the design of reinforced concrete floor beams and girders. It is permitted, however, to consider the maximum bending moment of such beams, when uniformly loaded from end to end, as the total load multiplied by one-tenth of the span, rather than one-eighth of the span as would be taken were the beams simply supported at each end. This is a widely used method for continuity, in favor of which much can be said. It is extremely doubtful whether perfect continuity is attained in any case, but it is certain that a material advantage is secured over the condition of a beam simply supported at each end. The one-tenth rule, as it may be called, is a reasonable compromise.

Another condition insisted upon in the design of this building was a metallic provision for taking the end shears of beams and girders. By referring to the plans there will be observed inclined portions of the round steel reinforcing rods to which attention has already been called. In every case there is sufficient steel in these inclined portions of rods to take the total end shears multiplied by the secant of the inclination rods to a vertical line without stressing the steel to an unsafe extent. While the tension in the steel produced in this manner, ignoring entirely the shearing resistance of the concrete, is higher than would normally be prescribed, it is far below the elastic limit, and forms a safe provision for the entire end shear in case any exigency should arise producing such a break in the concrete as practically to destroy its capacity for shearing resistance. In addition to this condition, there is sufficient concrete also at the ends of beam and girder spans to carry the shear at an intensity of 50 lb. per square inch of concrete section as permitted by the New York Building code. This, also, has been considered one of the essential details of a concrete-steel building designed for a heavy and otherwise fatiguing service.



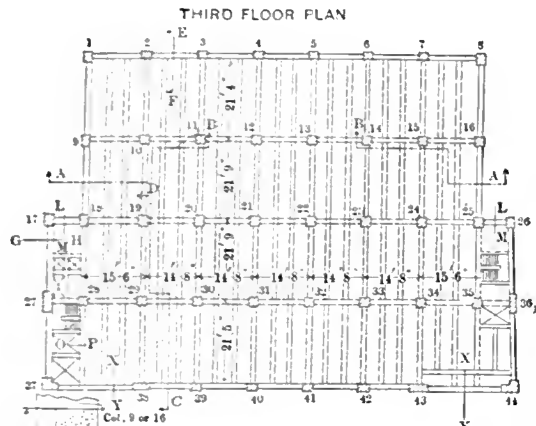
General Plan and Sections of Typical Floor, McGraw Building.

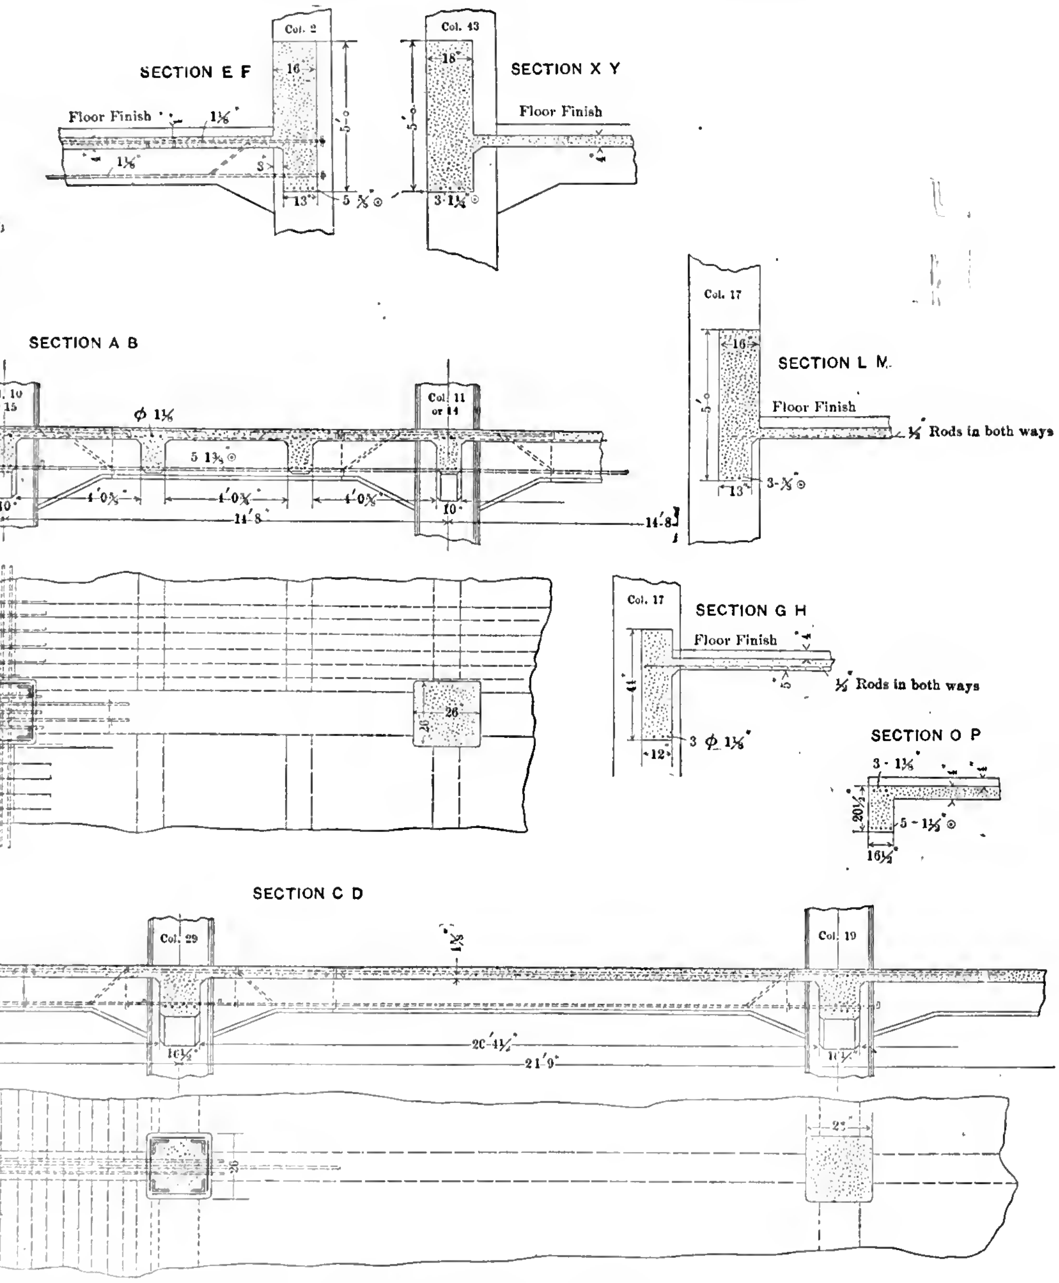
The floor slabs spanning the spaces between the floor beams are 4 in. thick in the lower floors, carrying the heaviest loads, and 3½ in. thick in all the higher floors. Their reinforcements are ½ and ⅝-in. rods, long enough to extend over a number of panels or spans so as to make these also continuous. Their general design is similar to that of the floor beams and girders. As the distance apart of the centers of the floor beams is about 5 ft. 2 in., the clear span of these floor slabs varies from about 4 ft. to a little more than 4 ft. 4 in., according to the thickness of the adjoining floor beams on either side of the span.

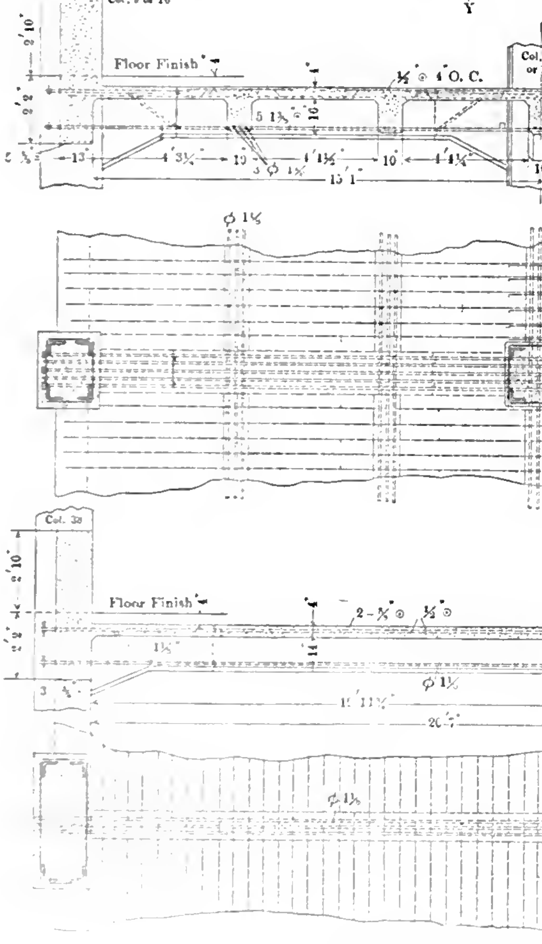
The proper design of the wooden forms or moulds for a concrete steel building, in order to secure expeditious and economical work, is the most difficult part of the entire undertaking, and the principal improvements to be made in it are those which pertain to perfecting a proper system of construction of the forms and their ready handling. The quantity of lumber required in them, and the carpentry work necessary in making repairs consequent upon their use and re-use for successive floors, and in their supports, constitute far larger items of cost than might at first be supposed. If these costs are to be reduced, as they must be for heavy concrete-steel construction of the best class, the principal study of the engineer must be directed to this particular part of his work. While these ends may not and probably have not been completely attained in this instance, the system of forms used gave excellent results in the quality of the concrete produced, and led to reasonable economy and efficiency. The weight of concrete and the relatively large quantities used in such individual members as beams, girders and columns make heavy forms imperative and substantial support necessary.

The details of the timber forms for the floor beams and girders where they meet the column forms require especial attention. A proper design of the parts where the floors and columns join will result in great economy in the details of the forms. If the shapes of the exterior surfaces of the concrete are complicated and require-

careful fittings of the column and floor forms, expensive carpentry work will be required wherever a column pieces a floor, whereas simply shaped concrete surfaces will eliminate that work and greatly expedite the construction. Similarly, it is highly desirable that there shall be as few changes as possible in the exterior dimensions of the columns. If exterior column dimensions could be retained unchanged from basement to roof, it would make possible complete uniformity of the details of column and floor forms throughout the entire building, eliminating a great amount of fitting and carpentry work otherwise unavoidable.







Plan and Sections of Typical Floor Beams and Girders Showing Steel Reinforcement.

It is obvious that it is essentially impossible to retain uniform exterior column dimensions throughout the series of floors from the bottom to the top of the building, but the most scrupulous care should be exercised to make these changes as few as possible and in such a way as to reduce to the utmost extent changes of details in the forms.

A reference to the plans will show that the floor forms between the beams consisted of large shallow boxes with truncated corners between the sides and the bottom. They were placed bottom up on stable supports and separated by the thickness of the adjoining floor beams at the sides and by the thickness of the main floor girders at their ends. The bottom of the opening between the adjoining sides of any two of them was then suitably closed with planks or boards so that when the concrete was finally poured over their tops to the thickness of the floor slabs, the desired paneling of those slabs between the beams and girders was secured. It is imperative, for expediting the work, as well as for economy, that these box forms for the floors shall be constructed so that they may be removed readily after the concrete becomes sufficiently hard. To secure this important result, such forms must be readily collapsible at both ends and sides, and, at the same time, they must be substantial enough to hold the wet concrete without distortion and so well made that they may be handled in removing from one floor and replacing on a higher one without sensible damage. This constitutes one of the most essential points in the design of these forms, which, in this case, were collapsible although perhaps not as freely as might be desired. When the forms stick to the concrete in the process of removal laborers use sledges and iron bars, driving the latter between the new concrete and the forms and making a fulcrum of the former. This results in seriously marring what might otherwise have been a highly satisfactory concrete surface. The same general observations apply to the forms for the columns. Whenever the art of reinforced concrete construction is brought to the high state of excellence which it must ultimately reach through a proper design of the forms, making their erection, support and removal expeditious and free, the labor bills for the work and the repairs of the forms themselves will be so greatly reduced as to give this class of construction material economic advantage.

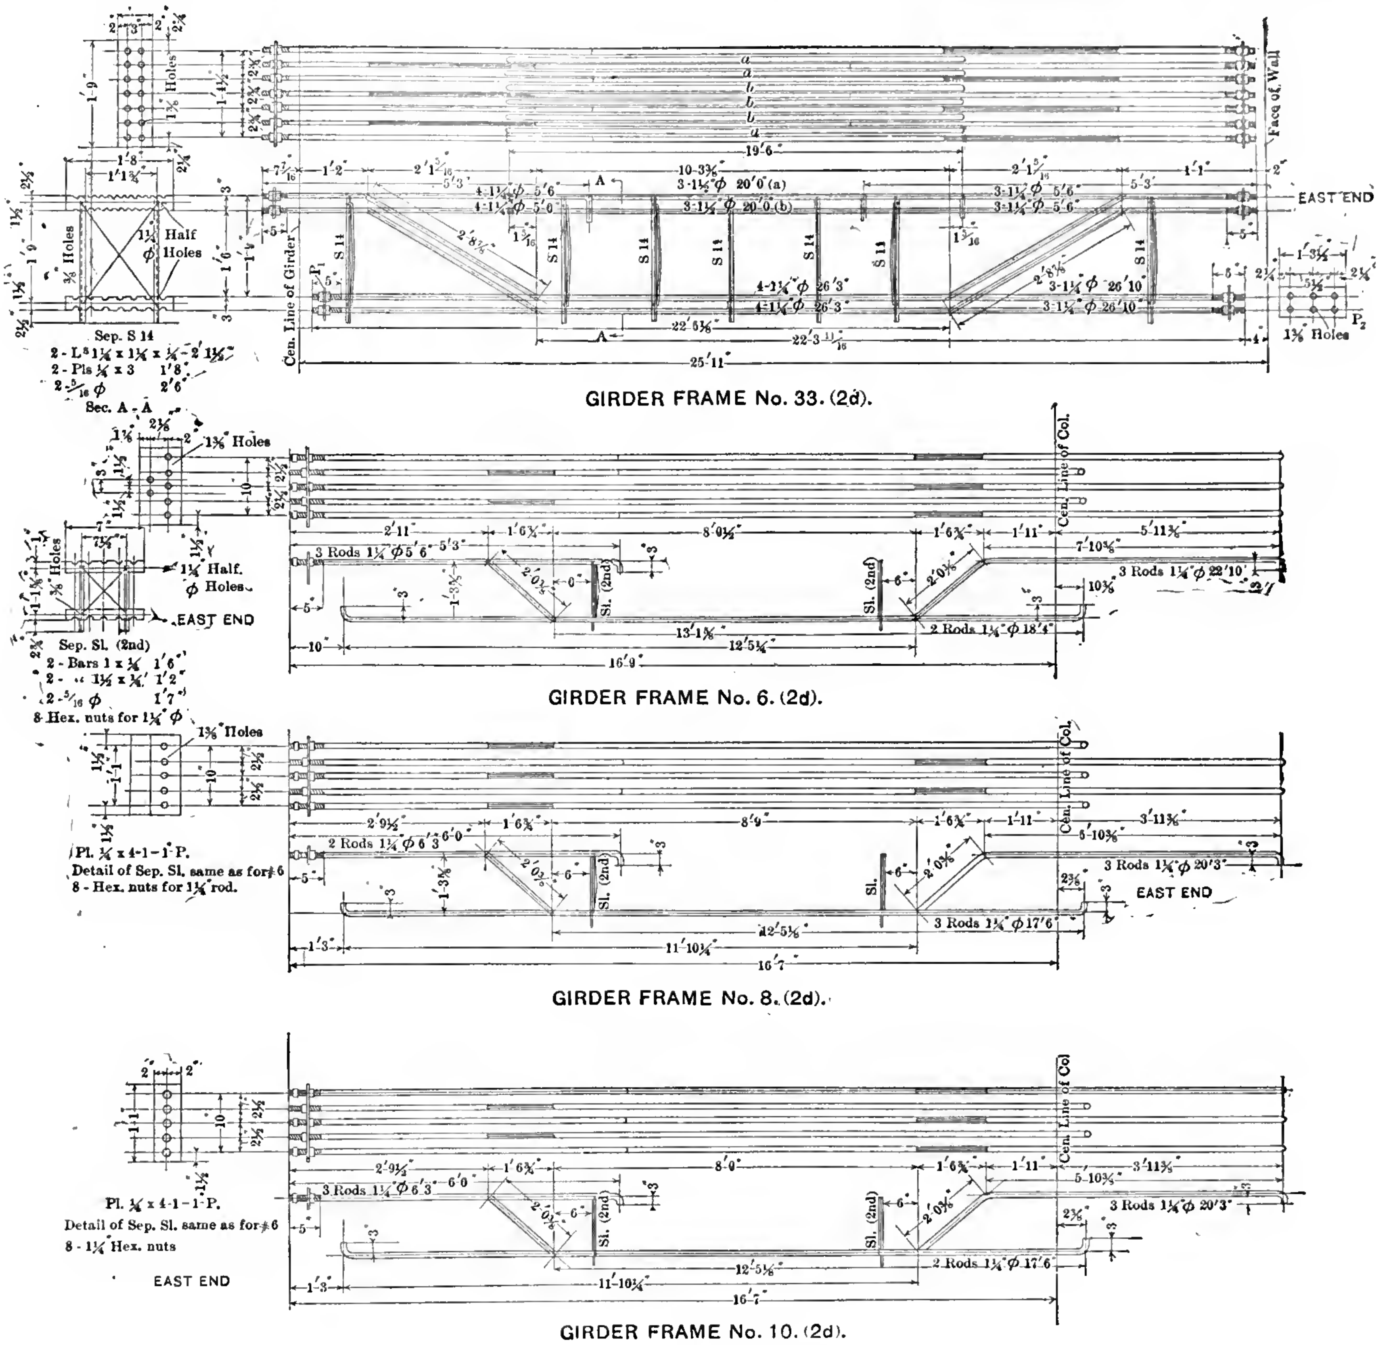
The length of time which the forms should remain in place supporting fresh concrete will depend on the temperature, and hence on the season as well as on the character of the work designed. It is clear that, with the substantial steel reinforcement of the columns of this building, a minimum of time would be sufficient for the column forms, but as it was not convenient to remove the latter until the floor forms were also ready to come down they were all kept in place for at least 19 days. Three entire sets of forms for floors and columns were made, so that, while concrete was being poured for the uppermost floor being constructed, the two stories immediately below were still supported by the timber forms. The lowermost set of forms was then taken down and placed above the freshly formed concrete last put in place. In this manner the forms could be left in place long enough to satisfy the requirements of even the Winter season.

The concrete work of the building proper was begun in the basement in September, 1906, and the concrete parapet walls on the roof were carried on almost uninterruptedly throughout the Winter. A few of the coldest and stormiest days of the Winter were sufficiently severe to cause the work to be suspended for the day. When it is remembered that from the latter part of January until the early part of March the weather

was phenomenally severe, it is demonstrated by actual experience that reinforced concrete building work may be conducted under proper conditions through a New York Winter without material interruption.

After the completion of the lower two or three stories, when the organized force had become accustomed to the character of the work and the sequence of operations required, the average rate of progress, including the delays and occasional interruptions caused by the Winter weather, was about twelve calendar days to a story.

From the early part of December to the latter part of March the window openings of the story below the floor in process of construction were closed with canvas, behind which, distributed over the entire floor, salamanders burning coke were constantly kept in operation. These salamanders were to some extent concentrated under the freshly poured concrete. By these means entirely satisfactory temperatures could be maintained, so that the retarding influence of the frost on the setting of the concrete was to a great extent eliminated, except for the fact that occasionally the top surface of the fresh concrete was frozen. The warmest air produced by the salamanders would rise to and remain in the overhead cellular spaces of the timber floor forms and act there with a high degree of efficiency.



Steel Reinforcement of Typical Girders, McGraw Building.

In connection with the operation of the salamanders below the fresh concrete, the top of the latter, as fast as poured, was always protected by a covering of hay or canvas, or both. These protective measures were scrupulously enforced throughout the winter with entirely satisfactory results. Indeed, there was no evidence to be found throughout the whole building to show that any part of the concrete whatever was affected injuriously to the slightest extent by the frost. During a considerable portion of the winter a few salamanders were kept burning in the second floor below the work in progress.

All the construction work of the building was carried on from a high central temporary timber tower running from the basement to a height of nearly 75 ft. above the roof. This timber tower was 31 ft. square and built with 10x10-in. yellow pine spliced corner posts properly braced. Each 10x10-in. corner stick carried a derrick boom 75 ft. in length. These derricks were first placed low down on the tower, and then raised from time to time to elevations required by the progress of the work. The booms were long enough to command the entire area of the work, and had a sufficient swing or reach to pick up material, including sections of the steel columns, delivered in the street in front of the building, and put it in its proper permanent place. The hoisting engines were placed in the basement, and steel cables ran from them up to the derricks.

It was a question at first whether the cost of this tower and derricks was justified by the amount and character of the work to be done, but they were found to be fully justified and well adapted to their purpose. It was probably as economical and expeditious a method as could have been devised for handling the materials and serving the work. As the building was carried up, the work within the limits of the tower was completed, with the exception of the points where the corner 10x10-in. sticks pierced the respective floors where enough free room was left for the operating cables. After the concrete work was finished the tower was taken down through the succeeding floors of the building, and the holes left for the corner posts were filled.

There was nothing unusual about the character of the materials used throughout the building. The material and workmanship of all the steelwork were supplied and manufactured under Cooper's Specifications. The Portland cement used was the Dragon brand, and it was tested and supplied under the standard specifications recommended by the Special Committee of the American Society of Civil Engineers. The sand, broken stone and gravel were supplied by different parties about the city of New York. Some of the broken stone came from the north, down

the Hudson River, and most of the sand and gravel came from Long Island. Throughout the building proper, 3/4-in. broken stone—trap rock and limestone—was used, with the exception of considerable quantities of gravel in which no pieces had a greater maximum diameter than about 3/4 in. In some of the larger masses of the retaining walls and other similar parts of the foundation and basement of the building, 1 1/2-in. broken stone was used.

The proportions of the concrete for the entire building were: One of cement, two of sand, and four of broken stone or gravel by volume. The consistency of the concrete was very nearly or quite wet enough to be that termed semi-liquid, so that it was truly "poured" into all forms for columns, walls and floors. Such a consistency of concrete is imperative for reinforced concrete construction of this class. It enables the concrete to form an intimate and dense matrix around the steel reinforcement, and produces a most excellent quality of material. While the concrete was being poured laborers with long thin sticks continually agitated the fresh concrete in order to release all air bubbles and insure a dense and continuous product and the best possible bond with the embedded steel. There was no sensible excess of water in the concrete, but it was practically semi-liquid—too thin even to quake. The results throughout the entire work, in this respect, have proved to be in the highest degree satisfactory. The total quantities of the principal materials used were: Cement, 8,500 bbl.; sand, 3,000 cu. yd.; broken stone, 4,300 cu. yd.; gravel, 1,066 cu. yd.; steel in angle columns, 655 tons, latticed; steel in round reinforcing rods, 507 tons.

Ornamental Foot Bridge in Bronx Park.

A handsome foot bridge of rubble masonry has been constructed recently in the New York Botanical Garden, Bronx Park, New York City. It is 110 ft. long from face to face of the abutments and is made up of three 20-ft. and two 16-ft. spans, one of the latter being at each end of the bridge. The piers have a uniform thickness of 7 ft. and are 29 ft. wide at the base and 27 ft. wide at the level of the springing lines, above which level they are curved in gracefully to meet the parapet walls. The arches are segments of circles and their thickness is uniformly 2 1/2 ft. The parapet walls are 2 ft. thick and rise 3 ft. above the top of the foot path at the crown points of the arches. Weep holes are provided at each pier and a 6-in. layer of concrete, covered in turn with asphalt waterproofing, is laid over the entire upper surface of the arches and piers.

The bridge is built entirely of material selected from the old stone fences in the park which are gradually being destroyed. The stones forming the parapet walls and the exterior surfaces of the arches and piers were specially selected and disposed to make the best possible appearance. The facing stones of the arches are placed radially anad by selecting stones decreasing in length from the haunches to the crown, with a keystone at the center, a pleasing effect was obtained at little expense. In constructing the arches, to prevent the mortar from running down and entirely filling the interstices between the soffit stones, the latter were bedded in a layer of sand laid on the centering; when the centering was removed the sand dropped out and the outer surfaces of the stones were free from mortar as was desired. The bridge was designed and built under the direction of the Department of Parks, Borough of the Bronx, New York City, of which Mr. Martin Schenck is chief engineer, and Mr. W. P. Hennessy is assistant engineer.

Gas-Power Central Station of the Duquesne Light Co., Pittsburg, Pa.

A paper read before the American Institute of Electrical Engineers, Pittsburg Branch, by Norman C. MacPherson.

Although the territory now supplied by the Duquesne Light Co. was already covered by the distribution system of another company. there seemed to be room for further business for a central station securing the advantages of more uniform regulation and distributing directly from the center of gravity of its load, thus obviating the first cost, the maintenance, and the losses of long transmission lines. Work was begun on June 28, 1906, and by October 5 the power station and distribution system were far enough completed to start regular 24-hour service. During the following six months the service increased so rapidly that the station is now heavily loaded and running on an excellent load-factor. The service consists of residential and commercial lighting and power, and these merge into a load having an exceptionally long hour evening peak and a fairly even day load. The 60-cycle generators are wound three phase, star connected, and the distribution is partly underground and partly overhead to standard 2,200-volt transformers, which in turn are connected to 110/220-volt secondaries.

The power station In the choice of site and equipment, several factors had to be carefully considered.

a. Proximity to electrical "center of gravity."

b. Coal supply for steam or gas plant.

c. Natural gas supply for gas plant.

d. Water supply for condensing or cooling purposes.

The power house site chosen—near the junction of Penn avenue and the Pennsylvania Railroad—is approximately the center of the system, extending as it does about two miles in every direction from this point. Although the Pennsylvania Railroad passing the property offered excellent fuel facilities, the absence of a natural supply of water in the East End practically barred a steam plant. The high pressure pipe line of the Pittsburg Natural Gas Co., delivering 24,000,000 cu. ft. of gas daily to the mill district of this city, passes within 1,000 ft. of the power house site, and this fuel was finally decided upon for its availability and cheapness. Should the natural gas ever fail or reach a prohibitive price, a producer plant will be erected on the company's adjoining property, the coal used being elevated from the Pennsylvania Railroad tracks. In this case the present engine equipment will be retained, as it is entirely adapted to either natural or producer gas—a good illustration of the flexibility of power gas work. In the building proper—a sub-station fire-proof structure of brick, concrete and steel—the one feature out of the ordinary is that the entire building is devoted to generating machinery, no boiler or producer room being necessary. When complete with four units, the station will total about 3.7 sq. ft. per rated kilowatt, a low figure for a plant of only 720 kw. capacity.

Generating units. Each of the two generating units at present installed consists of a 3-cylinder, vertical, single-acting gas engine, with cylinders, 18 in. in diameter by 22 in. stroke, running at 200 r. p. m., direct connected through a flexible spring coupling to a 180-kw., engine-type, 60-cycle, alternating-current generator. These units are of standard construction and include the very best features for obtaining satisfactory parallel operation, uniform speed under variable loads, continuity of operation, and low operating expense.

Auxiliaries. The auxiliaries include apparatus for supplying compressed air for starting the engines, 4-volt and 110-volt direct current for ignition purposes, 110-volt direct current for exciting the main generators, and water for cooling the engines.

Compressed air supply. The compressed air supply for starting the engines must be independent of the engines themselves, as it must be ready for use when the rest of the station is "dead." For this purpose, a small horizontal, single-acting gas engine is used, which is belted to a two-stage compressor; for breakdown purposes, a separate compressor is installed, belted to a countershaft which in turn can be driven by either of the main engines. The supply of air normally needed for starting the engines, is stored in two 16-in. cylindrical tanks at 200 lb. pressure. In addition, four more of these tanks, each controlled by its own valve, have been installed, which, as they are not to be drawn from except for emergency work, constitute a reserve for the engine-driven compressor. The six tanks total 102 cu. ft., or over ten times the cylinder displacement of one engine.

Ignition current. For initial ignition, there has been provided one set of primary "dry" batteries and one set of storage batteries, either of which is sufficient to operate the plant for some time. For ordinary use, however, a motor-generator set has been provided, taking current for its motor from 110-volt, direct-current, exciter bus-bars, and delivering from its shunt-wound generator, direct current of the same voltage. This supplies current to the ignition points which are operated in series with suitable resistance lamps. The storage batteries, however, are connected inside the lamps and work directly on the ignition points, thus allowing the batteries to "float" on the circuit, at all times fully charged and ready automatically to furnish the ignition current in case of accident to the motor-generator. Whenever necessary the 110-volt exciter circuit can be thrown directly on the same resistance lamps, but this has the drawback of permanently grounding the one side of the field winding of the alternating-current generators.

Excitation. The direct-current excitation for the main generators is provided by two 110-volt, compound-wound dynamos, either of which has sufficient capacity for both of the main units. These exciters are direct connected to induction motors which, in turn, are fed directly from either set of main switchboard bus-bars. These motor-generator sets are also provided with pulleys for belt connection to a countershaft which, in turn, can be run by either of the main engines through friction clutches. This clutch and belt device is occasionally a decided convenience in different ways, but its normal and important use is only for a few minutes, namely, after an accident has deadened the main alternating-current switchboard bus-bar. In this case the first main generator secures its excitation by means of an exciter set driven by its belt; the main generator is then switched on the bus-bars and supplies current to the induction motor of the other exciter set. Next, the exciters are paralleled, the load transferred to the second exciter, and finally the friction clutch driving the first exciter set is released.

Cooling water. The simplest method of cooling the cylinder jacket is, of course, to use fresh water directly from the city mains; this method, however, is rather expensive, and a circulating system has been installed which permits the use of a given quantity of city water over and over again until its temperature is too high. For this purpose, a two compartment concrete tank has been constructed on the roof of the building, provided with overflow and risers, connected with engines and city water piping. In these roof tanks a sufficient amount of surface cooling has been obtained to reduce the quantity of water required by the plant to about one-half of that needed without this circulating system, and this

proportion will be still further reduced by a simple form of cooling tower now being constructed on the roof. For emergency use, it is proposed to employ well water, although impurities will not permit its steady use. The jackets do not work under full pressure head from the tanks, about 35 ft., but deliver into a supplementary tank located on the mezzanine floor of the engine room, giving about 5 ft. of pressure head on the engine jackets. This is sufficient to provide solid water at all points and to prevent air pockets. From this tank a centrifugal pump, driven by a 3 horse-power induction motor, delivers this water to the roof tanks.

Piping. The engine exhausts are carried out though the building walls with easy bends, and then rise 40 ft. to clear the roof. As water is used in the exhausts, these risers are drained near the engines. A simple steam exhaust head capping each riser completely deadens the exhausts, thus avoiding the difficulty sometimes experienced with gas plants located in residence territory.

The gas is delivered at the power house at about 15 lb. pressure, but this is reduced to 8 ounces before being metered. This pressure is further lowered to 2 ounces by the regulators furnished with each engine. Ample storage capacity in the shape of liberal piping, has been provided on both sides of the engine regulators to insure a moderately uniform flow of low pressure gas.

Parallel operation and regulation. As this is a 60-cycle, polyphase plant, carrying a mixed load of lights and motors, it is apparent that good voltage regulation is necessary and that satisfactory parallel operation is an indispensable feature. The very fact that the plant is able to give so good a quality of service is proof that the parallel operation bugaboo held over the gas engine for years, has been driven to cover especially with direct-connected 60-cycle generators. These units are paralleled in precisely the same manner as the ordinary steam unit, on an "opening throttle;" that is, the new unit is brought slowly up to synchronism with the one in service, and after the switches are closed, the throttle is spun open. There is an important advantage, however, over a steam engine of ordinary construction; namely, that the tension of the governor spring may be easily changed by hand while the engine is running, thus changing its speed and consequently its load also. As a matter of fact, instead of altering the governor spring, a pair of springs at the mixing valve working against the governor spring is adjusted, thus securing the same result. This adjustment, consisting simply of a pair of thumb screws, gives an opportunity to bring up the load on the new unit as slowly or as rapidly as desired, and to any point. Thus the fresh unit may be given more than its share of the load for a time to relieve the temperature of the other; or should an igniter on either engine give trouble, the load may be dropped to two-thirds rating without taking the unit out of service. This adjustment is also sometimes used to bring the engine into synchronism. The effect of a misfire in one of the cylinders is never noticeable on the line, except when the misfire continues for several cycles, which is rare. Naturally, it induces some little surging between the two machines, owing to the temporary disablement of a cylinder, but the shock is readily absorbed by the spring coupling and does not show the slightest tendency to throw the engine out of step. In general, the regulation from this plant is fully as good as could be expected from any steam plant, and is entirely due to the method of controlling the quantity of mixture by the governor, which is a fundamental feature of the 4-cycle gas engine.

Ignition. This is one of the most vital points in gas engine work and should receive careful attention from both the designing and operating engineer. There should be at least two separate sources of ignition current continuously available, which are provided for here by the small 110-volt shunt-wound generator and the set of 4-volt storage batteries, as before described. Only one case has occurred where an engine has been shut down from the loss of igniter current, and this was due to a ground in the conduit between igniter switchboard and engine. This occurred in spite of the precaution of running all wiring through loricated iron conduit. A few spare igniters are always kept on hand, and it is only a few minutes work to replace a disabled one. If, however, these are changed regularly and cleaned, as they should be, they give very little trouble. On these engines there is a device for changing the point of ignition while running. It is very necessary in gas engine work that ignition take place at the proper point, otherwise inefficient combustion shown by a badly distorted card, will result. But a good engineer can very readily determine whether the ignition is at the right point merely by the sound of the explosion. Should the gas change in quality for any reason, the ignition can be readily adjusted, as well as the mixture, in a few seconds, without in the least disturbing the running of the engine.

Starting. One very great advantage of gas engine work is the absence of standby losses after the engine is shut down, unlike the steam plant where there are condensation, radiation, and stack losses. The gas engine may stand for an hour or a month without incurring any losses whatsoever, and yet be in readiness for starting within a minute or two of the signal; but a steam engine must be warmed up and "turning over," previous to loading. In the Duquesne plant, compressed air is used for starting the engines. A supply several times greater than that actually required is aways kept stored in steel tanks at 150-lb. pressure. A single air valve controls each engine, and as soon as the air is turned on, the engine automatically comes up to speed, usually in about 45 seconds, so that the unit may be loaded within about one minute from the start, or at least two minutes. This is evidently a good feature in case of emergency spare units.

Station Efficiency. A power station is, in one sense, only a machine for converting the potential heat energy of fuel gas or coal into electrical energy. The efficiency of conversion depends almost entirely upon the type of plant. With steam engines, 4 pounds of coal per kilowatt-hour may fairly be assumed to be well above the average results obtained in lighting plants of less than 1,000 h.-p. capacity. Now 4 lbs. of bituminous coal of 14,000 B. t. u. per lb. (equal to 53.3 cu. ft. of natural gas of 1,050 B. t. u. per cu. ft.), is equivalent to a heat consumption of 56,000 B. t. u. per kilowatt-hour at the switchboard, or an absolute thermal efficiency (1 h. p. = 2,545 B. t. u.) of 6.1 per cent. between the coal pile and switchboard.

Curves were prepared to show the fuel consumption of the Duquesne Light Company's engines, and display the total hourly gas per engine, the gas per kilowatt-hour and the absolute thermal efficiency from gas to electricity. The "total gas" curve, from which the others were calculated, was determined by reducing the actual station records to the equivalent performance of a single engine, and was checked up by a number of readings taken at various loads. We will tabulate for illustration, the values for two different engine load-factors; namely, 40 and 80 per cent. These are extreme limits—a plant requiring five engines to carry its peak load should be able to operate at an average engine load-factor of 80 per cent. and a plant requiring two engines for its peak load would probably run with an average engine load-factor of 40 per cent.

Summarizing the tabulation, we find that natural gas of 1,050 B. t. u. per cu. ft. will give a kilowatt-hour on 21.2 cu. ft., with an average engine load-factor of 40 per cent.; if the engines can be run on an average load-factor of 80 per cent., the gas required will be only 15.2 cu. ft. per kilowatt-hour. These values can be reduced, for sake of illustration, to equivalent pounds of coal having 14,000 B. t. u. per pound; namely, 1.7 and 1.23 lb. per kilowatt-hour, respectively. If it is desired to compare these results with steam data expressed in terms of indicated horsepower these values will be approximately 0.96 and 0.78 lb., respectively.

Engine load-factor.	Cu. ft. gas per kw-hr.	B.t.u. per kw. hr.	Absolute efficiency of unit (gas to electricity).	Equivalent coal —B.t.u. basis— Lb. per kw-hr.	Lb. per i.h.p.-hr.
40%	21.2	22,200	15.35%	1.7	0.96
80%	15.2	16,000	21.4%	1.23	0.78

The comparison of the fuel consumption of the steam station described above, (operating on an equivalent of 53.3 cu. ft. of natural gas per kilowatt-hour) with the gas rate of a gas engine station which lies somewhere between the limits of 21.2 and 15.2 cu. ft., is a striking illustration of the great fuel economy of the gas engine, and is, in itself, a measure of the relative thermal efficiencies of the two methods of developing power from natural gas.

Cost of Power. All the various items entering into the cost of power are, at present, difficult to obtain in segregated form, but have been estimated as closely as possible from two different prices of gas.

	25c. Gas. % of total.	25c. Gas. Cents per kw-hr.	15c. Gas. Cents per kw-hr.
Fuel gas	47.6	.440	.264
Wages	28.3	.260	.260
Supplies—			
Oil waste 11.3			
Water 9.0			
	20.3	.187	.187
Repairs	3.8	.026	.026
Totals	100.	.913	.737

This estimate, based upon the present load-factor and the complete plant, shows a total operating cost well under 1c. per kilowatt-hour for the highest priced gas, and 0.75c. for the lowest.

In the near future, this will be somewhat lowered by a reduction in the cost of water due to the cooling system mentioned above. Such a low cost shows the possibility of developing a large daylight power load, which feature appeals strongly to electric light managers.

It is difficult to compare these fuel costs per kilowatt-hour with those of ordinary steam plants, as so much depends upon the character of their service and apparatus, but a large number of electric light plants under 1,000 horsepower will have a fuel consumption varying between 4 lb. and 8 lb. of coal. It is also fair to assume that their expenses, outside of the fuel item, will not differ materially from those given above (in a great many cases their wage item will materially exceed 0.26 per kilowatt-hour).

On this basis, then, natural gas at 25 cents per 1,000 cu. ft. is competitive with coal at $2.20 per ton, on a consumption of 4 lb. per kilowatt-hour, also with $1.10 coal, on the basis of 8 lb. per kilowatt-hour. Similarly, 15c. gas is competitive with coal at $1.32 per ton with a coal consumption of 4 lbs. per kilowatt-hour and with coal at 66c. a ton on a consumption of 8 lb. per kilowatt-hour.

Conclusion. It is well to keep clearly in mind that a gas power station can utilize to better advantage a larger number of generating units than can a steam station. The reason for this is that the gas engines are practically as efficient in small as in large sizes, and that the cost per kilowatt, and floor space occupied per kilowatt of rating, is likewise nearly uniform. Consequently, it is better to split up the station capacity as much as possible, thereby enabling the operator to fit his units into the load curve and obtain a better efficiency for the station. The available space

power will also be better distributed, and this multiplicity of units more readily provides for the possibility of losing an igniter. With one unit running, the disablement of one cylinder amounts to 33 per cent. of the rated capacity; with two units running this deficiency amounts to 16.6 per cent.; with three units, the deficiency is reduced to a little over 11 per cent. of the total capacity in operation. With four units running, the deficiency is but 8 per cent., which can be readily taken care of by the overload capacity of the remaining cylinders.

General experience with the Duquesne Light Company's plant thus far indicates that good service, combined with low operating costs, may be expected if proper attention is given to keeping the equipment in good working order. It is true that inexperienced or careless men cannot get the best results from a gas equipment, but with an experienced, active engineer in charge, the equipment is as trustworthy as a steam plant.

Mr. J. R. Bibbins contributed the following discussion of the paper:

One of the most important is the question of relative spare capacity. In planning a new station, this question arises right at the outset after the problematical load curve has been determined upon—how many, and what size of units will be installed. Although one or two units yield the simplest form of plant, when one considers the average running efficiency the unit will give under the given load-factor it is a different matter.

In a recent study of this point, a 1,000-kilowatt maximum load curve was assumed with 1, 2, 3, 4 and 5 service units and a single spare unit. By "blocking in" the engine curves corresponding to the actual capacity in service at a given time, the average load on the engine was obtained in per cent. of its rating, this being obtained by integrating both load and engine curves. Thus the relative heat consumption under average running conditions was obtained. For this particular load curve the first three unit combinations worked out best in horizontal units, the last two in vertical. For five units this condition works out to an average heat consumption of less than one-half that required by a single unit; in other words, an efficiency of twice as great. As to the cost of spare capacity for the single-unit plant, we must provide a spare unit equal to the running capacity—100 per cent., two units, 50 per cent., etc., down to 20 per cent. for five units.

It may be contended that the relative heat consumption and the cost of spare capacity are only small factors in the final solution of the problem, but this is not the case. The modern gas engine requires, in the larger sizes, a type of construction which does not permit of very great reduction in cost over smaller sizes which embody the vertical self-contained construction. It thus develops that the price of a large gas-engine unit is very little lower than that of a medium-sized unit. Again, we find that the heat efficiency of the large unit is but very little higher than that of the smaller sizes, due largely to the inherent properties of the combustion cycle rather than to any precise refinement in design or construction which so clearly disclose the character of steam engine construction. Analyzing the labor cost in the station, we find that with the compact, self-contained, vertical unit, this item is very nearly the same as for equivalent horizontal capacity. Thus the problem practically reduces itself to that of relative operating efficiency and investment in spare units with the result above noted.

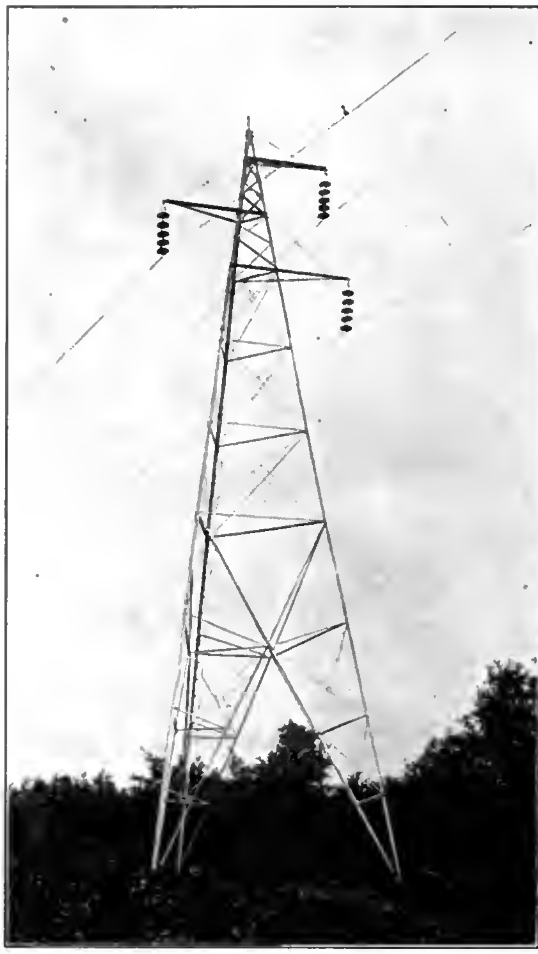
On the question of spare units we may assume as a possible contingency that an igniter will give trouble at some time. This throws a certain part of the engine out of service, but does not necessarily disable it. With one unit running, the loss of an igniter would cause 25 per cent. loss of power, and with five units, 6.6 per cent., but on the standard overload ratings each engine cylinder is capable of delivering 10 per cent. overload continuously. This overload capacity thus comes to the rescue of the disabled igniter. With two running units in the plant, we will barely be able to carry full load; with three units the extra capacity will tide us over; with five units the plant will develop 2.7 per cent. in excess of the rating in spite of the disabled igniter.

An overload capacity of 10 per cent. seems small compared with the similar capacity of a steam engine or steam turbine unit. While a steam unit gives its best economy at full load or under, the economy of the gas engine increases up to the maximum load, which makes it desirable to rate the engines and operate them as close to maximum as is permissible, and while the gas engine has a decided advantage for steady central station service, it is somewhat at a disadvantage on rapidly fluctuating loads. This, however, may be overcome by the use of a storage battery. A system has recently been devised by which the generator load may be held practically constant while the e tire fluctuating load may be taken up by the battery. This is accomplished by a load regulator, a simple instrument of the relay type, installed on the switchboard and operating in connection with the booster. In a recent test with this system, the external load was instantly varied through a range equivalent to 300 per cent. of the generator capacity, yet these variations were entirely absorbed by the battery, and the generator kept within a few per cent. of its rating, irrespective of the suddenness or the violence of the fluctuations. This instrument is particularly useful in gas engine work as it permits full loading of the unit with impunity whereas it might be necessary to reduce the average loading to one-third of the rating in order to take care of the fluctuations.

Denatured Alcohol to the amount of 1,744,272 gal. was produced in the United States during the first six months of this year. The free alcohol law took effect Jan. 1, 1907.

Three Low-Head Hydro-Electric Developments in Michigan.—Part II.

Big Rapids Dam Development.—The Big Rapids development, 18 miles up the river from Croton, is at a point where the river valley is 800 ft. wide and 40 to 50 ft. deep. The dam renders available a head of 40 ft., which is utilized by equipment having a total capacity of 6,000 h.-p. The dam consists of an earth embankment, with a concrete waste-gate section built in it, toward one end, and a power house also built in it across the original channel of the river, which was at one side of the valley. The whole site is underlaid by hardpan that is covered with coarse sand and gravel. At the power house, in the channel of the river, this overlying sand and gravel was 20 to 50 ft. deep, but graded off in depth toward both sides of the valley, the flood-gate section being built directly on the hardpan. A continuous line of steel sheet piling, extending entirely across the valley under the site of the dam, was driven into the hardpan far enough to form a complete cut-off wall in the sand and gravel, and is carried into the sides of the valley to prevent leakage around the ends of it. The embankment contains a 10-in. reinforced-concrete core wall, built on this row of steel piling; the latter is also at the upstream limits of the concrete in the gate section and the power house. Some of this steel piling was driven to a depth of as much as 56 ft., the long pieces being spliced. The core wall, like the one in the embankment of the Croton dam, is located so its top is at the intersection of the surface of the water in the pond and the slope of the embankment. The power house is carried entirely by wooden piles driven down to the hardpan. The substructure of the power house is also enclosed on all four sides by sheet piling, driven to the hardpan, the row of steel piling forming the upstream side of this enclosure and wooden sheet piling the other three sides. The



Tower of 100,000-Volt Transmission Line.

Strain Insulators at a Change in Grade.

wooden piling consists of 6 x 8-in. and 7 x 9-in. tongue and grooved timbers, in 12 to 26-ft. lengths.

The embankments of the dam were made by teams and scrapers, most of the material being obtained from a borrow pit on the power house side of the valley. This material is largely all sand and gravel similar to that used in the Croton dam. The embankments have slopes of a 2 to 1 on the downstream side and of 3 to 1 or flatter on the upstream side.

Waste-Gate Section.—The waste-gate section, with a total width of 150 ft., is arranged practically the same as the waste-gate section of the Croton dam. It contains six Tainter gates, each 20 ft. wide and 12 ft. high, three of which are on each side of a log sluice, 6 ft. wide. These gates are raised and lowered by motor-driven hoisting crabs, the same as those described in connection with the Croton development. The spillway on which the gates seat when closed is a hollow reinforced-concrete dam, of the same general design as the one at Croton, the water falling from it into a tumble bay formed by an overflow weir, 69.5 ft. downstream from the gates. This tumble bay is divided into two parts by the walls forming the sides of the log sluice. Each of these parts is arranged with outlets so it can be drained when the three gates discharging into it are closed. The retaining walls on both sides of the waste-gate section are extended downstream for 240 ft. from the gates, forming a waste-way channel, 180 ft. wide. A second row of steel sheet piling is placed across this channel just below the tumble bay, and for 50 ft. from the latter the bottom of the channel is protected by rock-filled timber cribs, with the filling in these cribs grouted. The bottom of the remainder of the channel enclosed by the retaining walls is protected by a concrete lining.

Power House.—The concrete substructure of the power house is 50 x 95 ft. in plan, with its center line normal to the axis of the dam, and has concrete wing walls extending up and downstream from both ends of it. The power house proper is a brick structure 40 x 50 ft. in plan on the downstream end of this substructure. It contains two 3-phase 30-cycle 6,600-volt revolving field Westinghouse generators, each direct-connected to two pairs of 45-in. horizontal center-discharge Samson turbines in one of two open steel-plate penstocks of the Rickey type, which are erected over the upstream end of the substructure. The units operate at 225 r. p. m., each generator being capable of developing the full 3,000-h.-p. capacity of the four turbines which

connected to the shaft of the main unit, furnishes excitation current for each generator. A Tirrill regulator is provided to control the voltage of each generator. The operation of each set of two pairs of turbines is controlled by a Type N Lombard governor, belted to the main shaft of the unit.

The 6,600-volt current delivered by the generator is stepped up to 72,000 volts for transmission to Muskegon and Grand Rapids by three oil-insulated water-cooled transformers in a separate 28 x 40-ft. fireproof building on the side of the valley, about 50 ft. from the power house. The busbars in this building are in separate fireproof compartments and all connections to them are provided with special hand-operated oil switches, in fireproof cells.

When the development was completed the turbine plant was tested in place under the supervision of Professor Gardner S. Williams, of the University of Michigan. The power output of the generators was measured electrically, while the water was measured over a 112-ft. steel-crest weir, according to Francis' directions and formula. The testing of the electric equipment was in charge of the Electrical Testing Laboratories of New York. The results obtained agreed essentially with the turbine makers guarantees.

Inclined racks placed across the open upstream end of each of the penstocks intercept such floating debris that passes under a log boom in the pond which is arranged to direct the debris through the log sluice in the waste-gate section. These racks consist of $\frac{1}{4}$ x 3-in. bars bolted together in sections and carried by a frame of structural steel shapes. Stop-log grooves are also provided in the sides of the penstocks, in front of the racks, so the openings may either one be closed. These stop-logs are handled by one of the hoisting crabs used in operating the Tainter gates, the track for the crabs being extended from the waste-gate section into the house over the penstocks. This house is a frame building with sheet iron sides and roof, which is provided to protect the men clearing the racks, or working on the stop-logs.

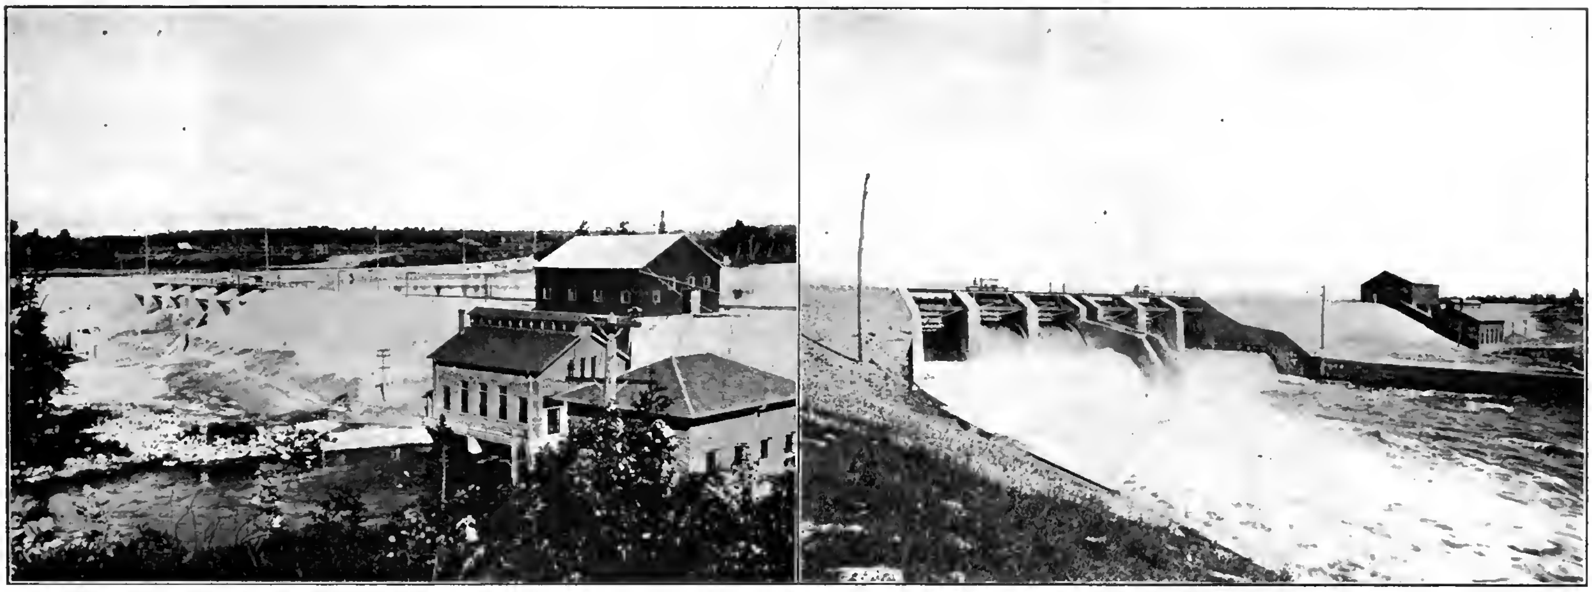
A draft tube for each pair of turbines is formed in the concrete base of the substructure, the two draft tubes of each two pair of turbines discharging into one of the two parts in which the tail race is divided by a longitudinal wall under the building. The draft tubes are lined with steel plates and are designed to deliver the water to the tail race quietly. The bottom of the tail race is protected by a concrete apron that extends 20 ft. downstream from the substructure, a row of wooden sheet piling being driven under the

of piling which were along the sides of the latter.

Construction of Big Rapids Dam.—The Big Rapids dam was also built on force account by the Grand Rapids-Muskegon Power Co. under the direction of the same engineers mentioned in connection with the Croton project, except that Mr. N. F. Johnson was superintendent in charge. The construction plant was assembled during the winter of 1904-05, and active work was begun March 1, 1905, the generators being placed in operation on March 15, 1907. The construction plant was essentially similar to that used at the Croton dam, except that it was all steam-driven; the construction methods employed were also very similar to those followed on that work. The river was allowed to follow its channel until the work had been carried up to it on both sides, when it was diverted through temporary openings in the waste-gate section until the power house was finished. The water was then turned through the penstock and the temporary openings in the waste-gate section were closed.

This dam required 18,000 cu. yd. of concrete, in which natural bank gravel, obtained immediately at the site, was used. The plant for handling the gravel and concrete was very similar to the one at Croton which has been described, the gravel being delivered in scrapers directly from the pit to charging hoppers at the mixing plant. The cement used in the concrete was shipped in cloth sacks in January and February and was hauled $1\frac{1}{2}$ miles from the railroad in sleighs on the snow. It was stored in 40 x 90-ft. sheds, with a one-third pitch batten roof, covered with tar paper, in the usual manner of lumber camp construction. The floor of this shed consisted of two courses of 6-in. poles, laid on the ground, the second course being at right angles to the first. These poles were covered with about one foot of loose straw, on which was placed a single layer of tarred roofing felt; the sacks were then piled five high on end on this felt. No cement was lost by caking, and in fact, the only cement that showed effects of dampness was that on top, which gathered some moisture from the air, and caked in places to a depth of about $\frac{1}{2}$ in. If tarred paper had been put over the tops of the sacks, it is believed that even this small amount of caking would probably not have occurred.

Transmission Lines.—When the Big Rapids development was made a transmission line, carried by poles, was built from the dam to a switch station at Casnovia, 33 miles from the dam; one branch of the line was extended from this station to Grand Rapids, 21 miles, and a



Two Views of the Big Rapids Development.

line passes close to the Croton development, the generating equipment of which is connected with it. The line has been operated satisfactorily at 66,000 volts and will be operated at 72,000 volts in the future. Power is delivered to three sub-stations, one in Muskegon, one near Grand Rapids and one in that city.

Michigan and Idaho cedar and Southern cypress poles, 45 to 60 ft. long and placed 40 to the mile, carry the three conductors of the transmission line, which are No. 2 solid copper wire. These wires are carried by Locke insulators, 14 in. in diameter and 18 in. high, at the corners of a 72-in triangle. These insulators are mounted on two cross arms carried by the poles, wooden pins being used on straight-line work, and iron pins at angles; all pins are 18 in. long and are 2 in. in diameter at the shoulder. A No. 6 iron wire, grounded at every fifth pole for lightning protection, is carried by the upper cross arm on the poles.

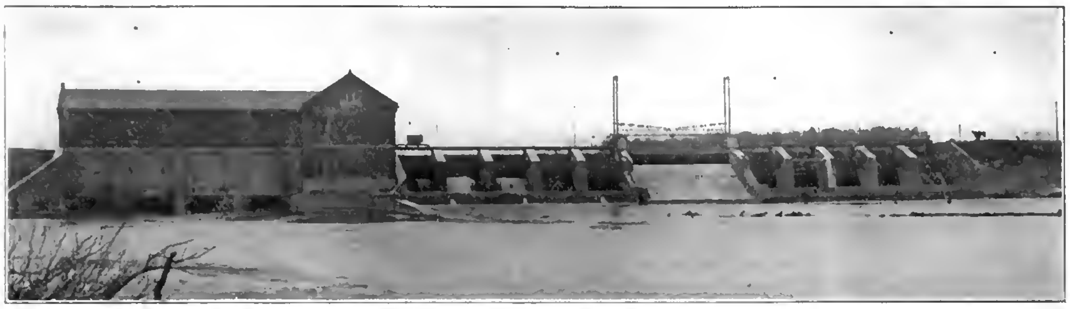
A second transmission line, 35 miles long, is being built from Croton directly to a sub-station in Grand Rapids and will be operated at 100,000 volts. This line will be entirely distinct and separate from the original one, so a duplicate line between Croton and Grand Rapids will be provided when it is completed. Interruptions to the transmission system between these two points, due to the local thunderstorms, which occur in this section, will thus be avoided largely, since a disturbance affecting one line would very probably not affect the other.

The new line is carried by triangular steel towers, 40 to 60 ft. in height, which were built by the Aermotor Co. These towers are placed about 500 ft. apart, and have each leg anchored to a 3-in. steel angle, 7 ft. 10 in. long, buried in ground. The angles are incased in concrete to prevent the corrosion that would probably take place rapidly in the porous sandy soil. These angles are each extended about 10 in. below the bottom of the concrete in which they are encased, to provide a ground for the transmission line. The three conductors are equivalent to No. 2 wire, being stranded copper wire with a hemp center. They are carried by suspension insulators on cantilever arms at the top of the tower. These insulators each consist of five umbrella-shape porcelain sections, 10 in. in diameter, having two interlinked semi-circular holes, through which tie wires that attach the sections together are passed. These holes are so arranged that the tie wires which pass through them exert a compression strain on the porcelain. In case a section breaks, the tie wires remain intermeshed, and as the sections are in series, and have a factor of safety, the remaining sections prevent a ground. A strain insulator, consisting of disks with grooved flanges, the mechanical and electrical features of which are essentially the same as in the umbrella-shape sections, is used at turns and at various intervals to support and anchor the line on curves and in similar places.

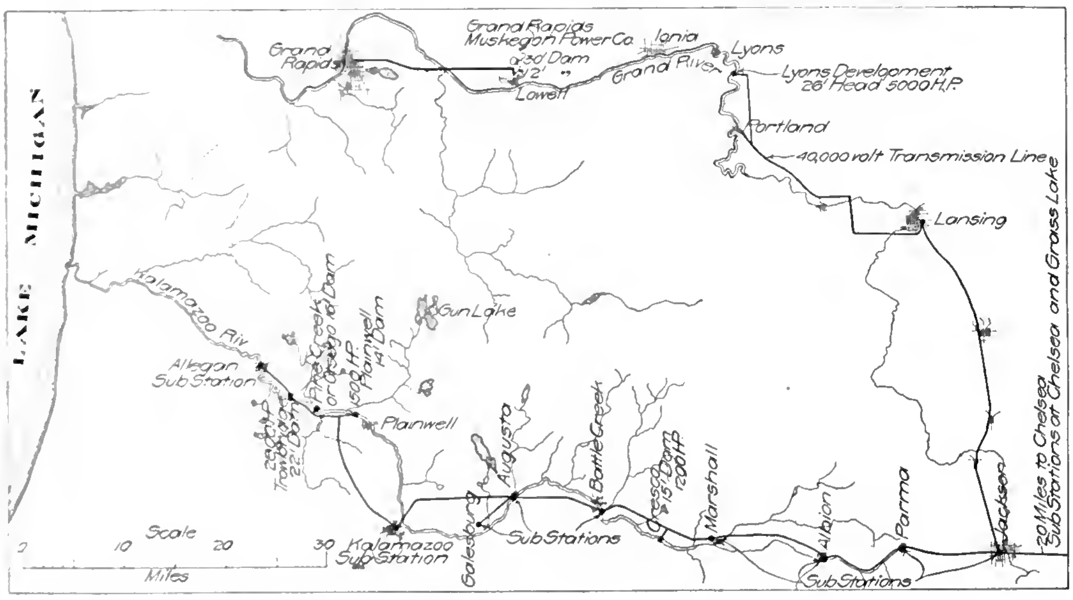
The angles to which the legs of the towers are anchored were encased in concrete at the mixing plant at Croton, and were distributed along the line by railroad shipments and in wagons, after the concrete had set, each complete anchor weighing about 275 lb. A set of removable forms, built for casting the concrete around the angles, proved very satisfactory. The cross section of this enclosing concrete is an ellipse with 4½ and 6-in. axes. One 3-in. 4-lb. channel and several short reinforcing rods, fastened horizontally near the bottom of each main angle as anchors, are also enclosed in a disk of concrete, 5 in. thick and 1.5 ft. in diameter, which is cast with the column enclosing the main upright angle. The form for the concrete columns consists of No. 16 black sheet iron bent to the shape of the column, and divided on the long axis of the cross-section of the column into two parts; these parts overlap at the joints and are held together by four hinged clamps of ¼ x ½-in. band iron. The form for the disk of concrete at the base is also made of No. 16 black iron, and has a collar at the center which slips into the column form to a tight fit. These forms are set up in groups, with the base down, on a platform close to the mixer so they can be filled with concrete readily. This work is thus handled quite economically, while it would practically be impossible to make provisions for mixing the concrete and placing it around the anchors at each tower.

The Lyons Development.—The Commonwealth Power Co. of Jackson, Mich., by which the development on the Grand River near Lyons was recently completed, also owns and operates six hydro-electric developments on the Kalamazoo River. The location of these various developments and of the transmission lines extending to the cities served by them are shown in an accompanying map. All of the developments supply power for public service systems in Lansing, Jackson, Battle Creek, Kalamazoo and Allegan and intermediate towns. Interurban electric railways extending from Jackson to Kalamazoo, Jackson to Lansing, Lansing to St. Johns, the local street car lines in Jackson and Lansing, and that part of the Detroit United Rys., from Jackson to Ann Arbor, are also supplied with power from the generating stations of this company.

The Lyons development is a few miles above the low flat stretch of the river which extends from Ionia to Lake Michigan. The catchment area of 1,750 square miles above the development is largely clay soil; hence, severe floods occur, while during periods of drought, the minimum flow drops to about 200 cu. ft. per second. The



General View of the Lyons Development from the Downstream Side.



Map Showing Plants and Transmission Lines of the Commonwealth Power Co.

dam develops a head of 26 ft., and is built entirely of reinforced concrete, excepting a short embankment at both ends. In order to provide a passage for flood water, without materially raising the surface of the 1,775-acre pond, ten steel Tainter gates, each 20 ft. wide and 13 ft. high, are provided in a waste-gate section at one end of the dam. Five of these gates are on each side of a sluiceway opening, 60 ft. wide, in which a movable crest, or bear-trap dam of that width is operated. The arrangement and design of the Tainter gates are the same as for those of the Croton development. These gates are also raised and lowered by worm-geared, hand or motor-operated portable hoists of the same type as those used at Croton.

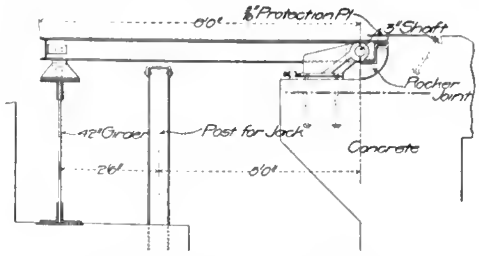
The details of the design and construction of the 60-ft. movable-crest dam in this waste-gate section are similar to those of the movable-crest dam at Croton. The Lyons dam has a movable leaf, 8 ft. wide and 60 ft. long, which turns on a shaft in a hinge along its upstream edge, thus permitting the downstream edge to be raised and lowered through a vertical travel of 5 ft. The leaf is counterbalanced by two 20,000-lb. weights, one of which is placed in a compartment in the dam beyond each end of the movable crest. The leaf is raised and lowered by two series of worm and spur gears, each driven by a 10-h.-p. motor and operating in connection with the counterweights.

A built-up steel girder, 42 in. high, extends the full length of the 8-ft. leaf, and is suspended from the front edge of the latter by hinged joints. These joints permit the girder to remain in a vertical plane at any position of the leaf, the verticality being maintained by a parallel-motion arrangement. When the leaf is at its lowest position with its upper surface horizontal, its weight and the load on it are carried by the girder, the latter resting on the bottom of the depression in which the movable crest is set. When the front edge of the leaf is raised to the full height of its travel, it is also carried by the girder, which is blocked up on jack screws set on steel posts projecting above the bottom of the depression under the crest.

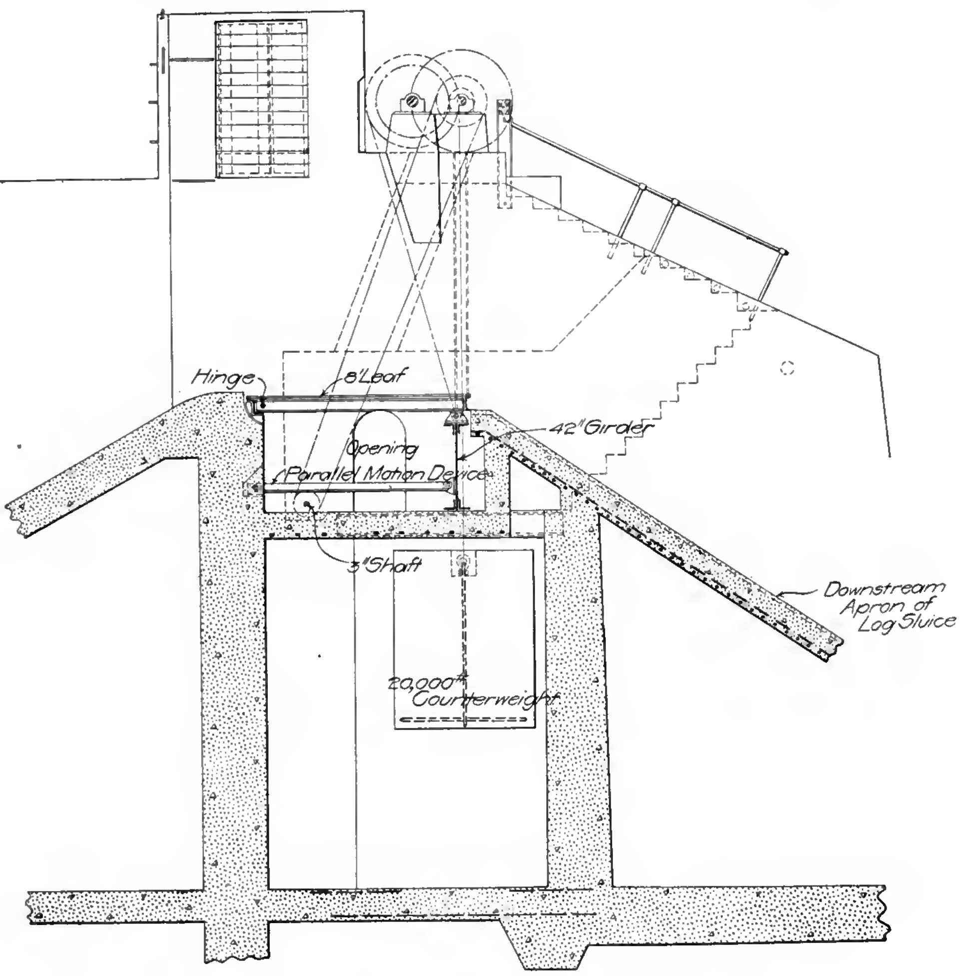
The 60-ft. opening controlled by the movable

crest is spanned by a two-leaf trunnion foot-bridge. Each of the leaves of this bridge can be turned sufficiently on a trunnion, on the guyed steel tower that carries it, so the 60-ft. opening is practically unobstructed when the two are open. The leaves are raised by cables on hand-operated worm winches.

Power House.—The power house adjoins one end of the waste-gate section and is L-shape in plan. The construction and arrangement of the Lyons power house is very much the same as in the case of the power house at Croton. The long axis of the power house proper is normal to the axis of the dam, with a row of four pen-



Detail of Movable Crest Dam.



General Arrangement of Movable Crest Dam at Lyons.

stocks forming the stem of the ell. It contains a single 3-phase 30-cycle 6,600-volt revolving-field 2,500-kw. General Electric generator, direct-connected to four pairs of 50-in. center-discharge Samson turbines in the penstocks by a shaft 138 ft. long, that is normal to the direction of flow through the dam. The whole arrangement of this equipment, including most of the details, is very similar to that of the equipment in the power house at Croton.

Construction of Lyons Development.—The construction of the dam at Lyons was started in March, 1906, and the equipment was placed in service in March, 1907. The foundation throughout is a hard clay at a depth of from 6 to 15 ft. below the surface of the river, so no piles or sheet piling was used under the dam, although some of the wing walls at the ends of the dam, and the dividing wall between the tail race and the waste-way channel from the Tainter gates are on piling.

Power for all of the construction plant used at the Lyons dam, except one steam shovel, was furnished by a 500-volt direct-current generator supplied with steam from a 200-h.-p. plant. Coal for this plant was hauled three miles from the cars by teams. The steam shovel was used in making the excavation required to provide a waste-way channel for the flood-gate section.

The material removed from this excavation was handled in 4-yd. dump cars which were hauled out of the pit on an incline leading through the dam by means of a motor-driven hoist. Motor-driven hoists were also used on the derricks. The concrete mixing plant at this dam was located at the land end of the waste-gate section,

Table 2. Cost of Placing Material in Embankment Section of Lyons Dam.

Labor and Coal Cost.	
Setting pumping plant, labor on house for same, placing pipe, etc.	$531.38
Labor at power house	577.20
Labor at pump house	486.60
Sluicing labor, building flumes and trestle	3,117.50
675 tons of coal	1,687.50
	$6,400.18

Earth moved from pit, 23,400 cu. yd., = $0.273 per cu. yd. for labor and coal.

Cost of Sluicing Plant at Lyons Dam.	
2 6-in. rotary fire pumps, new; 1 5-in. rotary fire pump, second-hand	$1,300.00
Pipe fittings, trough, etc.	1,200.00
Lumber and sundries	500.00
Total first cost	$3,000.00
Less salvage, on sale of plant	1,800.00
Cost to be charged to this work	$1,200.00

$1,200 divided by 23,400 = $0.0513, cost of plant per cubic yard of earth moved.

Labor cost per cubic yard of earth moved	$0.273
Plant cost per cubic yard of earth moved	$0.0513
Total cost per cubic yard of earth moved	$0.3243

Ran 45 24-hr. days, Dec. 5, 1906, to Feb. 20, 1907.

and was quite similar to the one used in constructing the dam at Croton; the methods for handling concrete from this plant to various parts of the work were also the same as used in building that dam.

The power house proper was built on the edge of the river channel, the waste-gate section extending across the flats to the low bluff of the river back of it; and the penstocks, 100 ft. out into the original channel of the river, on the other side. Beyond the penstocks an earth embankment, about 150 ft. long, extends to the high clay bluff that forms the river bank on that side. This embankment contains some 23,000 cu. yd. of material that was placed during December, 1906, and January, 1907, with a hydraulic sluicing plant.

Hydraulic Sluicing at Lyons Dam.—The operation of a hydraulic sluicing plant for making an embankment during the winter months in this climate was contemplated with much anxiety. As suitable filling material was difficult to obtain otherwise, without a long haul, and as the pumps required were on hand, the plant was set

A Close View of the Movable Crest Dam at Lyons.

up and started late in November, 1906. The bank of the river from which the material for the embankment was obtained is a clay bluff, about 70 ft. high, capped with about 10 ft. of sand and gravel. The clay was so tough and compact as to be very expensive to handle by ordinary sluicing means, so the fill was made almost entirely from the sand and gravel overlying it. As the bluff did not have a very steep slope, several expensive trestles were necessary to carry the flumes in which the material was handled from the face of the excavation to the fill. These trestles and the difficulties from ice made the cost of the fill much above that usual for such work, when more favorably situated and carried on in warmer weather. The sluicing plant was stopped when the temperature approached zero, with the result that when it was started again the face of the bluff, being saturated with water, had frozen to a depth of several feet meanwhile and had to be blasted. Even at the cost of 33 cents per cubic yard for the material moved out of the sluicing pit and deposited in the embankment under these most unfavorable conditions, as shown in Table 2, it is to be doubted whether any other method of moving material into the fill would have been less expensive. At any rate, the sluicing plant was certainly a valuable aid in making a fill so the river could be quickly closed, and also at times of flood during the two months it was in intermittent operation, in raising the cofferdams used in the construction of the penstocks.

The general offices of the Grand Rapids-Muskegon Power Co. are at Grand Rapids, Mich. Mr. W. G. Fargo is hydraulic engineer for the company and was supervising engineer during the construction of the Big Rapids and Croton developments. Mr. J. B. Foote is electrical engineer for the company and Mr. Anthony J. Bemis was manager during 1905 and 1906. Mr. J. B. Foote is general superintendent of the Commonwealth Power Co., which has its general offices at Jackson, Mich. Mr. W. G. Fargo was consulting hydraulic and supervising engineer to the company during the design and construction of the development at Lyons.

The Benguella Railway, Africa.

The Benguella Ry. is one of the most interesting undertakings of its sort now under construction in Africa. It starts from Lobito Bay in Portuguese Angola and follows the coast to Benguella, whence it runs inland to Katanga in Belgian Congo. The total length is about 800 miles; 50 miles are in operation, 200 miles under construction, and surveys and plans are completed for another 250 miles. Lobito Bay has an excellent harbor which is now being improved so that the large steamers of the Union Castle, Elder, Dempster and other lines can be accommodated. Katanga is the center of a remarkable mineral district. About 8,000 men are now employed on construction, and it is expected that 4,000 more will be engaged very soon. At one point on the line it is necessary to use a rack railway for about 1¼ miles, and there is some rocky country where heavy earthwork is necessary. These are about all the difficulties encountered except one very dry territory, where it has been found advisable to use camels for transport during construction. The work is being done by Griffiths & Co., with Sir Douglas Fox & Partners and Sir Charles Metcalfe as consulting engineers.

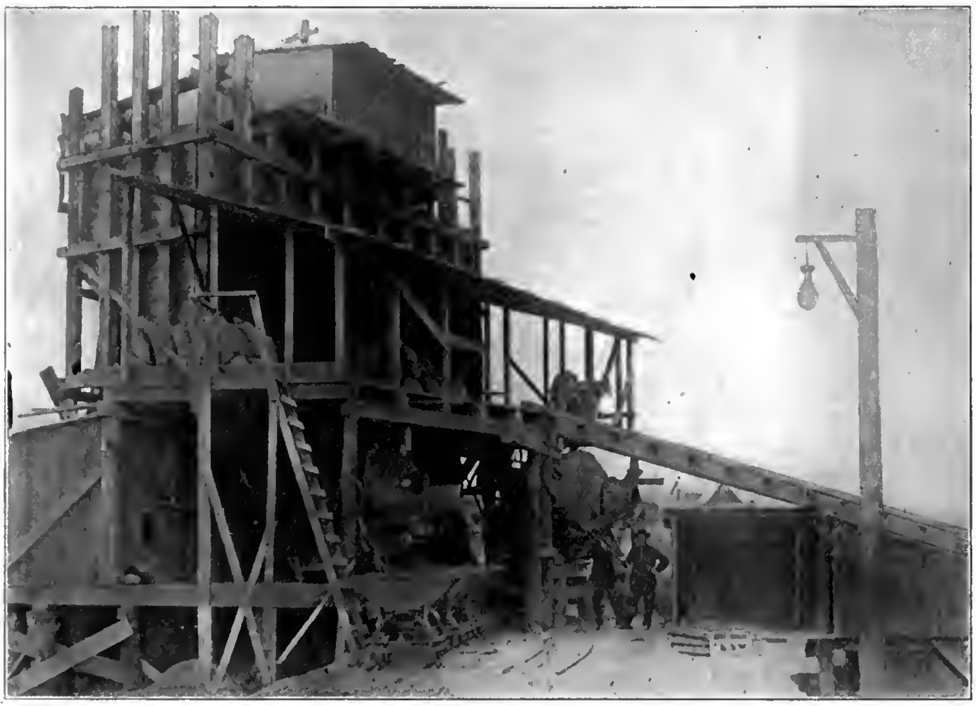
The Total Production of Coal throughout the world in 1906 has been estimated at 1,106,479,000 short tons, of which the United States produced 414,157,000 tons. In 1906 the United States produced 43.7 per cent. more coal than Great Britain and 85 per cent. more than Germany.

Heating and Ventilating the Commercial National Bank Building, Chicago—Part I.

The new Commercial National Bank building is an eighteen-story steel frame office building that has recently been completed on the northeast corner of Adams and Clark Sts., Chicago, Ill., fronting 181 ft. on Adams St., and 190 ft. on Clark St. It is a structure of large size, with a basement and sub-basement and rises 300 ft. above the level of the sidewalk. Its exterior has been treated in granite and terra cotta throughout, while the interior is elegantly finished in mahogany and white marble. The structure is supported on caisson foundations, of which there are 82, ranging from 6 ft. in diameter to 10½ ft., that extend down about 110 ft. to bed rock. The greater part of the second and third stories and the basement are devoted to the needs of the Commercial National Bank, while the upper floors from the fourth to the eighteenth inclusive, are devoted to rented offices. A feature of the interior arrangement is the concentration of all the toilet rooms for the rented office floors, together with a barber shop and a ladies' retiring room, on the eleventh floor. The building has a floor space on each of its three lower floors of over 32,000 sq. ft., and on each of the upper floors of about 25,000 sq. ft., owing to a light and ventilation court rising from the third floor level to the top, which makes a total floor area of over 470,000 sq. ft., exclusive of the basement and sub-basement.

The extensive mechanical plant required for the operation of the building service is housed in the sub-basement and a portion of the basement, the greater part of the former and nearly half of the latter floor being thus utilized. The sub-surface floors have additional space excavated underneath the sidewalk areas, the basement 190 x 195 ft. in size, having a total floor area of over 37,000 sq. ft., while the sub-basement, which was excavated only to within about 60 ft. of the easterly wall, owing to difficulties encountered with the foundations of the Marquette Building adjoining, has a floor area of nearly 27,000 sq. ft. Each of these floors has a ceiling head-room of only about 13 ft., on account of which the boiler room, 72 x 98 ft. in size, in the northwest corner on the Clark St. side, and the engine room, 58 x 85 ft. in size, adjoining at the rear, were carried up from the sub-basement through the basement floor level in order to secure the needed additional head-room to accommodate overhead piping and to facilitate the handling of the machinery. The remaining portions of the sub-basement are devoted to the hydraulic elevator equipment, ventilating apparatus, other auxiliary machinery, a machine shop and storeroom and locker rooms for the employees of the building, while on the basement level there is, in addition to the boiler and engine room, considerable additional ventilating equipment.

The power plant of the building has been installed with a complete equipment for all classes of service, embracing 4 boilers, aggregating 1,400 h.-p. in capacity, for steam generation; an electrical generating equipment of 650 kw. capacity, an extensive hydraulic elevator plant, refrigerating machinery and pumps. The exhaust steam from the plant is utilized for the heating of the building. The boilers are of the Sederholm type of fire-tube boilers, built by Chalmers & Williams, and are installed in four 350-h.-p. units, arranged in separate settings on the east side of the boiler-room with space reserved for an additional future unit to be installed at the south end if required. The boiler units are brick set, the settings being covered with vitrified asbestos, and each is equipped with a Greene chain grate stoker. The arrangement of units is such that there is a 10 to 12-ft. space at the rear of the settings for blow-off piping, steam mains and smoke breechings, a 16-ft. firing floor in front of the stokers and 7½-ft. spaces between settings as necessitated by the arrangement of building columns. The front portion of the boiler-room is occupied to a width of 16 ft. by a coal storage bunker, 88 ft. in length, which has a capacity of over 700 tons of coal. Arrangement has been made for delivering coal to the plant by way of the Chicago freight subway lines, a branch of which has been constructed from Clark St., underneath the boiler-room; from cars on the subway line the coal is dumped into a receiving hopper from which a bucket traveling conveyor, built by the Link Belt Machine Co., Chicago, elevates the coal to the storage bunker. The coal is also mechanically handled from the bunker to the stoker hoppers by means of screw conveyors which transfer it into small circular hoppers above the stokers, fitted with adjustable spouts. The ashes are dumped from the furnaces into a pit below the boilers which has connection with a tunnel leading to the branch track from the subway line, through which the ashes are delivered by special ash cars to cars of the tun-



Concrete Plant at Hydro-Electric Development at Lyons, Mich.

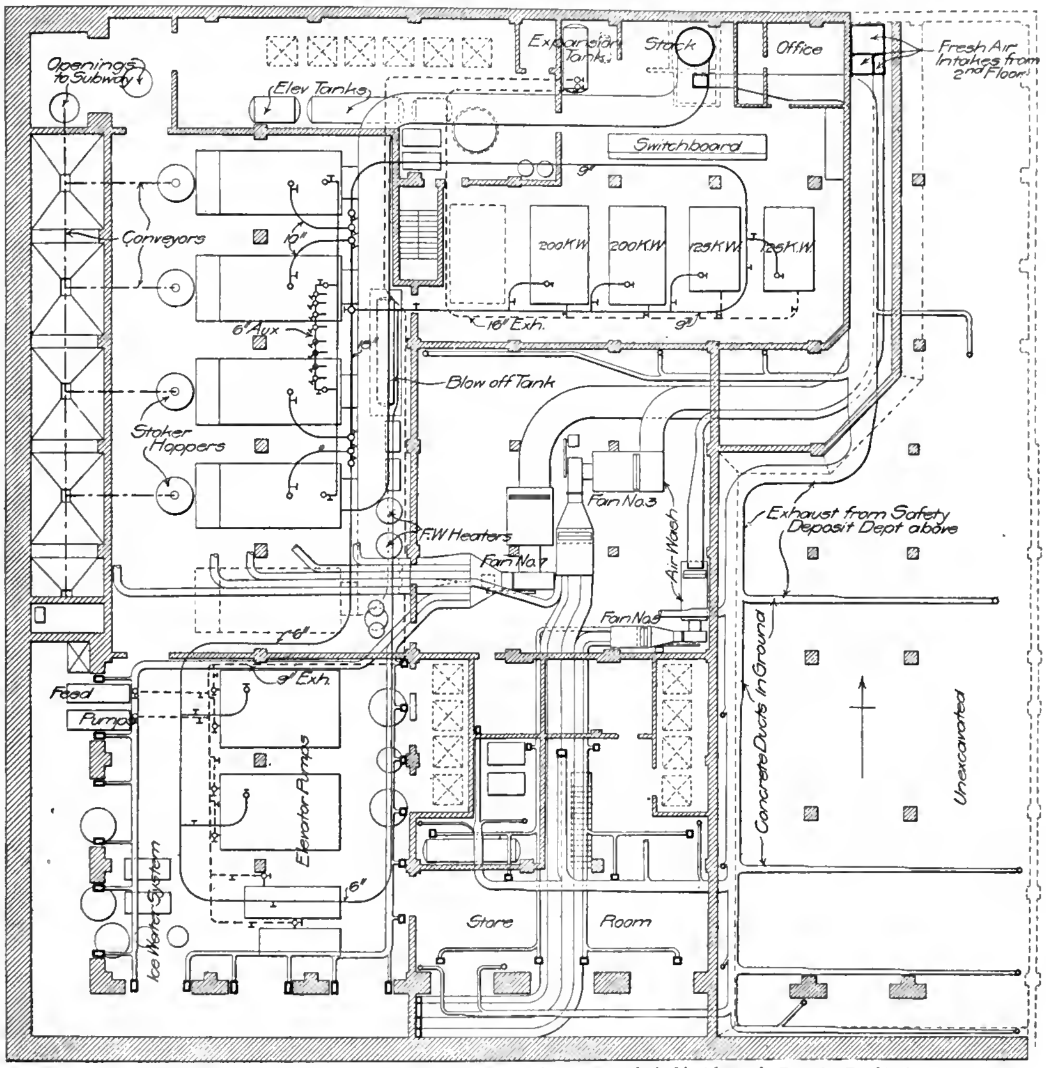
nel line for removal. The products of combustion are removed from the boilers by a steel stack, 90 in. in diameter, that rises to the roof, a height of 350 ft. above the grates. Connection is made from the settings to the stack through a rectangular iron breeching carried on the ceiling at the rear of the boilers and both the breeching and the stack are lined throughout, the stack with a 2-in. lining of vitrified asbestos, supplied by the Chicago Fireproof Covering Co.

As the exhaust from the steam using machinery of the power plant is used largely for the heating of the building, the feed water supply is principally of condensation return from the heating system, with make-up from the city water mains as required. The condensation return lines from the heating apparatus and low pressure apparatus connect at the rear of the boiler-room into an 8-in. valved header, which in turn makes connection to each of the two open feed-water heaters which are provided for preheating of the boiler feed before delivery to the boilers. These heaters are Webster Star vacuum heaters and purifiers, each having a capacity of filtering and heating 30,000 lb. of water per hour from 45° to 210° Fahr. These heaters have connections to the 12-in. exhaust main extending over them from the pumproom to the expansion tank at the rear of the engine-room. The boilers are fed by an equipment of two Worthington duplex pumps of the outside center packed plunger type, which are brass fitted throughout for the handling of hot water, and each is designed for a capacity of 30,000 lb. of water per hour with a piston speed of not over 25 ft. per minute, so that each pump is capable of feeding the entire boiler equipment under normal conditions of service. They are located at the north end of the pumproom and have connection to suction and delivery lines in duplicate, the mains being so valved that one pump may deliver from the feed-water heaters to one or more boilers, and the other from the surge tank to the other boilers, or in any other combination desired. One of the feed mains, known as the hot-water feed line, is fitted with a Worthington meter by means of which the feed delivery to the boilers is measured. The blow-off system of the plant consists of a 4-in. blow-off header at the rear of the settings with 3-in. connections to the mud drums of each boiler unit and a 6-in. delivery connection into a large blow-off tank in a pit at the rear of the settings; this blow-off tank is a cylindrical steel tank 3 ft. in diameter by 13 ft. long, and has a 6-in. overflow to the sewer, so located as to maintain in the tank sufficient water for partially cooling the blow-off discharge as received. The vapor from the hot discharge is removed by an 8-in. vapor line which is carried up above the roof through a pipe shaft alongside of the smoke stack and terminates with an exhaust head.

The piping systems of the plant consist of a ring or loop header for the high pressure steam and two large single exhaust lines for the low pressure exhaust. The high pressure ring main originates in an 18-in. header located 9 ft. above the floor, at the rear of the boiler settings, with 8-in. long-radius pipe bend branches to each boiler unit, valved at both header and boiler nozzles; delivery connections extend up and into the engine-room as a 9-in. loop main and into the pumproom as a 6-in. loop main, the ends of these two loops meeting at the rear of the boiler-room and there being connected to the middle of the high-pressure header by a 9-in. cross connection. The main header is of mild steel with flanged joints and copper gaskets and is designed for 300 lb. test pressure. The loop main is sectionalized by globe valves at the middle and gate valves at either end of the 18-in. main header, and by globe valves so placed in the engine and pumproom loops as to enable all the more important steam-using apparatus to be supplied from either of two different directions, through independent connections from the header. The entire high-pressure line is dripped by a gravity return drip line which parallels the mains and delivers to the boilers through a connection at the rear of the settings. Steam for the auxiliary machinery, including pumps, etc., is supplied from a 6-in. auxiliary header over the boilers that is distinct from the main high-pressure header, being connected to the boilers through the safety valve nozzles; from this header branches extend to the feed pumps, to the hot water heaters for house service, to the vacuum pumps, to the stoker engines, and to the roof for melting ice which may form in the down spouts during the winter, and a 6-in. line to the expansion tank for live steam make-up to the heating system when the exhaust steam supply is insufficient. The exhaust steam system consists of a 16-in. ceiling line in the engine-room and 12-in. line from the pumproom which connect with the steam using units and deliver each independently to the expansion tank at the rear of the engine room, which forms the basis of the low-pressure steam supply to the heating system. Thomas Acme grease extractors in these exhaust lines near the tank remove oil from the exhaust steam.

The steam-using machinery of the power plant consists principally of electrical generating units and the elevator pumps, all of the ventilating fans, the air compressors, the refrigerating machines and other auxiliary apparatus being driven by motors. There are four electrical generating units installed, consisting of vertical compound engines direct connected to Western Electric Co. multipolar generators, two of which units are of 125-kw. capacity, and the other two of 200-kw. capacity, while additional room has been reserved for the addition of another 200-kw. unit if future demands for power should require. The engines are of the vertical cross-compound automatic cut-off type, built by the Bates Machine Co., and are supplied with steam by 5-in. and 6-in. branches respectively, with Cochrane separators, from the 9-in. overhead loop in the engine room, exhausting through 8 and 10-in. branches into the 16-in. overhead exhaust line. The elevator plant of the building embraces 14 passenger and one freight elevator, which are hydraulically operated and require two compound high-duty pumps, which normally take care of the full elevator load, a compound duplex pump of capacity equal to either of the high-duty pumps for reserve purposes and a night pump of half this capacity. The high-duty pumps are Chalmers & Williams cross-compound duplex pumps with Corliss steam valve gear and have 15 and 25x7⅞x24-in. cylinders. There is in addition a jack pump installed for operation in connection with the freight elevator in lifting safes, and machinery, and heavy loads.

Heating System.—The building is heated throughout, above the first floor, by direct radiation, for which a total of 51,463 sq. ft. of direct radiation has been installed, exclusive of the tempering coils of the fresh air supply systems, the fresh air supply being raised to the temperature of the interior of the building before delivery. The radiators, supplied by the American Radiator Co., are installed in the usual locations under window sills, a standard arrangement having been adopted embracing two units to each wall panel of three windows, which is found to most easily accommodate the sub-divisions of floors into various office groups. The standard distribution is one 48 sq. ft. and one 24 to 30 sq. ft. radiator to each panel of three windows, the larger radiator being installed where partitions come so as to limit one unit to two windows, and the smaller unit where only a single



Power Plant in Sub-Basement of the Commercial National Bank Building.

window is served. The radiators are installed in general in 26-in., 2-column units, excepting in the first, second and third stories, where 32 and 38-in. 2-column radiators are used, and in the main entrances, where 44-in. 4-column units are installed. Sky-light exposure is encountered to a considerable extent only above the main banking floor, where at the fourth floor level, a 58x92-ft. skylight fills the area at the base of the light and ventilation court between the two upper wings of the building; this glass exposure is counteracted by 28 pipe coils of 1¼-in. pipe, each coil containing 50 sq. ft. of surface. Radiation in all parts of the building is proportioned to maintain temperature to 70° Fahr. when the outside temperature is 10° below zero, for which an average of 2,450 sq. ft. of radiation has been installed on each of the floors above the first. The first floor contains 3,196 sq. ft. of radiation, including that in the entrances, while the skylight coils have 1,400 sq. ft.

Steam is supplied on the one-pipe system to all of the radiation above the first floor by an overhead distribution system, which consists of mains in the attic and down supply risers, while the radiation on the first floor is supplied independently by a system of distributing mains on the basement ceiling. The low pressure heating supply originates as above stated, in the expansion tank into which all exhaust steam from the power plant is delivered. From this a 6-in. connection extends to the basement distribution system for supply to the first floor radiation and a 16-in. supply main to the attic to supply the overhead distribution system. The latter supply main is carried up a pipe shaft alongside of the smoke stack enclosure at the rear wall of the building to the attic space above the eighteenth story, and there connects through an expansion loop to a system of horizontal distribution mains, which divides into a number of branches of 6 and 8-in. mains that supply different groups of risers along the various side walls of the building. The 6-in. basement supply main supplies radiation on the first floor only, tapering to 5 in. and thence to 3 in. in size as branches are taken off. Other steam supply connections from the expansion tank consist of a 5-in. line to the skylight coils above the main banking floor, an 8-in. line to the tempering coils of the fresh air supply systems, and a 7-in. connection to the hot water heaters of the plumbing service. The exhaust steam supply to the expansion tank from the steam-using machinery is supplemented by a 6-in. connection from the auxiliary high pressure steam header in the boiler room with two Davis pressure reducing valves. One of the valves adjacent to the high-pressure header, reduces the pressure of the live steam supply from the boiler pressure of 150 lb. to 15 lb. and the other next to the expansion tank reduces from 15 lb. to atmospheric to augment the low pressure supply automatically in case of deficiency of the exhaust steam. A feature of the low-pressure piping connections is to be noted in the use of a separate 16-in. riser to the top of the building for purposes of atmospheric relief to the exhaust steam system in case of back pressure, instead of utilizing the main 16-in. supply riser to the overhead heat distributing mains; the back pressure valve is here located at the expansion tank, from which the atmospheric relief riser is carried up above the roof through the pipe shaft alongside of the 16-in. steam supply riser and terminates with an exhaust head.

The down-feed risers supplying radiation on the upper floors are 80 in number, the greater part of which are 2½ in. in size, and supply from 440 to 700 sq. ft. of radiation each, the average amount supplied from each 2½-in. line being about 500 sq. ft. There are 62 of the 2½-in. risers, while of the remainder two are 4-in. lines, seven are 3-in. lines, and nine 2-in. lines; these all decrease in size toward the lower floors as radiator supply branches are taken off, the greater part of them being carried down to the basement as 2-in. lines, with the exception of the 2-in. risers, which decrease to 1½ in. at the base. The 4-in. and 3-in. risers occur principally in the corners of the building and exposed locations and carry 750 to 1,240 sq. ft. of radiation each, the average amount carried per 3-in. riser being about 850 sq. ft.; the 2-in. risers are used behind the elevators on the Clark St. side and in certain locations on the upper floors, and carry on an average about 300 sq. ft. each. Owing to the length of the risers, approximately 270 ft., they are all erected in four sections with anchorages to the building structural work at midpoints of each section and expansion loops or joints midway between anchorages; the expansion joints or loops occur at the fourth, tenth and sixteenth floors in each riser, while the anchor points for the sections thus formed occur at the second, seventh, thirteenth and attic floor levels. Wherever possible the loop type of expansion joints was provided for, but in a group of five 2-in. risers at the rear of the shafts of the six elevators rising from the Clark St. entrance, lack of space necessitated the packed sleeve type of slip expansion joints. As the radiation is operated on the one-pipe system, all radiator branch connections are given a uniform slope from the radiator to the riser against the flow of steam and are so located that they cannot be trapped by movement of the riser in expansion; these radiator branches are of 1¼-in. pipe for radiators up to 50 sq. ft., 1½-in. pipe for units having between 50 and 85 sq ft., while 2-in. pipe is used to supply all units up to 120 sq. ft. All of the low-pressure piping and risers are covered with H. W. Johns-Manville moulded asbestos sectional covering, ¾ in. in thickness, the covering extending on all risers from cups provided to support it up inside of the floor sleeves above; all exposed risers are covered with air-cell covering.

Condensation returned from the radiation is collected by two systems of gathering mains on the ceiling of the basement, one of which connects with the bases of the down-feed risers, and the other with the steam supply mains in the basement to supply the first floor radiation. The former is installed in three divisions, each consisting of a 6-in. line connecting with risers in different sections of the building, while the latter is laid out in two sections, one a 3-in. line extending to the front part of the building, and the other a 1½-in. line to the rear. Other condensation return connections consist of a 4-in. return line from the tempering coils of the fresh air supply fan systems, a 3-in. return from the skylight coils, and a 1-in. return from the downspout heads to which high pressure is supplied at the roof. These returns all connect into the 8-in. condensation header in the boiler room, which has a 4-in. connection from either end to the two open feed water heaters. All of the return lines have check valves near the header and between these and the header, gate valves. To insure positive circulation of steam in the heat distribution mains the Paul vacuum system has been installed, consisting of a system of air piping, connecting with the air valves on all radiator units and terminating in the boiler room where connection is made to the usual exhauster apparatus used with this system. The air piping system has been extensively sub-divided so that the shutting down of a portion of the apparatus will not interfere with the successful operation of the remainder, and connections are also made from this system to the feed water heaters and hot water heater to prevent air binding in them. The heaters are also arranged for operating in summer time when the heating equipment is not in use.

The mechanical plant was designed by the architects of the building, D. H. Burnham & Co., of Chicago, under the direction of Mr. John D. Small, chief mechanical engineer. Thomas & Smith, Chicago, were contractors for the heating system and power plant piping, and designed the details.

(To be continued.)

The Soft-Coal Producer Plant at Pasco, Wash.

The town of Pasco is a division point on the Northern Pacific Ry., and is located near its crossing of the Columbia River. At present there are about 1,000 inhabitants, one-half of whom have located there during the last eighteen months. The Pasco Light & Water Company, composed chiefly of Spokane men, has installed a gas producer plant to furnish to the town both water and light and some small quantities of power.

The water obtained from wells in this region is markedly alkaline, and is undesirable for use in steam boilers. The Light & Water Company pumps its water from the Columbia River and delivers it to the town and to the tanks of the railway company. The question of track convenience and franchise stipulations made it necessary to place the power house near the railway yards, close to the town. On the other hand the pumping station is located as near the river as high-water conditions permit.

The power house is a frame structure boarded up with rustic finish on the exterior; the engine and dynamo room is ceiled to protect the running parts as much possible from the fine sand and grit which is carried by the winds in the dry season.

As shown in the plan, the power house is compactly arranged. The producer is of the suction type, built by the Smith Gas Power Company especially for bituminous and lignite coal. A sawdust purifier is added as an extra precaution to prevent carrying over tar to the engine. This is a Rathbun three-cylinder vertical type gas engine of 100 h. p. capacity. It is belted to the generator, a General Electric 75 kw. three-phase alternator, operating at 2080 to 2300 volts and 60 cycles per second. The exciter has a capacity of 3.5 k. w. and is belted to the generator.

The switchboard consists of two standard panels of the General Electric design. One is the generator panel equipped with three alternating current ammeters, one alternating-current voltmeter with potential transformers, receptacles and plugs, a direct-current field ammeter and switch, exciter rheostat and control for the generator rheostat and oil switch. The other is a two-circuit feeder panel equipped with one ammeter and an oil switch for each circuit. One side of this panel controls the lighting circuit, which is three-phase three-wire primary and single-phase three-wire secondary, 115 volts. The other side controls the pump circuit, three phase 2080 volts.

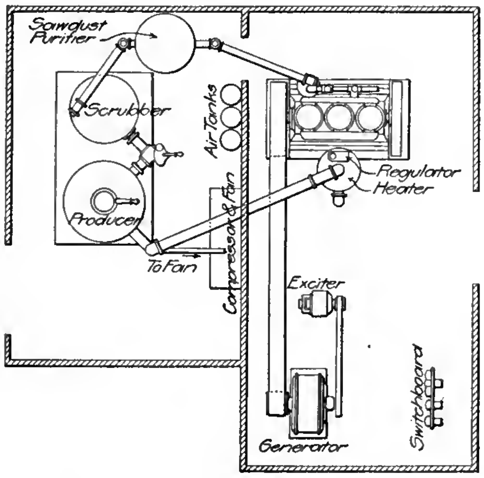
The pump house is situated on the river about 7,400 ft. from the powerhouse. A 40 h.p. three-phase induction motor directly on the line at 2,080 volts operates the pump. The line consists of three No. 8 B. & S. hard-drawn bare copper wires spaces 14 in. between centers. The pump is a submerged triplex with a capacity of 400 gal. per minute. It is mounted as shown in the illustration at the bottom of a concrete well and the motor operates the working head above by means of a belt.

A test was made of the plant immediately after its installation. The proper load was put upon the generator by means of a water rheostat to give the engine its full rated load. For a portion of the time the plant was operated at part load only, running the pump to fill the pipes. This load varied from 22.1 to 29.5 h.p. as the head in the pipes increased. The test lasted seven hours and showed the consumption of 696 lb. of coal

for 512.9 h.-p.-hr., or 1.35 lb. of coal per h.-p.-hr. The local cost of coal brings the fuel cost per h.-p.-hr. to about 0.3 cent. The coal used was a washed lignite nut coal and contained considerable earth and clay.

Book Notes.

The British Fire-Prevention Committee, 1 Waterloo Place, London, has issued a "red book" describing tests of a hydrant fitted with an "adaptor" for automatically putting the hydrant into action. The "adaptor" is described as a device whereby any fire hydrant, cock or tap may be made automatic in action, enabling an operator, by simply grasping the hose attached to the device and running with it to the scene of a fire, to have at hand a supply of water without the necessity of unscrewing the valve in the ordinary manner. The construction of this device, which is made by W. Featherstone & Co., Rochester, England, is illustrated in the report. The "adaptors" tested were fitted to 1-in. and 2½-in. hydrant valves, the water supplied for the smaller hydrants being under a pressure of 8 to 25 lb.



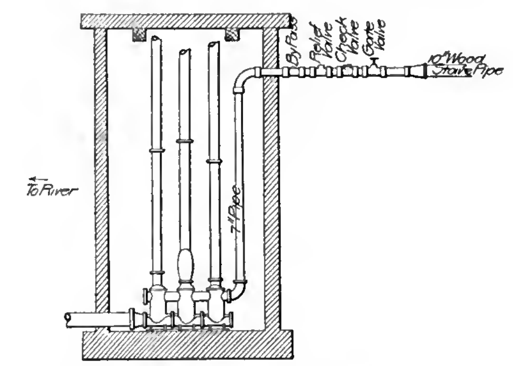
Plan of Producer Plant at Pasco.

per square inch, that for the larger valves varying from 40 to 45 lb. Seventeen tests were made in all, which are fully described in the report.

The excellent manual on "Stereotomy" by Profs. A. W. French and H. C. Ives has been so successful that a new edition has been prepared, in which the typographical errors of the first edition have been corrected and a number of changes made. The book is one of those practical manuals equally useful in the classroom and the engineering office. The authors state that they have drawn their material from previous books, but they deserve credit for making such good use of it and for the well-selected examples of actual structures that are used for illustrating the principles and methods explained in the text. The book is essentially a description of the procedure to be followed in designing the stone work of all kinds of engineering and architectural structures, and the instructions for preparing templates and drawings are thoroughly practical. (New York, John Wiley & Sons, $2.50.)

An excellent book on the most important machine tool and its uses is "Modern American Lathe Practice," by Oscar E. Perrigo. It gives an outline of the evolution of the tool, describes its use for various classes of work, and illustrates the different types of lathes used in American shops. A gratifying feature of the volume is the absence of catalogue pictures, for every illustration was made specially for the book. There are five chapters on lathe design, two on lathe work, two on engine lathes, and others on lathe attachments, rapid change-gear mechanisms, lathe tools, tests, heavy lathes, high-speed lathes, special lathes, regular turret lathes, special turret lathes, and electricall driven lathes. The book is a comprehensive treatise of reliable character and will be found of value by all who are interested in its subject. (New York, Norman W. Henley Publishing Co., $2.50.)

While a large amount of information is available concerning the engineering features of heavy electric traction on railways previously using steam locomotives, such installations are so recent that practically nothing has been published concerning the operation of these lines. Accordingly the 190-page book on the subject forming a section of the "Street Railway Journal" of Oct. 12 is a unique volume. A careful study was made of the methods used on the New York Central & Hudson River R. R., the Long Island R. R., the West Jersey & Seashore R. R., the West Shore R. R., the New York, New Haven & Hartford R R., the Erie R. R., and the Interborough Rapid Transit Co., and Mr. Philip Dawson contributed an article on what has been done in England and on the Continent. This information will be of great value not only to the officials of steam railways who are contemplating electric traction, but also to the managers of electric traction companies The latter have worked



Concrete Pump Well of Pasco Plant.

out their problems along certain lines, but as the high-speed electric road is the outgrowth of the city line it is not surprising that the conclusions reached by their officials differ from those obtained when the same questions are taken up from the steam railway standpoint and when the electric railway is operated as part of a large trunk line. The book is beautifully printed and profusely illustrated, and is an unusually important contribution to the publications on heavy electric traction. (New York, Street Railway Journal.)

Some day a great novelist will awake to the possibilities of irrigation as the central theme for a powerful story, and people will be amazed to learn from him what a tremendous influence it plays in every-day life in some sections. The facts are all at hand for him, in the dry statistics of government reports, in the laboriously deciphered hieroglyphics of the Pharaohs showing that upon it depended the glory of their dynasties, in the translations of Hammurabi's cuneiform inscriptions proving that it was perennial irrigation which made ancient Chaldea a great nation, and in the writings of Sir William Willcocks and others who have not only taken part in the great national irrigation works of to-day, but have studied those of the ancient nations. It is a fascinating study as a factor in civilization, wholly apart from those technical features that appeal only to the engineer, and it is noticeable that engineers who have played an important part in great irrigation undertakings, in their books on the subject generally introduce unknowingly a certain flavor of special interest on account of the intimate relation between works and striking results that marks such enterprises. The great Chenab canal in India, for example, has turned some two million acres of waste land in India, on which a very small nomadic population existed precariously, into the bountiful home for a million people. This special feature of books on irrigation is marked in Sir Hanbury Brown's "Irrigation; Its Principles and Practice as a Branch of Engineering." The author's long service in such works in India and Egypt enables him to speak as one having authority and not as the scribes. In setting forth the subject he has drawn on this knowledge, particularly that gained in Egypt, for illustrations and examples, and the result is a book of deep interest, particularly at this time, when irrigation in the United States is at last beginning to receive due recognition. To engineers, the great merit of the book lies in the fact that it is on irrigation, and the design of high dams, and other works of a special character is left to treatises on such subjects. It opens with a chapter on what irrigation has done and is doing in many countries, and the subject is handled in a way that arouses regret that this part of the book was not published in some magazine of wide circulation, for the information of the general reader. The essential features of basin and perennial irrigation are pointed out in two chapters, and there are some notes on the "duty" of water, introduced at this place in order that this important feature of irrigation work may be understood at the outset. The author uses the term to indicate the amount of irrigation water ought to accomplish and not what it actually does in any case, thus giving the word a more restricted significance than it usually has in the United States. The fourth chapter, on sources of supply whence water may be obtained, contains some interesting notes on India's irrigation methods and the extent to which it is possible to extend irrigation in Egypt, given to illustrate the general principles laid down. A chapter on dams and reservoirs is introduced next, in which the author deals mainly with the purposes of such works and their general features. It is followed by one on weirs and barrages, containing a large amount of interesting information concerning works of this nature in India and Egypt. In building many of these works unusual conditions were encountered and a chapter on methods of construction is given for the purpose of bringing together in one place all notes on the subject; these relate mainly to foundations, and the account of the methods on constructing dams and weirs on gravel, clay and sand foundations deserves special attention. The chapter on canals and drains is particularly interesting for the emphasis laid by the author on the importance of providing means for draining the irrigated land as well as for bringing water to it. An omission to make any reference to methods of lining canals to prevent seepage seems rather surprising to an American reader on account of the special interest shown in the subject in the United States at the present time. The various masonry works along the line of irrigation canals are described in a chapter explaining the purpose of regulating works, fall, syphons and aqueducts, illustrations of notable structures being given. The methods of distributing water, assessing the charges for it, and of administration in various countries are explained in one of the most instructive chapters in the book, and it is interesting to learn from it how universal has been the experience that some measure of public control over water for irrigation is necessary. Two chapters are devoted to flood banks, river training and navigation, and there is a particularly good chapter on agricultural operations and reclamation works. The book as a whole is particularly timely for American readers and should prove of much value to those who desire a general knowledge of irrigation. (New York, D. Van Nostrand Co., $5.00.)

Letters to the Editor.

MISUSE OF DERRICK CARS.

SIR: An accident that took place about a fortnight ago during the erection of a bridge on the Nickel Plate road over the Cuyahoga River again calls attention to a grave misuse of derrick cars often made. In this particular case a 50-ton car was being used to lift a pedestal weighing about 10 tons. It was raised and then the boom of the derrick swung around to the side. As it swung, the car tipped slowly but steadily to such a degree that those nearby were alarmed and shouted to the men on the car to turn the boom back again. They continued to revolve it, however, and suddenly the car was overturned off the deck span on which it was standing, and the men were killed in its fall.

It would hardly be worth while calling attention to this accident were it not for the fact that bridge erectors are constantly taking chances of this sort. A few months ago an unusually powerful derrick car was built for handling very large girders. It was a special machine and the designer naturally watched its operation during the first few days it was in service. Although he had perfect confidence in the car, the manner in which it was employed in lifting high loads at right angles to the track on which it stood filled him with serious apprehension, and as a result he warned the owners of the car in writing against attempting any such feat. Even when a derrick car is supported by jacks under the outstanding arms on either side, its base is so narrow that a heavy load lifted far out on either side is likely to overturn it. No trouble is experienced in lifting such loads ahead of the car on account of the long wheel base, and the freedom from trouble when the boom is in such a position is likely to cause an unwarranted feeling of safety in the ability of the car to stand up when lifting heavy loads at the side of the track. I think it would be well for your journal to call attention to this dangerous condition.

Very truly yours,

ERECTOR.

CONDITIONS ON THE ISTHMUS OF PANAMA.

SIR: Your little note in your issue of last week concerning the conditions at the Isthmus of Panama is interesting to me, for it shows that the official reports contained in the "Canal Record" are appreciated in your office. Fortunately the grumblers at the Isthmus have now been largely returned to the United States, whence they never should have gone to take part in canal work. It is a fact that the conditions on the Isthmus are by no means those to which a number of the younger engineers and other employees were accustomed. They went to the Isthmus evidently expecting it to be a sort of glorified picnic ground. They were disappointed and in some cases their families were put to much inconvenience. These people have all very naturally expressed their adverse opinions of the conditions. On the other hand those of us who have been accustomed to work in the field in different parts of the United States have almost without exception been satisfied with the manner in which the government is endeavoring to make us comfortable. The line of the ditch is a good ways from home and it takes money and men to build houses and carry on large camps. It also takes time, and inability to appreciate the importance of this last factor is the primary cause of most of the complaints that were formerly current concerning the canal work.

Where new work is being started it goes without saying that the accommodations for some of the men are naturally cramped. This is so on every large piece of construction with which I was ever acquainted. I have been forced to sleep under shacks many times while camps were being constructed, and accordingly the temporary accommodations provided on the Isthmus on new work did not seem at all out of the ordinary, except as they were somewhat better than those that are usually provided in the States. Nevertheless, some young men, whose experience on construction had been obtained wholly in connection with municipal work, considered themselves terribly abused by being obliged to sleep in cramped quarters for a few weeks. I noticed that it did little good to endeavor to explain to them that the conditions were only what they would encounter in the United States under similar conditions, for out of their experience in the vicinity of cities where plenty of quarters was always available, they have proceeded to criticise everything that has been done for their comfort in a very silly manner.

In the camps that have been established for some time, the accommodations have been far better than those provided by the average contractor, while the attention paid to sanitation is really remarkable. The medical supervision of all the men leaves nothing to be desired, and any engineer who wishes to become familiar with construction under tropical conditions and is not afraid to live away from the bright glare of the electric lights along Broadway cannot do better than to join our force. We have plenty of opportunities for recreation, and various amusements are being arranged as opportunity arises. In fact, from all I can learn, the only organization which at all compares with our own in the general attempt to get together in the most sociable way is that of the Board of Water Supply of the City of New York. Our organization is a good deal larger than that, and naturally there are more grumblers in it. I doubt if you ever saw an organization of 250 people in which there was not more or less jealousy, and a few of the class which is never happy without grumbling. Our staff is so big that we have a good many of these people; we are accustomed to them and pay no attention to them, for we know that they are not happy without grumbling, and many of them are otherwise good fellows and work hard. But the kicks they make are apparently misunderstood among the people at home, and it is for this reason I am sending you these few comments.

Very truly yours,

ON LEAVE.

IMPERMEABLE CONCRETE.

SIR: Your editorial discussion on impermeable concrete in the issue of Oct. 19 is interesting to the writer on account of the strong intimation it gives regarding the usefulness of a certain amount of clay in concrete mixtures. This is a subject that has been debated so much of late that until really accurate experimental work is carried on, such as that which Mr. Gaines is evidently conducting, the view that any engineer will take of it is likely to be based on his personal predilections and limited observations, rather than on any careful sifting of all evidence. It will doubtless be recalled by many who had an opportunity to hear the discussion of the subject at the Asheville convention of the American Society of Civil Engineers that the use of alum and other substances has been adopted successfully to render concrete watertight, while some engineers have long claimed that a moderate amount of clay was of value for the same purpose. There is, of course, a great difference in the qualities of clays and consequently statements regarding this material have to be accepted with a mental reservation in each case that the term covers such a wide variety of substances that the information is of only very general value.

I do not recall that any experiments prior to those of Mr. Gaines have been made to ascertain the effect of a combination of alum or some other similar substance and clay with the regular concrete materials. In fact it may be questioned whether the experiments on which Mr. Gaines has based his statements in the "Transactions" of the American Society of Civil Engineers have been carried far enough, and my own belief is that it is very desirable in investigations of this nature to defer the drawing of any precise deductions from such results until the experiments have included many series of tests which vary between themselves by a modification of only one or two factors, so that the effect of changes in those factors can be fully determined. It seems to be true, however, that the use of alum and clay under certain conditions may yield a very watertight concrete, and there are other substances for which similar claims can be made. Hence I would suggest that it might be advisable for you to discuss the extent to which impermeable concrete of this character can be safely applied. We can all agree with your statements that waterproof concrete is highly desirable material for engineering purposes, but it seems to me that in any discussion of this nature it is very desirable to bear in mind that waterproof concrete is, after all, concrete, and must be regarded like any other artificial stone.

The investigations that are being made by Mr. Gaines are evidently conducted with a view to ascertaining, among other things, the availability of various substances to render concrete in long aqueducts impermeable. Aqueducts are generally sufficiently covered by earth or otherwise protected against the weather to be free from any material changes in temperature. The problem presented by concrete under such conditions is very different from that presented by a long retaining wall holding back a bank of earth or loose rock likely to be fully saturated with water during a considerable portion of the year. In the former case there is no tendency to crack, while in the latter there is every tendency for cracking to occur. In the former case water is likely to cause trouble only by percolating through interstices of the concrete. In the latter case the temperature changes are likely to cause fissures into which considerable quantities of water may enter and there freeze, causing a bad shattering of the concrete in numerous places. Consequently it is manifest that the problem of water-proofing in the two situations is wholly different. I mention this difference because it seems to me that there may be a tendency to require impermeable concrete for situations where other water-proofing is a far better protection. It has long seemed to me that where long concrete walls or floors are exposed to the direct outside air and are resting against earth containing water, the only safe water-proofing method lies in the use of some of the so-called "membrane" processes. These have sufficient flexibility to protect the concrete from water even when the concrete becomes cracked.

Between these two extreme cases lie many in which the judgment of the engineer must naturally decide what kind of process must be adopted in order to secure an impervious wall or floor. Unquestionably there are situations where the temperature conditions may render a perfectly stiff and stony material like concrete so free from the likelihood of cracking that water-proofing by rendering it impermeable is safe to use. It is for this reason that the methods are so important and that all investigations of them should be encouraged. Nevertheless, it is far more important for most classes of engineering work to obtain a thorough knowledge of methods of water-proofing concrete which will keep the walls impermeable after the concrete has cracked, for most concrete work with which the engineer has to do is subject to such cracking.

Very truly yours,

C. E.

THE ENGINEERING RECORD

PUBLISHED WEEKLY BY THE

McGraw Publishing Company

James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.

MAIN OFFICES:

239 WEST 39TH STREET, NEW YORK.

BRANCH OFFICES:

CHICAGO: Old Colony Building.
PHILADELPHIA: Real Estate Trust Building.
CLEVELAND: Schofield Building.
SAN FRANCISCO: Atlas Building.
LONDON OFFICE: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico...........$3.00 a year
Canada ....$4.50 a year
Foreign subscription.....................$6.00 a year
25 shillings. 25 marks. 31 francs.
Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of THE ENGINEERING RECORD on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

REMITTANCES.—Remittances should be made by check, New York draft, or money order, in favor of THE ENGINEERING RECORD.

CHANGE OF ADDRESS.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

BACK COPIES.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.

DATE ON WRAPPER indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

CLUB RATE.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 16,000 copies are printed. Total circulation for 1907 to date, 642,000 copies, an average of 14,591 copies per week.

TABLE OF LEADING ARTICLES.

Cooling Tower Tests.

Although but a small percentage of power plants include a cooling tower in their equipment, the absence of a continuous and suitable supply of condensing water and high cost of fuel not infrequently combine to induce plant owners to install apparatus for the artificial cooling of the circulating water and the return of as much as possible of it to the condensers. In such plants it is quite as important to find out whether the cooling tower is operating efficiently as it is to run down wiring losses and minor leaks in steam pipes and traps, and the failure to keep cooling tower records on daily station log sheets may lead to considerable losses in the form of excessive coal or water consumption. Purchased water is decidedly worth saving in a large plant, and even a small station dependent upon a limited natural supply and forced to buy boiler or circulating water will run up quite a bill in the course of a year if the water is not economically handled. In one of the Boston elevated gas engine plants the cost of purchased water exceeded the cost of fuel prior to the securing of water by the company from a neighboring brook. The illustration simply indicates the importance of the water question, even under careful management.

The designs of cooling towers vary so widely, from the home-made apparatus often constructed by ingenious operating engineers to the carefully finished equipment of the manufacturing companies, that it is obvious the tests made in any given installation must be governed largely by local conditions. Certain fundamental data are required, however, in any comprehensive test which aims to show the fitness of a cooling tower outfit for its work. If time and facilities permit, the physical quantities collected and their resulting analysis can be made very extensive.

The temperature of the circulating water as it enters the condenser is the most important index of the performance of the cooling tower. Taken in relation to the temperature of the outside air, the supply temperature is of great interest as affected by the season of the year and the weather prevailing at the time. It ought to be clear to every operating engineer that the conditions must be known which may modify the action of a cooling tower installation if the best operating results are to be secured. Thus, in the jet condenser plant, the injection water and part of the condensation are mixed and pumped together through the cooling tower cycle. Here the make-up water required to replace the loss by evaporation in the cooling tower may come either from the hot well, or from a metered service, perhaps, in extreme cases. In figuring the quantity of circulating or injection water required to be passed through a cooling tower in a given run allowance must be made in a test of high accuracy for the assistance given by the engine exhaust. Fortunately for simplicity of testing, the cooling tower and the surface condenser plant afford a much easier equipment to study, for here the exhaust and the circulating water are, of course, never intentionally mingled.

A thorough test of the efficiency of a cooling tower will obtain the volume of air supplied by the fans, if the installation be of the blower type; the temperature of entering and departing air, and if possible its relative humidity, and the height of the barometer; the power consumption and speed of the fans, determined from kilowatt-hour records on the motors or indicator cards from the engines; the quantity of water passed through the condenser circulating system, and if feasible the amount of make-up water; and the load upon the engines or turbines together with the condenser vacuum maintained. There is room for much research in connection with the reduction of operating expenses through a diminished pumpage and decreased fan movement, and in many cases the study of the effect of different arrangements of spraying and scattering the water drops in the cooling tower tank itself will richly repay the engineer who takes the trouble to go into the subject. Ingenuity will be required to confine the physical quantities which are to be measured in most instances, and the determination of meter accuracy, pump slippage, anemometer errors, and the like call for first-class work. Small errors in temperature and humidity measurements carry heavy weight in the final results, and failure to estimate the amount of external water supplied in cases where the cooling tower tank is utilized for general drainage purposes leads to inaccurate conclusions. The power plant which can be operated more economically without a cooling tower than with one, because of cheap or free water, or low cost fuel is fortunate, because it thereby avoids an extra complication in equipment. When the conditions require special cooling outfits, their careful observation and occasional test are essential for the best results in the way of keeping costs low.

Hydraulic Developments at Low Head.

The Engineering Record has recently published descriptions of several power plants which are notable for the clever utilization on a fairly large scale of very moderate head. The water powers of the United States are of a very variable character. In the Rocky Mountains and westward are found, in the main, rapid streams which can be utilized at very high head with tolerable ease. Heads of four or five hundred feet are common and those of a thousand feet or more by no means rare. The engineering work of development in such cases is frequently very simple, residing mainly in the system of conduits necessary for a relatively small volume of water. The dam is often merely a deflecting wall to turn the stream into the sand boxes. A few such high heads are found in the lower Appalachian region and fewer still elsewhere. Throughout the Middle West, however, the water powers, relatively few in number, are almost all at low head, say from 40 ft. down, and their utilization is correspondingly troublesome, involving long dams and a vast amount of material to be handled. The Michigan plants described in this and the last two issues are of this character. The two upon the Muskegon River are notable not only for their construction but from the fact that in this region the highest point yet touched in transmission voltage, 72,000 volts, has been reached. The stream itself is possessed of some valuable properties not usually found in rivers fed from more mountainous regions. A relatively flat drainage area, fairly well wooded, gives the stream an extraordinarily steady run-off. The maximum flow recorded, at least in recent years, is only about 8½ times the recorded minimum. When one considers that in the Connecticut River, a typical Eastern stream, this ratio is nearly 100:1 the vast difference in conditions is obvious.

In consequence of the favorable flow conditions it was practicable in both the Muskegon plants considered to make free use of earth embankments with mere core walls of reinforced concrete for large sections of the dams, using concrete construction only for the waste gate portions. In case of the Croton development no inconsiderable part of the material was moved by hydraulic sluicing, a process quite out of the question on most streams, while in the Big Rapids development the earth was mainly handled by teams and scrapers and the core of the dam was merely a 10-in. reinforced concrete wall built over sheet steel piling. In each case the waste gate section was of concrete, and the water passes from the gates into a tumble bay and thence over a low concrete weir into the waste channel. Another common feature is the use of Tainter sector gates on the waste gate portion, thus giving complete control of the head over a considerable range of variation. This evolution of the flashboard idea seems singularly well fitted for its work and is readily applicable to many cases in which, particularly at times of low water, the head must be kept at the highest available point and must be dropped for self-preservation at times of flood. The normal head in each case is

about 40 ft. The third of the plant considered, that near Lyons, on the Grand River, has less favorable natural conditions, the drainage basin being of clayey soil and giving a quick run-off, with much larger variation of flow than on the Muskegon. Here the dam was almost wholly of reinforced concrete, also equipped to the use end just noted with Tainter gates aggregating in cases less than 200 ft. in width. There is also, as at the Croton development, a spillway with a movable shutter. The head, however, is only 20 ft.

In each of the three plants, the usual trouble incident to low head was encountered. As such that a somewhat complicated wheel plant was necessary to give the requisite speed to the generators. It is open to question, indeed, whether too much was not sacrificed to a desire for a generator of large output. Four pairs of turbines, as in the Croton plant, united to their load by 110 ft. of 12-in. steel shafting, certainly strikes one as excessive duplication and does not favor, to put it mildly, great hydraulic efficiency. The Big Rapids plant has generating sets of more simple design and one might well hazard a guess that they will be more satisfactory in operation. The Lyons plant from its lower head has more excuse for extreme design, yet it seems hardly necessary to have installed four pairs of turbines, for the sake of driving 138 ft. of shafting and a single generator. Doubtless the generator cost was lowered, but will it pay in the long run as regards the entire plant? In none of these plants, fortunately, was there need of going to vertical shaft construction of which several examples have been recently seen. The vertical shaft does, indeed, enable one to keep the generating room above high water mark, but it is liable to cause extra cost for attendance on account of the step bearings. The plants here considered play an important part in the economy of railway and power development in southwestern Michigan, both in interurban railway work and in the ordinary work of electrical supply. The networks of which they form a part are rapidly growing in importance, and to the engineer are of peculiar interest on account of the extreme high voltage work which is being carried out. The completion of the 100,000 volt line from the Big Rapids plant will mark the beginning of a larger sphere for electric power transmission and will serve as a sort of trial horse for various immense projects elsewhere that require the highest voltage that can be made available.

Standardizing Power Station Records.

To a company operating several power plants in different parts of its territory, the importance of accurately comparing the performance of the various stations is unquestionable, if the best possible records in low power cost are its object. It seldom occurs, however, that the conditions in the different plants are alike in complete detail, even in cases where the plants are supplying power for the same kind of service. The installation of a number of plants rarely occurs at the same period with the same company, and differences in the design and arrangement of generating machinery are sure to creep in if the company takes advantage of the progress in the field of power equipment which is so striking a feature of modern mechanical engineering. Thus it may easily happen that a single street railway system will be supplied with exactly the same kind of power from a dozen different plants in which the individual machines run the gamut from the steam turbine to the vertical, marine type engine, and from the belted non-condensing auxiliary steam engine to the producer gas engine direct connected to its special generator. All this may occur in a single city, and when the range of plants operated by one central organization extends through different parts of a country, the problem of comparison becomes still more difficult.

Before the operating figures of scattered plants can be interpreted, a system of records must be standardized which will enable comparisons to be fairly made. Local conditions exert a profound influence upon the cost of power production, and a place must be provided for the setting forth of these, if just comparisons are to be made possible. Whether the records are to be made on a daily, weekly or monthly basis, the points in common between the different plants must form the basis of log sheet and record blanks from which comparisons are to be worked out. The greater the similarity in equipment, the more easily can the sheets be standardized. If the power generated in one plant is used for a single service and that in another for several kinds of application, it will be necessary to include a certain space on the form which can only be used by the station of varied duties, and which must be left blank by the plant to which the headings do not apply. To a narrow mind an unused space on a record blank looms large, but to the eye of discrimination and to the sense of proportion it becomes of slight importance whether all the items are alike in type, so long as the essential conditions of each case are presented.

In dealing with a number of plants under the same management two main objects are present: First, to compare the plants one with another in relative efficiency and general performance, and second, to employ as far as is practicable, the same blanks and forms in each. Unless one uses a sheet of mammoth proportions it is scarcely possible to incorporate the details of the daily log on a single form for several stations, though sometimes a large sheet is of great advantage in comparing the fluctuations of a single very important item. Thus, a street railway company operating eleven plants found it helpful to plat on a single sheet the total load upon its stations between 5 and 6 p. m. each day in the year, and the resulting curve of maxima required a wall space about 7 ft. long for its proper display. Compared with the afternoon peak loads of the previous year plotted beneath, the curve gave a valuable hint of the motive power requirements long before they actually came to pass. The same company also used to advantage a single blank which showed the maximum momentary station load, and the average hourly load throughout the entire day, with the number of machines in circuit from hour to hour in each plant. Space was provided to show during each of the three operating shifts in each plant the numbers of the engines, generators, boilers, gas producers and condensing apparatus not available for service, with a brief designation of the coal quality.

On a general comparison sheet there are a large number of items which can be recorded, regardless of the character of the machinery in each station. Among these are the total hours each station was operated, the total fuel consumption, the total power output in kilowatt or horse-power hours, the fuel consumption per unit of total output, the quantity of oil, waste and water required, the maximum load, duration of interruptions, repairs made, special inspections, weather, temperature of outside air, barometer and average temperatures and steam pressures. Some of these items would clearly be encumbrances upon a sheet where hydro-electric plants are listed beside steam driven or gas stations, but even here the practice of leaving inapplicable spaces blank is better than the multiplication of separate station records. In general, a large number of hour to hour readings in different plants and of many quantities, cannot well be listed on a comparison sheet, but the averages, maxima, minima and totals can be, to great advantage. To list all the items which can be profitably included in a general comparison sheet would require the space of a small catalog, but the above outline shows how wide the range may be, especially if one goes into performances on the unit basis.

In the matter of standardizing the forms of log sheets to be used in daily operation in each of a group of plants, the main consideration is to provide enough columns under each class of unit to enable both the largest and the smallest station to use the same kind of sheet. Daily report blanks for single plants necessarily must conform more closely to the local conditions than summaries of the performance of whole stations. For this reason it may in some cases be desirable to establish one form of log for one type of plant, such as fuel-burning installations, and another for hydro-electric stations. Among the items which can be employed to advantage on a standard form of record are, the hourly load curve; the hourly operation, banking or reserving of boiler units; the hourly temperatures and pressures, continuity of prime mover and generator service; names of men on duty each shift; use or non-use of auxiliary apparatus from hour to hour; outputs per unit and per feeder, the latter optional on a separate record if highly complicated; emergency happenings, inspections, receipt of fuel, machinery and supplies; service interruptions, voltage readings, supplies on hand and apparatus crippled. The use of a standard size of sheet with uniform dimensions for all plants, clearly printed and well arranged in headings tends to facilitate comparisons no less than the inclusion of the proper items. It is not to be expected that record forms will remain unchanged from year to year, but when these changes occur, they should be made by issuing a new series of records for the whole group of plants instead of attempting to get along with both old and new forms at the same time.

Some Considerations in the Design of Elastic Arches.

The design of elastic arches or arch ribs as they are more frequently called in early engineering literature had not been the subject of much consideration prior to the introduction of reinforced concrete. The capacity to resist tension given to that material by steel reinforcement adapts it admirably to the design and construction of arches with the added excellence of a grace of outline and proportions scarcely attainable in ordinary masonry. The extension of the recent application of reinforced concrete in the construction of arches of all practicable lengths of span makes it not only desirable but almost imperatively necessary to acquire a clear view especially of any doubtful points of design.

The theory of the inelastic arch considered as a series of blocks of unchanging form and perfect joints is one of the oldest analytic or graphical procedures in engineering, but the complete theory of the elastic arch has been considered only for a comparatively few years, in spite of the fact that Rankine set forth some excellent features of treatment in his original works. The full general scheme of treatment is now to be found in many authoritative works to which, as they are so well known, it is not necessary to make any special reference, but there are some considerations regarding rather the extent to which the treatment is to be carried than any detailed question of that treatment which are worthy of careful reflection.

The usual method of design conveying simply the application of the common theory of flexure involves the neglect of any change of form of the rib due to the effects of loading, as are constantly recognized. In spite of that recognition, however, it is an open question how far ... that

neglect is permissible. Obviously in comparatively long spans and small depths of rib the omission to give weight to the elastic distortion of the rib might mean a material error although it might rarely be a dangerous one. In short spans and under ordinary circumstances of design the recognition of this elastic deformation might properly be considered an unnecessary refinement, but there is a limit to which that neglect can be carried, although it may not be possible to make a definite assignment of that limit. This elastic deformation clearly results from both the bending of the rib and its shortening, due to direct compression, both of those influences leading to deflection. That deflection in turn changes the position of the closing line in the case of a continuous rib and modifies the bending moment correspondingly. Practically the same general condition results in the case of a rib with jointed ends, although the closing line is not changed in position. It is not a matter of any sensible difficulty to make the proper allowance for these elastic deflections. The difficulty arises rather in determining the conditions under which the necessary allowance should be made.

Another point of what may be termed important doubt arises in connection with a proper provision for the change of temperature which the material of an elastic arch may experience from one season to another. While probably the majority of engineers may accept a high estimate in range of temperature in this latitude there are others of extended experience in this class of work who believe that the subject of temperature allowance is much over-worked. It is clear that the mass of a reinforced concrete arch supporting a roadway platform above it with a body of water underneath cannot possibly be subjected to the same amount of temperature variation as an articulated steel structure. A range of 100° to 120° Fahr. is not unfrequently considered in connection with steel bridges, but there is little or no reason to believe that any such extreme range can take place in an arch. Indeed if the arch has much span and corresponding mass it would be more reasonable to assume that the extreme range may not be more than 20° to 30° from the mean. It requires but few computations to show that in an arch rib of comparatively small rise the assumed range of temperature variation may play a very important part in the computed stresses, and yet in some existing structures of this character where the atmospheric seasonal changes are great there appears no evidence of the corresponding intensities of stress. Where the rise of the rib is comparatively great these considerations become of much less importance although they are still material. There is still lacking a large amount of highly desirable data of this character.

These observations indicate some of the more important open questions in the design of elastic arches, although there are others, such as spandrel walls continuous with the supporting arches, which are frequently more or less troublesome to the designer. The construction of some long span elastic arches now in progress, as well as those already standing, when subjected to proper observation, could be made to supply much useful data of the kind indicated, and it is much to be desired that requisite observation should be made in the interest of this important field of engineering construction.

A Discussion of Steam Turbines.
